

ENCYCLOPEDIA *of*
SEDIMENTS *and*
SEDIMENTARY ROCKS

Kluwer Academic Encyclopedia of Earth Sciences Series

ENCYCLOPEDIA OF SEDIMENTS AND SEDIMENTARY ROCKS

Aim of the Series

The Kluwer Academic Encyclopedia of Earth Sciences Series provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students.

See the back of this volume for a current list of titles in the Encyclopedia of Earth Sciences Series. Go to www.eso.com to visit the "Earth Sciences Encyclopedia Online"—the online version of this Encyclopedia Series.

About the Editors

Professor Rhodes W. Fairbridge has edited more than 30 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He is currently Emeritus Professor of Geology at Columbia University and is affiliated with the Goddard Institute for Space Studies.

Professor Michael Rampino has published more than 70 papers in professional journals including *Science*, *Nature*, and *Scientific American*. He has worked in such diverse fields as volcanology, planetary science, sedimentology, and climate studies, and has done field work on six continents. He is currently Associate Professor of Earth and Environmental Sciences at New York University and a consultant at NASA's Goddard Institute for Space Studies.

Volume Editor

Gerard V. Middleton is Professor Emeritus of Geology at McMaster University, Hamilton, Ontario, Canada.

He was co-author of "Origin of Sedimentary Rocks" (Prentice-Hall), "Mechanics in the Earth and Environmental Sciences" (Cambridge), and author of "Data Analysis in the Earth Sciences using MATLAB" (Prentice-Hall). He is a Fellow of the Royal Society of Canada, and in 2003 received the Twenhofel Prize of SEPM, the Society for Sedimentary Geology.

Contents

List of Contributors	xiii	Authigenesis <i>James R. Boles</i>	27
Preface	xxvii		
Guide to the Reader	xxix	Autosuspension <i>Henry M. Pantin</i>	30
Algal and Bacterial Carbonate Sediments <i>Robert Riding</i>	1	Avalanche and Rock Fall <i>Michael J. Bovis</i>	31
Allophane and Imogolite <i>Roger L. Parfitt</i>	3	Avulsion <i>Norman D. Smith</i>	34
Alluvial Fans <i>Adrian M. Harvey</i>	5	Bacteria in Sediments <i>Nora Noffke</i>	37
Anabranching Rivers <i>Gerald C. Nanson and Martin R. Gibling</i>	9	Ball-and-Pillow (Pillow) Structure <i>Geraint Owen</i>	39
Ancient Karst <i>Brian Jones</i>	11	Bar, Littoral <i>Brian Greenwood</i>	40
Angle of Repose <i>Paul D. Komar</i>	15	Barrier Islands <i>Duncan M. FitzGerald and Ilya V. Buynevich</i>	43
Anhydrite and Gypsum <i>Lawrence A. Hardie</i>	16	Bauxite <i>Ray L. Frost</i>	48
Ankerite (in Sediments) <i>James P. Hendry</i>	19	Beachrock <i>Eberhard Gischler</i>	51
Armor <i>Rob Ferguson</i>	21	Bedding and Internal Structures <i>Franco Ricci-Lucchi and Alessandro Amorosi</i>	53
Atterberg Limits <i>Michael J. Bovis</i>	22	Bedset and Laminaset <i>John S. Bridge</i>	59
Attrition (Abrasion), Fluvial <i>Michael Church</i>	24	Bentonites and Tonsteins <i>D. Alan Spears</i>	61
Attrition (Abrasion), Marine <i>Hillert Ibbeken</i>	25		

Berthierine <i>Fred J. Longstaffe</i>	64	Clastic (Neptunian) Dykes and Sills <i>A. Demoulin</i>	136
Bioclasts <i>Paul Enos</i>	66	Clathrates <i>Miriam Kastner</i>	137
Bioerosion <i>Markus Bertling</i>	70	Clay Mineralogy <i>Stephen Hillier</i>	139
Biogenic Sedimentary Structures <i>S. George Pemberton</i>	71	Climatic Control of Sedimentation <i>Greg H. Mack</i>	142
Black Shales <i>Juergen Schieber</i>	83	Coal Balls <i>Andrew C. Scott</i>	146
Braided Channels <i>Peter Ashmore</i>	85	Coastal Sedimentary Facies <i>H. Edward Clifton</i>	149
Calcite Compensation Depth <i>Sherwood Wise</i>	88	Colloidal Properties of Sediments <i>Sandip and Devamita Chattopadhyay</i>	157
Caliche – Calcrete <i>V. Paul Wright</i>	89	Colors of Sedimentary Rocks <i>Paul Myrow</i>	159
Carbonate Diagenesis and Microfabrics <i>Robin G. C. Bathurst</i>	91	Compaction (Consolidation) of Sediments <i>Knut Bjørlykke</i>	161
Carbonate Mineralogy and Geochemistry <i>Fred T. Mackenzie</i>	93	Convolute Lamination <i>Gerard V. Middleton</i>	168
Carbonate Mud-Mounds <i>Pierre-André Bourque</i>	100	Coring Methods, Cores <i>Arnold H. Bouma</i>	168
Cathodoluminescence (applied to the study of sedimentary rocks) <i>Stuart D. Burley</i>	102	Cross-Stratification <i>David M. Rubin</i>	170
Cation Exchange <i>Balwant Singh</i>	106	Cyclic Sedimentation <i>Robert K. Goldhammer</i>	173
Cave Sediments <i>Brian Jones</i>	109	Debris Flow <i>Jon J. Major</i>	186
Cements and Cementation <i>Peter A. Scholle and Dana Ulmer-Scholle</i>	110	Dedolomitization <i>Mario Coniglio</i>	188
Chalk <i>Ida L. Fabricius</i>	119	Deformation of Sediments <i>John D. Collinson</i>	190
Charcoal in Sediments <i>Andrew C. Scott</i>	121	Deformation Structures and Growth Faults <i>John D. Collinson</i>	193
Chlorite in Sediments <i>Stephen Hillier</i>	123	Deltas and Estuaries <i>Janok Bhattacharya</i>	195
Classification of Sediments and Sedimentary Rocks <i>Gerald M. Friedman</i>	127	Depositional Fabric of Mudstones <i>Juergen Schieber</i>	203

Desert Sedimentary Environments <i>Joseph P. Smoot</i>	207	Features Indicating Impact and Shock Metamorphism <i>Wolf Uwe Reimold</i>	275
Desiccation Structures (Mud Cracks, etc.) <i>P.W. Geoff Tanner</i>	212	Feldspars in Sedimentary Rocks <i>Sadoon Morad</i>	278
Diagenesis <i>Kitty L. Milliken</i>	214	Flame Structure <i>Gerard V. Middleton</i>	281
Diagenetic Structures <i>Peter Mozley</i>	219	Flaser <i>Burghard W. Flemming</i>	282
Diffusion, Chemical <i>Bernard P. Boudreau</i>	225	Flocculation <i>Morten Pejrup</i>	284
Diffusion, Turbulent <i>Andrew J. Hogg</i>	226	Floodplain Sediments <i>Andres Aslan</i>	285
Dish Structure <i>Zoltán Sylvester and Donald R. Lowe</i>	230	Floods and Other Catastrophic Events <i>Victor R. Baker</i>	287
Dolomite Textures <i>Duncan Sibley</i>	231	Flow Resistance <i>Robert Millar</i>	293
Dolomites and Dolomitization <i>Hans G. Machel</i>	234	Fluid Escape Structures <i>Zoltán Sylvester and Donald R. Lowe</i>	294
Dunes, Eolian <i>Nicholas Lancaster</i>	243	Fluid Inclusions <i>Robert H. Goldstein</i>	297
Earth Flows <i>Rex L. Baum</i>	247	Flume <i>Basil Gomez</i>	300
Encrinites <i>William I. Ausich</i>	248	Forensic Sedimentology <i>Raymond C. Murray</i>	301
Eolian Transport and Deposition <i>Cheryl McKenna Neuman</i>	249	Gases in Sediments <i>Chris J. Clayton</i>	304
Erosion and Sediment Yield <i>Robert F. Stallard</i>	254	Geodes <i>Kitty L. Milliken</i>	306
Evaporites <i>Lawrence A. Hardie and Tim K. Lowenstein</i>	257	Geophysical Properties of Sediments (Acoustical, Electrical, Radioactive) <i>Anthony L. Endres</i>	308
Extraterrestrial Material in Sediments <i>Christian Koeberl</i>	263	Geothermic Characteristics of Sediments and Sedimentary Rocks <i>Daniel F. Merriam</i>	314
Fabric, Porosity, and Permeability <i>Gerard V. Middleton</i>	265	Glacial Sediments: Processes, Environments and Facies <i>Michael J. Hambrey and Neil F. Glasser</i>	316
Facies Models <i>Harold G. Reading</i>	268	Glaucony and Verdine <i>Alessandro Amorosi</i>	331
Fan Delta <i>George Postma</i>	272	Grading, Graded Bedding <i>Richard N. Hiscott</i>	333

Grain Flow <i>Charles S. Campbell</i>	335	Kaolin Group Minerals <i>Rossmann F. Giese, Jr.</i>	398
Grain Settling <i>Paul D. Komar</i>	336	Kerogen <i>Raphael A.J. Wüst and R. Marc Bustin</i>	400
Grain Size and Shape <i>Michael J. Church</i>	338	Lacustrine Sedimentation <i>Robert Gilbert</i>	404
Grain Threshold <i>Paul D. Komar</i>	345	Laterites <i>Yves Tardy</i>	408
Gravity-Driven Mass Flows <i>Richard M. Iverson</i>	347	Lepidospheres <i>Sherwood W. Wise, Jr.</i>	411
Gutters and Gutter Casts <i>Paul Myrow</i>	353	Liquefaction and Fluidization <i>Charles S. Campbell</i>	412
Heavy Mineral Shadows <i>Rick Cheel</i>	355	Load Structures <i>John R.L. Allen</i>	413
Heavy Minerals <i>Andrew C. Morton</i>	356	Lunar Sediments <i>Abhijit Basu</i>	415
Hindered Settling <i>Jon J. Major</i>	358	Magadiite <i>Robin W. Renaut</i>	417
Humic Substances in Sediments <i>Laura J. Crossey</i>	361	Magnetic Properties of Sediments <i>Mark J. Dekkers</i>	418
Hummocky and Swaley Cross-Stratification <i>Rick Cheel</i>	362	Mass Movement <i>Michael J. Bovis</i>	424
Hydrocarbons in Sediments <i>Martin Fowler</i>	364	Maturation, Organic <i>R. Marc Bustin and Raphael A.J. Wüst</i>	425
Hydroxides and Oxyhydroxide Minerals <i>Helge Stanjek</i>	366	Maturity: Textural and Compositional <i>Raymond V. Ingersoll</i>	429
Illite Group Clay Minerals <i>Jan Środoń</i>	369	Meandering Channels <i>Edward J. Hickin</i>	430
Imbrication and Flow-Oriented Clasts <i>Cyril Galvin</i>	371	Mélange; Melange <i>John W.F. Waldron</i>	434
Impregnation <i>Scott F. Lamoureux</i>	374	Micritization <i>Ian G. MacIntyre and R. Pamela Reid</i>	436
Iron–Manganese Nodules <i>Stephen E. Calvert</i>	376	Microbially Induced Sedimentary Structures <i>Nora Noffke</i>	439
Ironstones and Iron Formations <i>Bruce M. Simonson</i>	379	Milankovitch Cycles <i>Linda Hinnov</i>	441
Isotopic Methods in Sedimentology <i>Fred J. Longstaffe</i>	385	Mixed Siliciclastic and Carbonate Sedimentation <i>Robert K. Goldhammer</i>	443
		Mixed-Layer Clays <i>Jan Środoń</i>	447

Mixing Models <i>Bernard P. Boudreau</i>	450	Placers, Marine <i>David S. Cronan</i>	532
Mudrocks <i>Paul E. Potter</i>	451	Planar and Parallel Lamination <i>John S. Bridge</i>	534
Neomorphism and Recrystallization <i>J.A.D. Dickson</i>	460	Porewaters in Sediments <i>Jeffrey S. Hanor</i>	537
Nepheloid Layer, Sediment <i>I. Nicholas McCave</i>	462	Pressure Solution <i>François Renard and Dag Dysthe</i>	542
Neritic Carbonate Depositional Environments <i>Noel P. James</i>	464	Provenance <i>Abhijit Basu</i>	544
Numerical Models and Simulation of Sediment Transport and Deposition <i>Rudy L. Slingerland</i>	475	Pseudonodules <i>Geraint Owen</i>	549
Oceanic Sediments <i>Robert G. Douglas</i>	481	Quartz, Detrital <i>Harvey Blatt</i>	552

Sedimentologists: T. Wayland Vaughan

Preface

The study of natural sediments and sedimentary rocks has been called *sedimentology*. This encyclopedia is a thorough revision of the original *Encyclopedia of Sedimentology*, published by Dowden, Hutchinson and Ross in 1978: The field has advanced so fast, however, that all the articles in the present volume are new, and this is recognized by a new title.

The present encyclopedia interprets *sedimentology*, both more narrowly and more broadly than is often the case (see *Sedimentary Geology*—an entry in this encyclopedia—for further discussion). More narrowly, because the encyclopedia contains relatively little information about *stratigraphy*, the science concerned with stratified rocks. Stratigraphy and sedimentology overlap, particularly in the area of facies analysis and sequence stratigraphy. In general, however, stratigraphic topics have been reserved for full treatment in a companion *Encyclopedia of Stratigraphy*, which is now in preparation. More broadly, this encyclopedia includes topics that some sedimentologists tend to exclude, for examples: the mineralogy of clays and other minerals common in sediments; geochemistry of sediments (sediments are included in the *Encyclopedia of Geochemistry*); some features of sediments interesting to the general public but somewhat neglected by sedimentologists (e.g., clathrates, coal balls, geodes, resin and amber, speleothems, toxicity of sediments); contributions of engineering studies to sediment transport and soil mechanics; studies on the geophysical and petrophysical properties of sediments; and studies by physicists on granular matter.

Three other disciplines that are represented by separate encyclopedias also have overlapping interests in sediments: hydrology and hydrogeology (represented by *Encyclopedia of Hydrology and Water Resources*); geomorphology (represented by *Encyclopedia of Geomorphology and Landforms*, and also by *Encyclopedia of Coastal Science*); and environmental studies (represented by *Encyclopedia of Environmental Science*).

A final word about the selection of topics: there is always a subjective element in the choice of topics, but if the reader does not see an entry for the particular topic that interests him, then he or she should look in the index. The topic may be covered (perhaps in more than one article) under a different name. The editors have tried to make the coverage comprehensive, but we are aware of some partial omissions: unfortunately, willing contributors cannot always be found for all the topics that might be suggested.

Encyclopedias are not generally places to look for extended acknowledgments. This is a tradition dating back to the days when contributors were anonymous, or only identified by their initials (and imagine the space that would be taken up by acknowledgments from every author: the Academy Awards would pale by comparison!). On behalf of all the editors and contributors, therefore, we extend thanks to those colleagues who have assisted us by providing data, figures, critical reviews, and sustaining personal and financial encouragement. Thank you all—we hope you realize that your generosity is not forgotten, even if your contribution remains anonymous.

Guide to the Reader

This encyclopedia is devoted to the science of sediments and sedimentary rocks, a science generally called *sedimentology*. It does not address those broader aspects of stratified rocks concerned with the naming of rocks units, their correlation from one place to another, and their dating in geological time. Those aspects belong to *stratigraphy*, the subject of another encyclopedia in this series.

Sediments and sedimentary rocks can be approached from three main points-of-view:

1. Like other rocks, they have a mineral and chemical composition, physical properties, and structures and textures, all of which need description and interpretation in order that we may understand their origin. These are the *geochemical, mineralogical, petrological and petrophysical (geophysical)* aspects of sediments and sedimentary rocks.
2. Sediments are first laid down in *sedimentary environments*. The (primary) aspects of sedimentary rocks that were formed at the time of deposition (particularly, but not exclusively, their structures), are generally called their *sedimentary facies*. Facies analysis is concerned with using primary aspects of sediments to determine the environment in which they were deposited: and, in a complementary way, with understanding how modern sedimentary environments control, or are determined by, the characteristics of the sediments deposited in them. Sediments interact with many other aspects of the environment, including their biology.
3. Many sedimentologists try to understand the basic *physical, chemical and biological processes* that form sediments, transport and deposit them, and later convert them into sedimentary rocks. Such studies may be carried out in the laboratory, in the field (particularly by studying processes active in modern environments), and by theoretical and numerical analysis and simulation.

For those readers not already familiar with sedimentology, Table I indicates the major introductory articles in each of these three categories (there is, of course, some overlap in the approaches used in most of the articles). Besides these there are also introductory articles on Sedimentary Geology; Sedimentology—Organizations, Meetings, Publications; Sedimentology—History; and Sedimentologists (brief biographic sketches).

A good approach for readers unfamiliar with the subject is to begin with a general article, then follow the *cross-references* listed at the end of the article to find related topics. For example, one might begin to learn something about Sands, Gravels and their Lithified Equivalents, go on to Bedding and Internal Structures, then Paleocurrent Analysis, then Cross-Stratification, or some other specific topic.

A reader with more knowledge, might begin searching for a specific topic, for example, concretions. As it happens, there is no article with that name, but reference to Diagenesis, or Diagenetic Structures (or to the Index) would soon lead to articles that describe concretions of various types. If the reader needs more than he can find in the encyclopedia, most articles give copious bibliographic references, to both general texts and research articles.

A

ALGAL AND BACTERIAL CARBONATE SEDIMENTS

Calcified algae and bacteria

Only a few algae and bacteria calcify (Figure A1), but their abundance and wide distribution make them important in limestones of many ages and environments (Figure A2). Microbial carbonates appeared in the Archaean and are significant in Proterozoic carbonate platforms. Calcified cyanobacteria became important in the Cambrian, and calcified green and red algae in the Ordovician. Additional extinct organisms have been regarded as calcified algae or bacteria, but are still of uncertain affinity. These problems of affinity hamper paleoecological and phylogenetic interpretations.

Calcification

Environmental range and variations in cellular site and mineralogy of calcification reflect the organism's control over calcification. With decreasing control, calcification site moves from intra- to extra-cellular, mineralogy shifts toward that of ambient abiotic carbonate precipitates, and environmental distribution becomes restricted to locations where inorganic precipitation is favored (e.g., warmer water in marine environments). Strong control (e.g., coralline red algae) allows wide environmental distribution of calcification and is linked to intracellular sites of CaCO_3 nucleation. Weak control (e.g., halimedaceans and cyanobacteria) limits the environmental distribution of calcification, and is linked to an extracellular site of CaCO_3 nucleation and a polymorph in equilibrium with the ambient environment. Consequently, calcified algae and bacteria have potential to reflect past fluctuations in environmental controls over carbonate precipitation. Cyanobacteria, for example, calcify only when environmental conditions are favorable (Arp *et al.*, 2001). At present, this is only widespread in freshwater, but took place extensively in marine environments in the Paleozoic and Mesozoic.

marine calcified	Cyanobacteria	—	—	—	—	—	—	—	—	—	—

Figure A1 Principal groups of calcified benthic algae and cyanobacteria. Calcified red algae include corallines that are marine, calcitic, occur at all latitudes, and are important reef builders. In contrast, calcified marine green dasycladaleans and halimedaceans are aragonitic and mainly tropical. They mainly produce particulate sediment, although *Halimeda* creates reefs with its disarticulated segments. Charophyte green algae also produce bioclastic sediment, but are essentially freshwater, calcitic, and prefer temperate climates. Gymnocodiaceans and phylloids are certainly algae, but lack the distinctive features necessary to either subdivide or classify them. Solenoporaceans are a heterogeneous grouping.

Microbial carbonates

Microbes (bacteria, small algae, fungi) are widespread on wetted substrates. Carbonate precipitation, locally augmented by grain trapping, results in their accretion and preservation as microbial carbonates. Extracellular polymeric substances (EPS), produced by microbes for attachment and protection, provide nucleation sites and facilitate grain trapping. Precipitation is stimulated by photosynthetic uptake of CO_2 and/or HCO_3^- by algae and cyanobacteria, and by ammonification, denitrification, sulfate reduction and other metabolic processes in other bacteria.

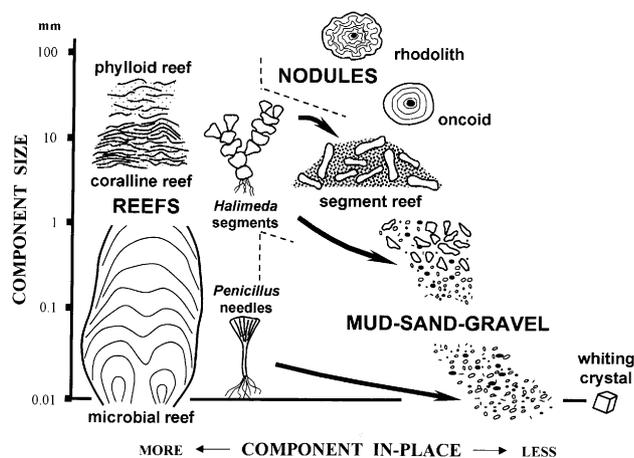

Figure A2 Algal-bacterial carbonate sediment. Variations in particle/component size and degree of movement. Sizes are for basic components in reefs (mud-grade to millimetric fabrics and calcified sheaths in microbial reefs, crustose thalli in coralline red algal reefs, and leaflike algal skeletons in phylloid reefs), and mud-sand-gravel. Internally, microbial domes may have stromatolitic, thrombolitic, dendrolitic, or leiolitic mesofabrics—or combinations of these. In nodules, size indicates overall rhodolith or oncoïd size. Whereas components in microbial, coralline and phylloid reefs are essentially in place, segments of the green alga *Halimeda* in segment reefs are parautochthonous. Centimetric nodules, built by red algae (rhodoliths) and calcified microbes (oncoïds) are also commonly parautochthonous. *Halimeda* segment reefs typically accumulate at depths of 20–50 m on low angle shelves and atoll lagoon floors. In contrast, on slopes and in shallower water, carbonate mud-sand-gravel produced by disaggregation of *Halimeda* and *Penicillus* green algae is commonly transported. In addition, numerous other freshwater and marine algae, such as green charophytes and red articulated corallines, produce particulate sediment. Whiting crystals form in surface waters and settle out of suspension.

Biofilms are very thin layers, usually only a few hundreds of microns in thickness, of heterotrophic bacterial cells $<2\ \mu\text{m}$ in size in an EPS matrix, on solid substrates. Calcified biofilm, characterized by peloidal/clotted (grumous) nanofabric, internal microchannels and external architecture of elevated towers and plumes, is widespread as micritic veneers on grain and reef surfaces.

Microbial mats are turf-like structures dominated by intertwined, often filamentous, cyanobacteria and algae, on solid or grainy surfaces. They are believed to form the accreting surfaces of most stromatolites and other relatively large benthic microbial carbonates. Organic material produced by the photosynthetic surface community is recycled by chemoorganotrophic bacteria deeper in the mat, producing well-defined microbial stratification and steep chemical gradients, all in a depth of a few millimeters. Fossil mats preserve only a fraction of this complexity, but can nonetheless retain distinctive features (lamination, primary fenestrae, clotted and peloidal fabrics from calcification of degraded organic material, discrete microfossils such as calcified cyanobacteria) although these do not necessarily all co-occur.

Dome and column morphologies characterize thick microbial carbonates and display laminated (stromatolite), clotted (thrombolite), dendritic (dendrolite) or aphanitic (leiolite)

macrofabrics. Nodules also form, usually with stromatolitic coats (oncoïds). Stromatolites probably appeared at 3540 Ma and contributed significantly to Paleo-Mesoproterozoic (2500–1000 Ma) carbonate platforms. Their Neoproterozoic decline has been attributed to eukaryote competition and/or reduced lithification. However, thrombolites and dendrolites were major Cambrian and Late Devonian reef-builders. In addition to domes and columns, less conspicuous but volumetrically significant microbial masses and layers are widespread in Phanerozoic algal-invertebrate reefs.

Modern marine examples at Shark Bay, Western Australia, and Lee Stocking Island, Bahamas, are coarse-grained agglutinated columns with crudely layered macrofabrics built by cyanobacterial-algal mats on wave-swept hypersaline shorelines (Shark Bay) or in normal salinity tidal channels (Lee Stocking). Thick fine-grained microbial crusts also form on Neogene coral-coraline reefs, and mats and biofilms calcify heavily in present-day calcareous streams and lakes. Temporal variation in abundance of marine microbial carbonate has been attributed to dependence on supersaturation state of seawater facilitating syndepositionary calcification.

Cyanobacterial calcification, in which the protective mucopolysaccharide sheath is impregnated with CaCO_3 , creates distinctive microfossils that contribute to dendrolites, some thrombolites, and skeletal stromatolites. Patterns of cyanobacterial calcification and microbial dome formation through time could reflect fluctuations in seawater chemistry (Riding 2000).

Reefs

Microbial. In the Paleo-Mesoproterozoic and Paleozoic, stromatolite and other microbial reefs are major components of carbonate platforms. Some of the largest examples, hundreds of meters in extent and with tens of meters of relief, formed in deepwater. Dendrolites and thrombolites built by millimetric calcified microbes, most likely cyanobacteria, such as *Angusticellularia*, *Epiphyton*, and *Renalcis*, are locally important as rigid microframes. In Cambrian reefs, (e.g., Siberia) they are often much more abundant than archaeocyath sponges, and can rival stromatoporoids in Late Devonian reefs (e.g., Canning Basin).

Phylloid algae. Carboniferous-Triassic phylloid algae are united by leaflike form more than affinity. Erect blades with internal medulla and cortex (e.g., *Anchicodium*, *Eugonophyllum*, *Ivanovia*) resemble halimedecean green algae. Prostrate crusts with internal cellular tissue and conceptacles (e.g., *Archaeolithophyllum*) resemble red algae, particularly peyssonneliaceans. Both forms build self-supporting skeletal frame reefs with substantial shelter cavities and abundant localized fine sediment that are common in the Late Carboniferous-Early Permian of the southwestern USA, Arctic Canada, and Russia.

Coralline algae. Cell-wall calcification and encrusting growth allow crustose coralline red algae (Cretaceous-Recent) to build reefs in wave-swept environments. Present-day coralline laminar frames are characteristic of Pacific algal ridges and Atlantic cup and boiler reefs. Corallines (e.g., *Lithoporella*, *Lithothamnion*, *Sporolithon*) have calcitic, often magnesium-rich, skeletons and range from tropical to cold and deep water. In mid-latitudes, for example, the Mediterranean, they form thick ledges (trottoir) close to sea-level, and reefs (coralligène) in deeper water. Branched forms create interlocking frameworks in high latitudes. Crustose corallines also form rhodolith nodules. Related articulated corallines disaggregate to sand.

Solenoporaceae, classically regarded as ancestral to coral-ines, are a heterogeneous group of algae and other organisms. Nonetheless, some Ordovician-Silurian fossils attributed to *Solenopora* closely resemble the extant coralline *Sporolithon*.

Peyssonneliaceae, (e.g., *Peyssonnelia*, *Polystrata*), also known as Squamariaceae, resemble crustose corallines in morphology and also participate in rhodolith formation, but are aragonitic and only calcify in warm water. They certainly range Cretaceous-Recent, but also show similarities with some Carboniferous phylloid algae.

Halimeda segment reefs. The heavily calcified (aragonite) tropical marine green alga *Halimeda* (Halimedaceae) is a major Neogene sediment-producer to depths of 150 m. The large branched thallus consists of articulated segments that are shed during life and after death. Rapid growth, up to 35 segments in 13 days, produces copious coarse sediment. In the Florida Keys, *Halimeda* is the single most important component of carbonate sand and gravel, and rivals coral in abundance. At depths of 20–50 m *Halimeda* sediment accumulates as parautochthonous matrix-supported Segment Reefs that extend for kilometers in the northern Great Barrier Reef, Indonesia and the Caribbean.

Cladophora. At calcareous lake margins, calcification of *Cladophora*-like green algae can form tufts of small (~100 µm) branching tubes that amalgamate into cones and ultimately build tufa bioherms several meters across, for example, Miocene of the Ries Crater, Germany.

Particulate sediment

Mud-silt

Post-mortem disintegration of the halimedacean *Penicillus* produces large quantities of aragonite mud-silt in modern tropical carbonate bays and back-reef lagoons. A similar role has been suggested for the calcified cyanobacterium *Girvanella* on Early Paleozoic carbonate platforms. Charophytes (Silurian-Recent, e.g., *Chara*, *Nitella*), large bushy algae that produce fine-grained calcite in freshwater calcareous oligotrophic lakes and streams, are important in the Cretaceous-Oligocene. Disintegration of their weakly calcified stems contributes to accretionary platforms around Holocene temperate ‘marl’ lakes. Sand-grade highly calcified female oosporangia (gyrogonites), 0.2–2 mm in size, remain intact.

Whitings. In calcareous lakes, photosynthetic uptake of CO₂ and HCO₃⁻ by seasonal blooms of picoplanktic cyanobacteria (e.g., *Synechococcus*), diatoms and the other planktic algae, stimulates water column precipitation of calcite crystals, mainly less than ~20 µm in size, that form milky suspensions in surface waters. Similar marine aragonite ‘whitings’ (e.g., Great Bahama Bank) may reflect the same biological stimulus, but inorganic precipitation has not been excluded. Whitings potentially account for abundant lime mud production on carbonate shelves. Stable isotope compositions may distinguish organic (e.g., photosynthetic) from inorganic (e.g., temperature induced) whiting precipitates in present-day sediments, but the origins of ancient lime mud are more problematic.

Sand-gravel

Dasycladaleans and halimedaceans, warm water aragonitic green algae that range Ordovician-Recent, readily disaggregate or fragment to coarse sediment. Dasycladaleans were

important in tropical bays and lagoons during the Late Jurassic-Early Cretaceous and Paleogene. Halimedaceans extend into deeper water and were important in the Upper Triassic and Cenozoic. Gymnocodiaceans, possibly related to halimedaceans, have a similar role in the Permian. Articulated (geniculate) coralline red algae consist of segments, ~0.5–6 mm in size, separated by uncalcified nodes (genicula) and also dissociate after death.

Nodules

Rhodoliths are centrimetric-decimetric coralline red algal nodules. They occur in bays and reefal environments, but are most extensive on current-swept platforms, in both warm and cold water, to depths of ~100 m. In northwestern France, rhodolith gravel is termed maërl. In the Neogene, rhodoliths form matrix-rich beds up to ~15 m thick. Locally, stabilized rhodoliths amalgamate into rigid coralline frame reefs (‘Crustose Pavements’).

Oncoids (oncolites, oncoliths) are millimetric-decimetric nodules with thick stromatolitic coats. They are common in shallow marine environments during much of the fossil record, and locally form marker beds in carbonate shelf sequences. In the Cenozoic they are more common in freshwater. Oncoid cortices are often complex associations of fine-grained and clotted microfabrics together with calcimicrobes. Oncoids in present day calcareous lakes and streams are usually dominated by calcified cyanobacteria.

ALLOPHANE AND IMOGOLITE

Allophane and imogolite are clay-sized minerals commonly associated with tephra deposits. They are also found in some non-tephric soils and sediments, as well as in streambeds and drains.

Definitions

Ross and Kerr (1934) showed that allophane was an X-ray amorphous material commonly associated with the clay-mineral halloysite. They suggested that “the name allophane should be restricted to mutual solid solutions of silica, alumina, water and minor amounts of bases but should include all such materials, even though the proportions of these constituents may vary.” Although this definition is still generally acceptable, some changes are required to (a) exclude imogolite, (b) allow for broad X-ray diffraction lines that are shown by allophane, and (c) allow for synthetic allophanes, that may not contain bases at low pH.

The definition given by Parfitt (1990a) is “Allophane is the name of a group of clay-size minerals with short-range-order which contain silica, alumina and water in chemical combination.” There are three main types of allophane: these are the aluminum-rich allophanes; the silicon-rich allophanes; and the stream-deposit allophanes.

Imogolite, a mineral made up of bundles of fine tubes, is excluded from this definition because it has long-range-order in one dimension (Farmer and Russell, 1990).

Structures

Imogolite is a tubular mineral; the walls of individual tubes are 0.7 nm in thickness; the outer surface is a gibbsite-like curved sheet, and the inner surface consists of O_3SiOH , with the oxygen replacing the inner hydroxyls of the gibbsite sheet. Allophane is made up of hollow spherules with a diameter of 4–5 nm. Al-rich allophane has an Al/Si ratio of about 2 and an imogolite-like structure. Si-rich allophane contains polymerized silicate, and has an Al/Si ratio of about 1. Stream deposit allophanes have Al/Si ratios of 0.9–1.8, with Al substituting for some Si in the polymeric tetrahedra.

Properties

Allophane and imogolite have large specific surface areas (700–1500 m²/g) and react strongly with anions, such as phosphate and arsenate. Organic matter is also strongly bound to allophane and imogolite, decomposing only slowly in allophanic deposits. Such deposits usually have large porosity and water contents; the pores being stabilized by the positive and negative charges on the surfaces of these minerals.

Identification and estimation

In the field, allophane deposits may be identified by their characteristic greasy feel. As little as 2% allophane can be detected in this way. Allophane and imogolite can best be estimated by dissolving in acid-oxalate, and measuring concentrations of Al and Si (Parfitt, 1990a). Imogolite can be estimated by electron microscopy and differential thermal analysis (Parfitt, 1990b). However, if the sediment contains more than about 0.5% carbon, the contribution of Al from Al-humus complexes that dissolve in oxalate must be accounted for and this can be achieved by using pyrophosphate reagent (Parfitt, 1990a).

Processes of formation

The rate of formation of allophane is chiefly controlled by macro- and micro-environmental factors, together with mineralogical and physicochemical composition of the parent deposits. The effect of time is subordinate to these factors (Lowe,

1986). The activity of silicic acid, the availability of Al species, and the opportunity for co-precipitation are very important. The Si and Al are controlled by leaching, organic matter and pH. Generally, allophane forms at pH values between 5 and 7, and a pH value of at least 4.8 is required for allophane to precipitate.

Allophane is commonly found in tephra layers under humid climates, where volcanic glass dissolves to produce allophane. On the face of open soil pits containing rhyolitic tephra, allophane has been observed to precipitate within a time frame of months (Parfitt, unpublished data). The mineral can also precipitate in drains. Allophane has been found in tuffs (Silber *et al.*, 1994), lava (Jongmans *et al.*, 1995), lacustrine sediments (Warren and Rudolph, 1997), and Silurian sediments (Moro *et al.*, 2000). Further, allophane is involved in the formation of indurated layers or pans in soils and sediments (Thompson *et al.*, 1996; Wilson *et al.*, 1996; Jongmans *et al.*, 2000).

Imogolite is usually found accompanying allophane, but the classical pure imogolite in Japan occurs as gel films over the surface of lapilli (Yoshinaga and Aomine, 1962).

ALLUVIAL FANS

Introduction

Alluvial fans are depositional features, formed of coarse gravel sediments, created where high-bed-load streams enter zones of reduced stream power, and deposit the coarser fraction of their loads. The resultant landforms are usually fan-shaped in plan and wedge-shaped in profile (Bull, 1977). They occur commonly in two topographic situations: at mountain fronts and at tributary junctions (Harvey, 1997). They are subaerial features, however if they extend into water they are known as fan-deltas.

Sediment transport and deposition processes on alluvial fans range from debris flows, to sheetfloods and channelized streamflows. Fans range in axial length up to 10s of km, though many fans described in the literature range in size between ca. 100 m and a few km. As scale increases there is a tendency for the dominant process to change, from small debris-flow dominated tributary-junction fans (debris cones), to mixed processes and sheetflood dominance at intermediate scales, and dominance by channelized fluvial flows at the largest scales.

Alluvial fans are important features within mountain fluvial systems, acting as sediment stores. They preserve a sedimentary record of environmental change, and act as major controls on the downstream fluvial system, often breaking the coupling between sediment source areas and distal fluvial environments (Harvey, 1997).

The published work deals with both the sedimentology and the geomorphology of alluvial fans, and to some extent the two are interdependent, however there are differences of emphasis. Much of the earlier work dealt with fans at faulted mountain fronts in the American southwestern deserts, hence there is an emphasis on fans as desert features and on tectonic controls. This emphasis occurs especially in the sedimentological literature, in relation to ancient fan sediments, perhaps because the preservation potential is high for fan sediments deposited at the margins of subsiding basins. However, fans do occur in many climatic environments, and in tectonically stable situations, in which case climate is often seen as a major control. This is perhaps the primary emphasis in the geomorphological literature, in relation to Quaternary and modern fans.

Historical context

Numerous studies in the American southwest provide the basis for our knowledge. Important papers by Blissenbach (1954), dealing with fan sediments, by Denny (1965) dealing with the Death Valley fans, and by Hooke (1967) linking fan processes, sediments and morphology were followed by a series of papers by Bull (for details see Bull, 1977), examined the relations between tectonics, fan morphology and sediments. Research on modern fans has continued in the American southwest and has developed in other regions (see Rachocki and Church, 1990), in other dry regions (e.g., Wasson, 1979; Harvey, 1990; Nemeč and Postma, 1993; Gerson *et al.*, 1993), in arctic and alpine regions (e.g., Leggett *et al.*, 1966; Ritter and Ten Brink, 1986), in humid temperate regions (e.g., Harvey and Renwick, 1987; Kochel, 1990) and in the humid tropics (e.g., Kesel and Lowe 1987).

Fan sedimentary sequences have been incorporated into the fluvial sediment sequence models of Miall (1977, 1978) and are also described in standard sedimentology texts (e.g., Reineck and Singh, 1973). Studies of alluvial fan sedimentary sequences, described from terrestrial environments throughout the geological timescale, are far too numerous to deal with in detail here. A comprehensive bibliography is given by Nilsen and Moore (1984).

Important studies have attempted to relate fan sedimentary sequences with fan processes (Bull, 1972; Blair and McPherson, 1994), especially in relation to individual flood events (Wells and Harvey, 1987; Blair and McPherson, 1998) and to infer catchment characteristics from past fan sediments (Hirst and Nichols, 1986; Mather *et al.*, 2000). For reviews of the alluvial fan literature, with emphasis on sedimentology see Nilsen (1982), Nilsen and Moore (1984) and Blair and McPherson (1994), and with emphasis on geomorphology see Bull (1977) and Harvey (1997).

Essential concepts: fan processes and sediments

There is a close two-way link between alluvial fan morphology and sedimentology. Fans are products of deposition and therefore the morphology reflects the depositional style. For example, fan gradients are higher for deposition by debris-flows than by fluvial processes (Kostaschuk *et al.*, 1986), and higher for sheetflood than for channelized fluvial deposition (Blair and McPherson, 1994). Similarly, deposition is conditioned by fan morphology, for example, by gradient and flow confinement. Because of this close relationship, fan morphological properties show relationships with the same catchment characteristics that control water and sediment delivery to the fan. Fan size generally shows a direct geometric relationship, and fan gradient an inverse geometric relationship to catchment area (Bull, 1977; Harvey, 1997).

In more detail, several fan styles can be identified, reflecting the relationships between erosion and deposition in fan environments. A non-trenched aggrading fan is one on which sedimentation takes place from the apex downfan. More common are telescopic or prograding fans, where the feeder channel is incised into the apex zone as a fanhead trench, but emerges onto the fan surface at a midfan intersection point, beyond which deposition occurs. Finally are various styles of dissecting fans, with dissection focused at the apex, in midfan or distally. The extreme would be a fan trenched throughout its length (Harvey, 1997).

Several groups of sedimentary processes are important: the primary debris-flow and fluvial processes delivering sediment to the fan, the secondary fluvial, and in arid areas eolian, processes reworking or eroding the sediment, and the tertiary pedogenic processes modifying the fan surface.

The primary processes depend on the water:sediment mix fed to the fan from the catchment during flood events (Wells and Harvey, 1987), and to a certain extent on the particle-size characteristics of the fine sediment. Debris-flow processes operate as sediment-rich flows, especially with a silt or clay matrix (Suwa and Okuda, 1983). Under greater dilution flows become transitional or hyperconcentrated and at higher dilution become fluvial flows. Debris flows are most common where sediment concentrations are high, for example, from small, steep catchments (Kostaschuk *et al.*, 1986; Wells and Harvey, 1987). Fluvial flows may operate within channels or as sheetflows. Channelized flows would be more common in proximal fan

environments especially where the feeder channel is in a fan-head trench, but may also occur throughout, especially on larger fans. On distal fan surfaces, channels may switch courses by avulsion, but sheetfloods are more common on the distal surfaces of desert fans (Blair and McPherson, 1994).

Fan sediments are coarse and texturally immature, having been deposited during floods either as debris flows or as fluvial deposits fed by steep mountain streams. Common sedimentary facies include matrix-supported gravels (Gms: after Miall, 1978), deposited by debris flows, and clast-supported gravels (Gm, Gt, Gp), deposited by both channelized fluvial flows and sheetfloods. Sandy facies and fines are of less importance except in distal environments. Debris flows will be represented by massive boulder- to cobble-conglomerates, with true debris-flow deposits exhibiting matrix-support and an internal fabric of crude oblique-to-vertical clast alignment resulting from compression and internal shear (Wells and Harvey, 1987; Blair and McPherson, 1998). Transitional deposits are usually massive, poorly sorted, clast-supported (fanglomerate) gravels, with less matrix than true debris-flow deposits. They have little or no internal structure or may exhibit weak bedding. Fluvial deposits within alluvial fans range from thin sheet gravels, often showing coarse and fine couplets, associated with maximum and waning flows (Blair and McPherson, 1994). They may show relatively little basal scour, in contrast with gravels deposited by channelized flows. These deposits will show characteristics of stream deposits, scoured bases, bedding (planar and locally cross-bedding), moderate sorting and often weak imbrication, though they are likely to show less order than perennial braided stream deposits, due to limited reworking and reorganization by moderate flows.

Because fans are generally flood-event related, receiving sediment only occasionally, and because sedimentation takes place on only parts of the fan, most of the fan surface undergoes weathering and soil formation for most of the time. This is accentuated on surfaces incised by a fanhead trench. Soils and paleosols are therefore important constituents of fans. They are especially useful for correlation and dating purposes, and have been used in this way on Quaternary fans in humid regions (e.g., Harvey, 1996a), in tropical areas (Kesel and Spicer, 1985), but above all in arid and semiarid regions (Wells *et al.*, 1987; McFadden *et al.*, 1989; Bull, 1991). Several aspects of desert soils on fan surfaces have been shown to change progressively with age, including desert pavement surfaces (Dan *et al.*, 1982; McFadden *et al.*, 1987; Al-Farraj and Harvey, 2000), soil B-horizon color, Fe-oxide and mineral magnetic properties (White and Walden, 1997; Harvey *et al.*, 1999a), and pedogenic carbonate and calcrete (caliche) characteristics (Lattman, 1973; Machette, 1985; Alonso Zarza *et al.*, 1998). There are implications for interpreting ancient as well as Quaternary fan sequences (Wright and Alonso Zarza, 1990).

The spatial and vertical variations of fan sediments depend on the relationships between fan morphology and processes. On many intermediate-sized fans debris flows may not travel much further than midfan. Sheetflood processes will occur only on non-dissected fan surfaces or on distal surfaces beyond the intersection point. Under both sheetflow and channelized fluvial flows transporting power may diminish downfan. These three trends lead to spatial patterns in sediment properties, with a tendency for proximal-to-distal variation in the relative importance of sediment types (Harvey, 1997) and an overall tendency for a downfan decrease in sediment size. Laterally there are also likely to be spatial variations in sediment types in

relation to the position of the axial channel and the probability of sediment reworking.

Such trends are likely to be expressed in vertical sections with differences between sequences from small or intermediate-sized fans and those from larger fans, and differences between proximal and distal environments (Harvey, 1997). In the proximal zones of smaller fans, sequences are likely to show rapid vertical variations between debris-flow and fluvial channel deposits (the Trollheim type of Miall, 1978), but in distal zones debris flows will be rarer and thin sheetflood sediments more common. On fluvially dominant fans (with sequences of the Scott type of Miall, 1978) alternations between channel and sheetflood sediment are common. In both cases paleosols could be important horizons.

In fan distal zones sediments may exhibit simple stacked stratigraphy, but proximal zones prone to fanhead trenching, may exhibit inset stratigraphy, preserving deep incisions of buried fanhead trenches (Harvey, 1987). Indeed the presence of fanhead trenches produces two contrasting models of fan sedimentary sequences. On non-trenched aggrading fans an overall fining sequence would be expected, associated with the progressive burial of the mountain-front topography, whereas on fans undergoing fanhead trenching sediment sequences would be expected to show overall coarsening as formerly proximal deposits are reworked distally (Heyward, 1978; Steel *et al.*, 1977).

Essential concepts: controls on fan development

Two main groups of controls influence the development of alluvial fans, those relating to the setting of the fan and those related to processes. Those related to the setting include the gross topography of the site, governed by tectonics and long-term geomorphic history (e.g., glaciation), and control the accommodation space. Those related to processes include the delivery of water and sediment from the mountain catchment, its transport to and deposition on the fan, and the potential for erosion of the fan surface. These processes are in turn controlled by the size, relief and bedrock geology of the catchment, by the climate, and by the fan morphology itself, including its relationship to local base levels.

These factors can be grouped into four partially related sets, any of which may be subject to change within the timescale of the existence of an alluvial fan. These sets are: (i) source area relief and geology, (ii) tectonic factors, (iii) climatic factors, and (iv) base level. Fan processes may respond to changes in these factors—the changes being recorded within the fan morphology and sediment sequences.

Source-area relief and geology influence the sediment yield of the catchment, but may change little over the short term. However, changes may occur in response to headwater stream capture (Mather *et al.*, 2000) causing sudden changes in water and sediment supply, or to long-term changes in sediment availability related to progressive erosion of the source area.

Past tectonics may have a major influence on the fan setting. Ongoing tectonics may cause uplift of the source area and an increase in sediment production, or may cause a change in fan gradients by tilting. At the regional scale uplift-induced dissection may cause a change in base level, triggering fan-toe erosion (see below). However the most significant role of tectonics for basin-margin fans is the ongoing creation of accommodation space brought about by continued basin subsidence. Within the literature on Quaternary fans, tectonics has been seen as

an important control on fan sedimentation (Calvache *et al.*, 1997) and on geomorphology (Bull, 1961, 1978; Silva *et al.*, 1992), but in the sedimentological literature as a whole is often seen as the primary control over fan sediment sequences in the ancient record (e.g., Sharp, 1948; Steel, 1974; Heyward, 1978).

Climate influences sediment availability within the catchment through weathering processes, and sediment delivery from hillslopes to channels through slope failure and slope erosion processes. Climate also influences both water and sediment supply to the fan through its influence on the flood hydrology of the stream system. Processes on the fan and the resultant morphology respond to climatically led sediment supply and flood hydrology regimes. The relationships between debris-flow and fluvial processes depend on the water-sediment mix during flood events (Wells and Harvey, 1987), and the erosional-depositional regime as a whole depends on the threshold of critical stream power (Bull, 1979), itself governed by the water-sediment regime. While it is recognized that alluvial fans may occur in any climatic environment, a climatic change may modify these relationships, resulting in changes in fan dynamics. Significant changes in erosion-sedimentation regimes resulting from Quaternary climatic changes have been identified in many dry regions including the American southwest (Bull 1991; Wells *et al.*, 1987; Dorn, 1994; Harvey *et al.*, 1999b), and the drier parts of the Mediterranean region (Roberts, 1995; Harvey, 1996a). Similarly in mountain areas glaciated during the Pleistocene, fan deposition has been identified as a paraglacial phenomenon, supplied with sediment from previously glaciated catchments (Ryder, 1971; Brazier *et al.*, 1988).

Most fans accumulate under relatively stable base-level conditions. However, a base-level change may cause a switch from deposition to erosion in fan-toe zones, which may progressively dissect the fan headwards. Base-level changes may be induced tectonically or as secondary effects of climatic change. These may be important on coastal fans following Quaternary eustatic sea-level changes, or on fans at the margins of pluvial lakes following changes in lake level. Similarly a base-level change may affect tributary-junction fans following climatically-induced incision of an axial drainage. However, the effects of base-level change are not necessarily straightforward. In the common case of a fall of base level, dissection will occur only if the newly exposed gradients are sufficient to trigger incision. On the other hand, a regional sea-level rise may cause fan dissection if it is accompanied by coastal erosion and fan-profile foreshortening (see Harvey *et al.*, 1999a). The effects are similar to erosional "toe-cutting" by a laterally migrating axial drainage (Leeder and Mack, 2001).

Interactions between tectonic, climatic and base-level factors form an ongoing discussion in the literature. The consensus is that, at least for Quaternary fans, climate appears to have the primary role (Bowman, 1978; Frostick and Reid, 1989; Ritter *et al.*, 1995).

Modern trends in alluvial fan research

In addition to considerations of interactions between the main groups of causal factors, several other trends in modern alluvial fan research can be identified. There has been detailed study of the relationships between the fundamental processes that affect alluvial fans and the properties of the sediments preserved. This is especially true of debris flows (see Costa, 1988; Blair and McPherson, 1998). Such an understanding

provides the basis for a clearer interpretation of ancient fan sediments, related to knowledge of modern fan processes and sedimentology.

In relating Quaternary fan sequences to the climatic sequence, the interdisciplinary nature of such studies is becoming increasingly apparent (Harvey *et al.*, 1999b). Fundamental here are advances in dating and related techniques, for example the application of cosmogenic dating techniques (Harbor, 1999), and more sophisticated analyses of soils (e.g., White and Walden, 1997) on alluvial fan surfaces will provide a much tighter framework for alluvial fan chronologies and environmental reconstruction.

Furthermore, the interdependence of geomorphology and sedimentology in alluvial fan research is becoming even more apparent. This is true not only for understanding the dynamics of alluvial fans themselves (e.g., Leeder and Mack, 2001), but also in relating alluvial fans to their source areas, where knowledge gained from the study of Quaternary and modern fans is being applied to interpreting older fan sequences (e.g., Mather *et al.*, 2000).

Summary

Alluvial fans are important sedimentary environments that are fundamental in a coupling/buffering role within mountain (especially but not exclusively dry-region) geomorphic systems. They preserve a sedimentary record, on modern fans of drainage-basin response to Quaternary climatic change, and in the longer term of the tectonic controls over sediment supply to sedimentary basins. There is a close two-way interaction between geomorphic and sedimentological processes on alluvial fans. Fan sedimentology and morphology respond to tectonic, climatic and base-level controls, and as such express the fundamental dynamics of geomorphic and sediment systems.

ANABRANCHING RIVERS

Introduction

An *anabranching* river is defined as a system of multiple channels characterized by vegetated or otherwise stable alluvial islands that divide flows at discharges up to bankfull. These islands may be excised by channel avulsion from extant floodplain (see Avulsion), developed from within-channel deposition or formed by prograding tributary-channel accretion on splays or deltas. Common usage has confined the related term *anastomosing* to a specific subset of relatively distinctive low-energy anabranching systems associated with mostly fine-grained or organic deposition (Smith and Smith, 1980; Knighton and Nanson, 1993; Makaske, 2001). Neither of these

terms now applies to braided rivers (see Rivers and Alluvial Fans) where the divided flow pattern is strongly stage-dependent around bars that are unconsolidated, ephemeral, poorly vegetated and overtopped at less than bankfull flow. In an anabranching system, the islands are about the same elevation as the adjacent floodplain, usually persist for decades or centuries, have relatively resistant banks, and support well-established vegetation. Anabranching always occurs concurrently with other patterns such that individual channels braid, meander or are straight. Such rivers occupy a wide range of environments, from low to high energy, and occur in arctic, alpine, temperate, humid tropical and arid climatic settings. They are more common than has been recognized previously; a total of 90% by length of the alluvial reaches of the world's ten largest rivers anabranch, and it is a particularly widespread river pattern for both large and small rivers in inland Australia. Numerous rivers in Europe used to anabranch but most of these have now been modified to more “convenient” single-thread forms in densely populated and heavily utilized valleys.

While research continues into the fundamental cause of anabranching, it has been argued that an advantage of anabranching is that islands concentrate stream flow and maximize bed-sediment transport per unit of stream power, particularly where there is little or no opportunity to increase channel gradient (Nanson and Huang, 1999).

Classification

On the basis of stream energy, sediment size and morphological characteristics, Nanson and Knighton (1996) recognize six types of anabranching river; Types 1–3 are lower energy and Types 4–6 are higher energy systems. Type 1 are *Cohesive Sediment* rivers (commonly termed anastomosing) with low w/d ratio channels that exhibit little or no lateral migration. They are divisible into three subtypes based on vegetative and sedimentary environment (Figure A3a). Type 2 are *Sand Dominated Island Forming* rivers and Type 3 are *Mixed Load Laterally Active* meandering rivers. Type 4 are *Sand Dominated Ridge Forming* rivers characterized by long, parallel channel-dividing ridges (Figure A3b). Type 5 are *Gravel Dominated Laterally Active* systems that interface between meandering and braiding in mountainous regions (Figure A3c). These have been described as wandering gravel-bed rivers (Church, 1983). Type 6 are *Gravel Dominated Stable* systems that occur as non-migrating channels in small, relatively steep basins.

Anastomosing rivers

Because of their fine-grained nature and tendency to accumulate substantial organic material, anastomosing rivers are a potentially economically important group of anabranching rivers. Modern examples were first described in detail in the alpine and humid environment of the Rocky Mountains of western Canada (e.g., Smith, 1973; Smith and Smith, 1980) but have subsequently been described in a wide variety of settings including arid environments (e.g., Gibling *et al.*, 1998; Makaske, 2001). In rapidly accreting humid settings, peats can accumulate in floodplain lakes and swamps to form coal, and sandy paleochannels may act as reservoirs for hydrocarbons. However, not all anabranching rivers are rapidly vertically accreting and in arid environments they do not accumulate organics. Makaske (2001) found no standard sedimentary

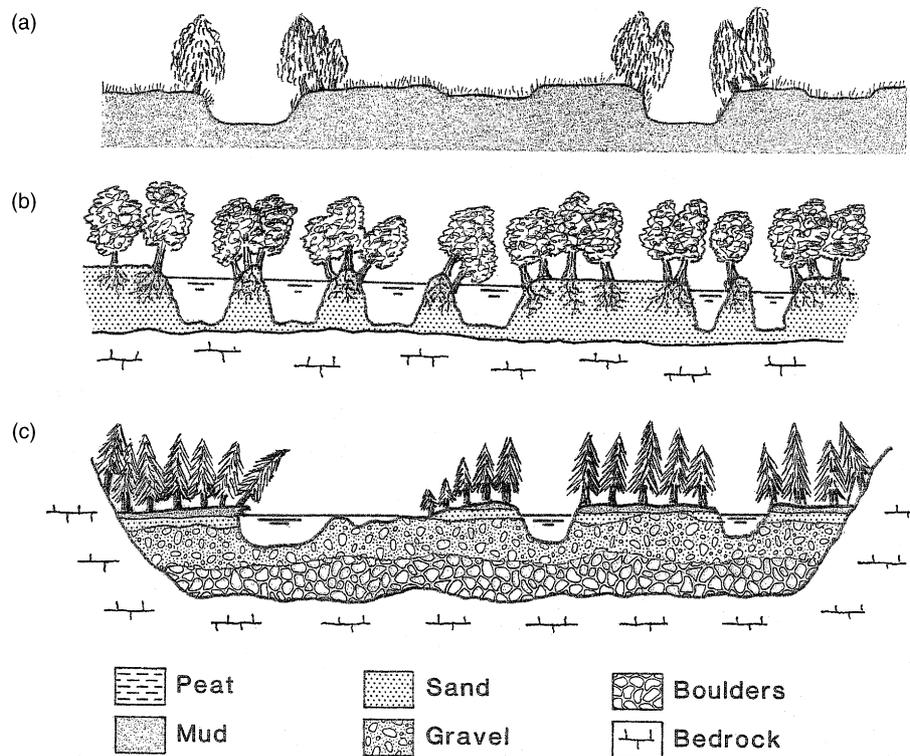

Figure A3 Examples from the range of anabranching river stratigraphy (a) Cohesive-sediment anabranching river; (b) Sand-dominated ridge-forming anabranching river; (c) Gravel-dominated laterally active anabranching river (after Nanson and Knighton, 1996).

succession for anastomosing rivers, however, he described them in three different settings and showed some common characteristics. His schematic diagram of the Columbia River is presented here as an example of the style of stratigraphy in a rapidly vertically-accreting humid montane setting with organic-clastic accumulation (Figure A4). Such anastomosing rivers (and delta distributary channels) tend to have fixed channels that aggrade with only limited lateral expansion, thus generating ribbons or narrow sheets (width : thickness ratio <15 and $15-100$, respectively) encased in floodplain fines. Most fixed-channel bodies are less than 10 m thick, with width : thickness ratios typically less than 30 and commonly less than 15. Many examples in the rock record *probably* represent long-lived anastomosing rivers that formed trunk drainage systems or transverse alluvial cones. Many of these deposits lie in rapidly subsiding settings, especially foreland and extensional basins characterized by large sediment flux and low gradients. Deltaic distributary channel bodies, many probably formed from relatively straight channels, typically comprise fills of mixed sand and mud, with marine- or brackish-water fossils, slumped masses, and a common association with coal. The avulsion of a major channel into wetlands may generate a splay complex with suites of small, transient anastomosing channels, with the eventual establishment of a stable, single-channel course. In arid environments, alluvial and eolian deposits can be juxtaposed, whereas in vertically accreting humid environments channel fills are flanked by silty levee deposits, lacustrine clay and coal.

There is a recent tendency to attribute all ribbon bodies in the rock record to anastomosing river systems, however, some could also be assigned to the more general *fixed-channel model* (Friend, 1983) because it is difficult to show that the original channels formed a synchronous anastomosing network (Makaske, 2001). Indeed, in a review of fluvial facies models, Hickin (1993) suggested that the anastomosing model is a somewhat premature concept based on the study of relatively few rivers, the full development of which should await detailed investigation of a much wider range of types.

Conclusion

Anabranching rivers represent a diverse group from low energy, organic or fine sediment-textured, to relatively high energy gravel-transporting systems. They are commonly associated with flood-dominated flow regimes, banks that are resistant to erosion, and sometimes with mechanisms to block or constrict channels and induce channel avulsion. They can develop as erosional systems that scour channels into the floodplains or accretional systems that build islands within, or floodplains around (as in subaqueous deltas), existing channels. Anabranching is commonly associated with laterally stable channels but individual channels can meander, braid or be straight. Anabranching rivers represent a widespread and distinctive group that, because of particular sedimentary, energy-gradient, and other hydraulic conditions, operate most

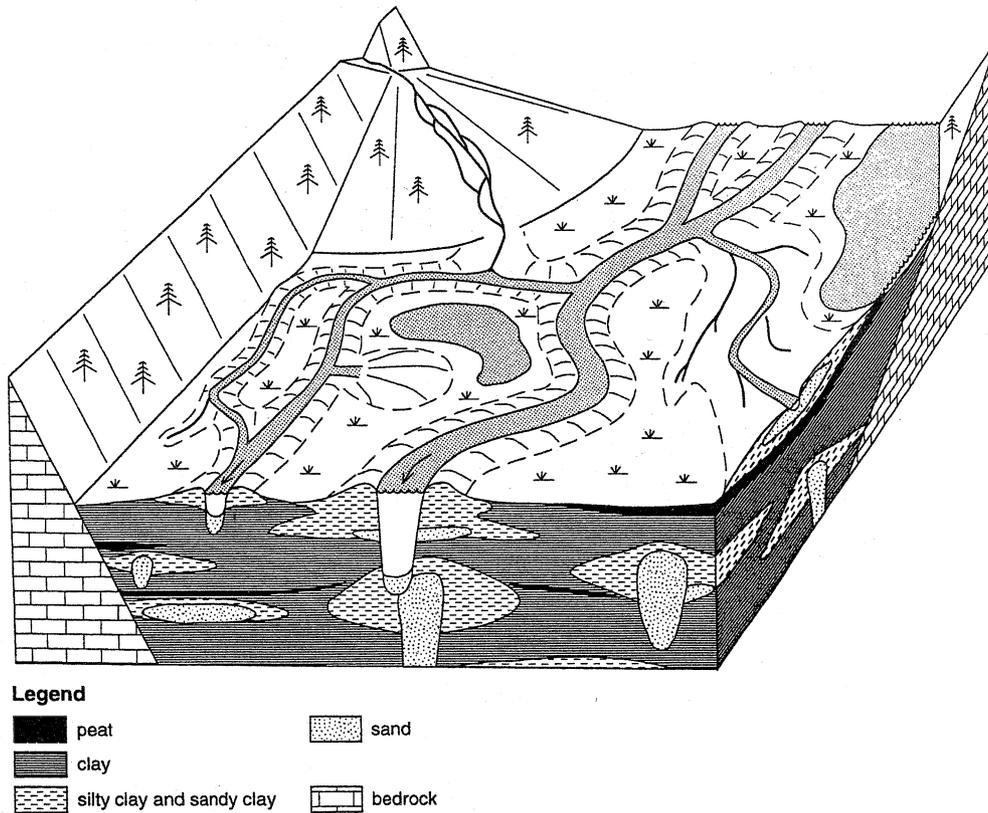

Figure A4 Textural facies model of the upper Columbia River (British Columbia, Canada), a rapidly aggrading anastomosing system in a temperate humid montane setting. Scale is approximately 2 km in width and alluvial thickness ~10 m (after Makaske, 2001).

effectively as a system of multiple channels separated by vegetated floodplain islands.

ANCIENT KARST

Introduction

Karst is characterized by spectacular surface topographies, caves, and subterranean drainage systems that have developed in soluble limestone, dolostone, or gypsum bedrocks (e.g., Jennings, 1971, 1985; Sweeting, 1973; Bögli, 1980; Trudgill, 1985). Karst is geologically complex because it represents the

balance between the diametrically opposed processes of dissolution and precipitation which are mediated by groundwater that flows over and through the bedrock. Thus, from a geological perspective karst is a subaerial diagenetic terrain. Esteban and Klappa (1983) defined karst as "... a diagenetic facies, an overprint in subaerially exposed carbonate bodies, produced and controlled by dissolution and migration of calcium carbonate in meteoric waters, occurring in a wide variety of climatic and tectonic settings, and generating a recognizable landscape." Similarly, Choquette and James (1988) defined karst to "... include all of the diagenetic features—macroscopic and microscopic, surface and subterranean—that are produced during the chemical dissolution and associated modification of a carbonate sequence."

Ancient karst (or paleokarst) includes relict paleokarst (present landscapes formed in the past) and buried paleokarst (karst landscape buried under younger sediments) as defined by Jennings (1971), Sweeting (1973), and Choquette and James (1988). Ancient karst is characterized by an unconformity that represents the original erosional landform and the underlying "karsted" rocks, which are characterized by diagenetic fabrics formed by dissolution and precipitation. Recognition of ancient karst is important because the karst surface represents a break in deposition that commonly constitutes a sequence boundary, and the diagenetically modified rocks beneath the karst surface may be superb reservoir rocks for hydrocarbons or hosts for various economically important ores.

Features of ancient karst

An ancient karst surface may be characterized by (1) stratigraphic–geomorphic features, (2) macroscopic surface and subsurface karst features, and (3) microscopic features (Choquette and James, 1988).

Stratigraphic–geomorphic features

The recognition and reconstruction of the topography of large-scale, ancient karst landforms, such as towers and dolines, relies on the availability of good surface exposures, high-resolution seismic profiles, or numerous closely spaced wells. The profiles of such landforms will only become evident if they are mapped relative to a datum that represents a time surface and was flat at the time of formation (cf. Choquette and James, 1988). The lack of fluvial sediments on the erosional surface indicates that it formed through karst rather than by fluvial erosion. An ancient karst surface may be difficult to recognize in small outcrops or core because the limited scale precludes recognition of the large-scale landforms. Indeed, on a small scale, an ancient karst surface may be identical to any other bedding plane in the succession. The Cayman Unconformity, for example, is a karsted surface that formed during the Messinian and now separates the Cayman Formation (Miocene) from the Pedro Castle Formation (Pliocene) on Grand Cayman (Jones and Hunter, 1994). In Pedro Castle Quarry it is apparent as a relatively flat surface that, at first glance, appears to be a bedding plane (Figure A5). Mapping across the island, however, shows that this unconformity has a rugged relief of at least 40 m (Jones and Hunter, 1994).

Potentially, a karst surface may separate sedimentary successions that formed in different depositional regimes. This, however, assumes that the depositional regime established following development of karst surface was significantly different

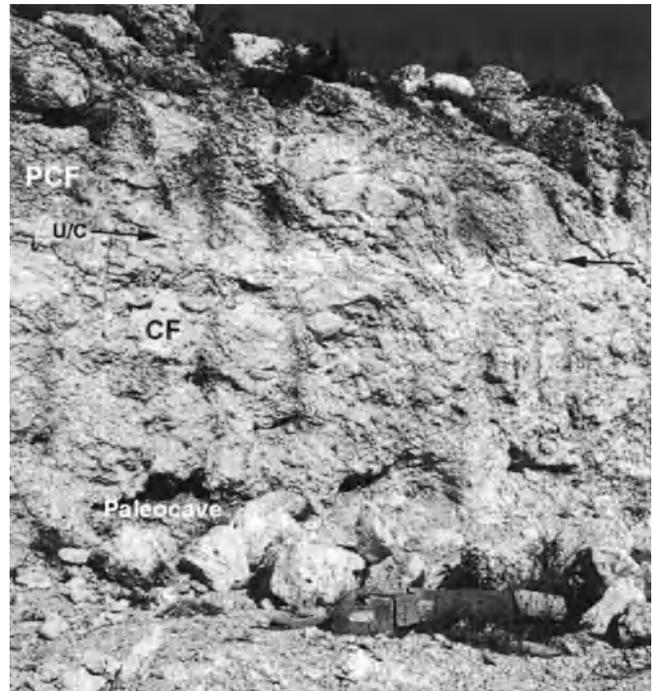

Figure A5 General view of the Cayman Unconformity (U/C) that separates the Cayman Formation (CF) from the Pedro Castle Formation (PCF) in Pedro Castle Quarry, central-south coast of Grand Cayman. Although horizontal in this quarry, this karst surface has a relief of ~40 m when traced across the island (Jones and Hunter, 1994). Note paleocaves located beneath the unconformity.

from those that existed prior to subaerial exposure and karst development. This is not universally true. On Grand Cayman, for example, the facies in the Pedro Castle Formation are similar to those found in the underlying Cayman Formation despite the fact that the two formations are separated by a high-relief, karsted unconformity.

In the simplest sense, strata located beneath a karst surface should be characterized by fabrics that are indicative of meteoric diagenesis whereas the rocks above the unconformity should be devoid of such fabrics. In many situations, however, this is not the case because the entire carbonate succession evolved through a succession of depositional-karst cycles with each phase of deposition being followed by a phase of karst development. Accordingly, virtually all parts of a succession will exhibit the results of meteoric diagenesis and many parts of the succession may be subjected to more than one cycle of such diagenetic alteration.

Macroscopic surface and subsurface karst features

Macroscopic surface karst features include various types of karren, phytokarst, kamenitzas, soils, caliche (see caliche—this volume), nonsedimentary channels, lichen structures, brown- or red-dish fracture fillings, and mantling nonsedimentary breccias (Choquette and James, 1988, table 2). Macroscopic subsurface features include caves and other smaller cavities, *in situ* brecciated and fractured strata, collapse structures, dissolution-enlarged features, rubble-and-fissure fabrics, cave

sediments, and irregular-shaped breccia bodies which may or may not be conformable with the host strata (Choquette and James, 1988, table 2).

Not all features will be found in every ancient karst terrain. Some may be absent simply because they were never developed. Other features may have been formed but then destroyed by erosion during the next transgression (e.g., Jones and Smith, 1988). Soils, including terra rossa, are typically unconsolidated and therefore prone to removal as sea-level rises and drowns the karst terrain. Similarly, phytokarst is commonly formed of delicate structures that are prone to destruction as they are submerged by rising sea-level. In many cases it may be difficult to recognize surface karst features because they are buried beneath younger sediments. If surface features are present, such as those recognized on the unconformity at the top of the Lower Ordovician Romaine Formation in Quebec (Desrochers and James, 1988), they offer important evidence of karst development.

Microscopic karst features

Microscopic karst features, usually recognizable only in thin sections, include products of dissolution (e.g., formation of fabric-selective pores; etched carbonate cements), bioerosion (e.g., sparmicritization, micritized grains), precipitation (e.g., meniscus, pendent, and needle-fiber vadose cements), and/or sediment transportation (e.g., vadose silt, eluviated soil) (cf. Choquette and James, 1988, table 2). Typically, these fabrics have an irregular to random distribution on a scale of millimeters. Thus, dissolution fabrics may characterize one pore in a limestone whereas a neighboring pore may be partly filled or filled with precipitated cements and/or vadose silt. Similarly, individual pores may contain interlaminated sediments and precipitates that are a record of temporal changes in the operative processes.

Karst surface or hardground

As transgressive seas flood a karst surface, various opportunistic encrusting and/or boring organisms will establish themselves on the hard rock that forms the new seafloor. Such colonization typically takes place during the transgressive lag period when sediment production is minimal. The Cayman Unconformity on Grand Cayman, for example, is characterized by numerous sponge, worm, and bivalve borings which were formed when those animals colonized the seafloor as the Messinian karst landscape was flooded. Similarly, numerous borings characterize the unconformity at the top of the Romaine Formation (Desrochers and James, 1988). These surfaces, however, will have many features that are also found on submarine hardgrounds (see hardgrounds—this volume). A bored karst surface, however, will cap a succession of rocks that display a variety of subsurface karst features. By comparison, a hardground will be found in a succession of marine sediments that display no evidence of diagenesis in a karst setting.

Open and filled cavities

Open and filled cavities, which range in size from micropores to large caves, are common features in many ancient karst terrains. Such cavities may have formed through the selective dissolution of metastable mineral components in heterogeneous

carbonates whereas others are independent of fabric. Preferential leaching of aragonitic fossils, for example, produces fossil-moldic cavities with morphologies that reflect the shape of the original fossils. Fabric-independent cavities, which cross-cut textures in the host rocks, tend to be much larger than the fabric-dependent cavities. The aggressiveness of the waters and the length of time over which they interacted with the bedrock controlled development of these cavities. In many cases, they are solution-widened features that were formed by aggressive waters widening preexisting features, such as joints, fractures, and bedding planes.

Cavities in ancient karst terrains may be open or contain speleothems and/or sediments. Although speleothems (e.g., stalactites, stalagmites, flowstone) are common in modern caves, there are relatively few examples of speleothems known from ancient karst terrains. Exceptions to this include the speleothems found in paleocaves in the Cayman Formation (U. Miocene) and Pedro Castle Formation (L. Pliocene) on Cayman Brac (Jones, 1992, figures 12–14). On a small scale, pores may be partly or completely filled with aragonite, calcite, and dolomite cements. Microstalactitic and/or meniscus cements may characterize the vadose cements whereas coarse, cavity-filling spar calcite may form in the phreatic zone.

Many cavities in ancient karst terrains contain sediments that range from mudstones to breccias (see cave sediments—this volume). Their composition is ultimately related to their point of origin because they may have been derived from sources external to the bedrock (exogenic) or from the bedrock itself (endogenic). Cave sediments are commonly characterized by complex arrays of sedimentary structures, including graded bedding, cross-bedding, and/or desiccation cracks. Cavities in the dolostones of the Bluff Group of the Cayman Islands, for example, are commonly filled or partly filled with a wide range of sediments that reflect complex depositional histories (Jones, 1992).

Complex intercalations of speleothems and cave sediments characterize cavities in some ancient karst terrains. Interpretation of these precipitates and deposits may offer important information regarding the conditions that existed following development of the original cavities. Speleothems, for example, typically formed during periods of high rainfall that engendered high groundwater flow and hence, speleothem precipitation. Unconformities in the speleothems typically mark periods of relatively dry climates when speleothem corrosion rather than speleothem precipitation was operative. Similarly, sediments found in a cavity are protected from erosion that may have removed their surface counterparts (cf. Smart *et al.*, 1988; Jones and Smith 1988). Accordingly, analysis and interpretation of the cave sediments may provide information on the geological evolution of an area that cannot be obtained in any other way. In many cases, the sediments found in a cavity can be divided into discrete, unconformity-bounded packages that reflect different phases of deposition. In other settings, unconformity-bounded packages of sediment alternate with speleothems (e.g., Jones, 1992).

Karst breccia

Brecciated masses that formed as a result of bedrock collapse or by angular lithoclasts being transported and deposited in open cavities (e.g., sinkholes) are found in many ancient karst terrains. These concordant and discordant karst breccia bodies form a substantial part of the succession in some karst terrains.

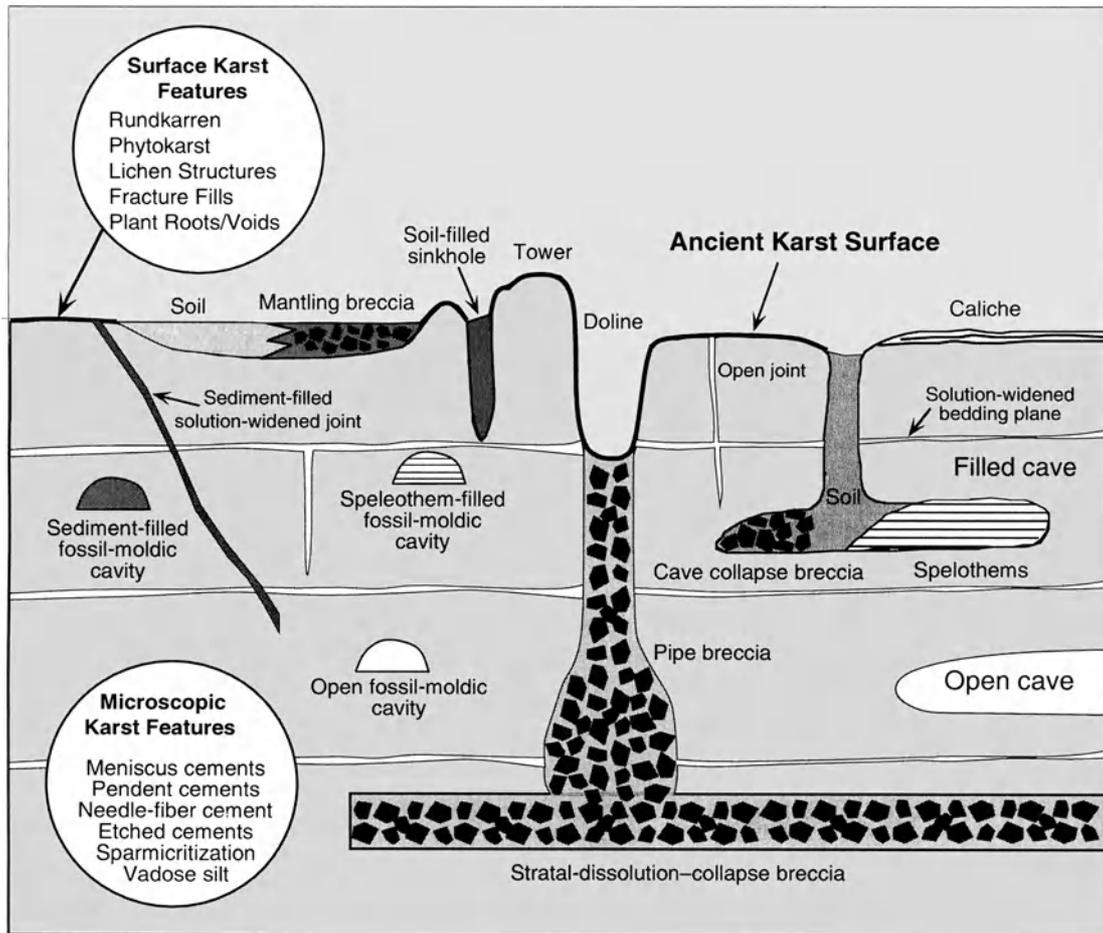

Figure A6 Schematic diagram showing features that may be associated with an ancient karst terrain.

Such breccias are economically important because they may host economically important deposits such as “Mississippi Valley type” lead-zinc-sulfide deposits (e.g., Sangster, 1988).

Karst breccia is virtually impossible to classify because it is so highly variable in terms of its composition, fabric, and external form. Choquette and James (1988, figure 5) suggested that karst breccias can only be classified by virtue of their location and inferred genesis. Mantling breccia, which lies on a karst surface, is formed of collapsed, surface or near-surface country rock that is intermixed with soil and/or sediment (Figure A6). Breccia pipes, which are typically formed by the collapse of strata beneath sinkholes, are usually formed of clasts derived from the bedrock, extraneous clasts that may have been washed in the sinkhole, soil, and sediment. The external shape of the resultant breccia body distinguishes it from mantle breccia (Figure A6). Cave collapse breccia, which generally has a tabular shape, is formed of poorly sorted clasts derived from the bedrock that once formed the cave roof and from external sources (Figure A6). These clasts are commonly held in matrix formed of soil and/or cave sediments that may be exogenic or endogenic in origin. Stratal-dissolution collapse breccia, which has a tabular morphology, commonly appears

to be part of the bedded succession (Figure A6). They usually form when brittle bedrock collapsed following removal of highly soluble rocks, such as salt and evaporates, by subterranean dissolution.

Summary comments

1. An ancient karst surface is an unconformity that formed during a period of subaerial exposure. As such it denotes an important stage in the evolution of ancient carbonate successions and commonly constitutes a sequence boundary.
2. Ancient karst is a diagenetically complex terrain that encompasses features formed by dissolution (e.g., caves), precipitation (e.g., speleothems), and deposition (e.g., cave sediments).
3. “Karsted rocks” are commonly characterized by complex diagenetic fabrics that are highly variable at all scales of observation.
4. Ancient karst terrains can be recognized by their stratigraphic—geomorphic features, their macroscopic surface and subsurface features, and their microscopic features.

Many of these features are subtle and can only be recognized through careful examination of the rocks.

ANGLE OF REPOSE

When sand cascades down the face of a dune, it comes to rest at a slope that has nearly the same angle as a cone-shaped pile of sand formed by a colony of ants. A pile of wheat develops a nearly identical cone having essentially the same slope. This slope angle must therefore be an intrinsic property of loose grains, a property that is generally termed the *angle of repose*, the acute angle that the slope makes with the horizontal. On average this angle is approximately 33°, but varies by a few

degrees depending on the sizes and shapes of the grains, as well as on other factors such as the moisture content.

Investigations of the angle of repose have produced the slope in the laboratory by: (a) carefully pouring loose particles into a pile, (b) removing one side of a container to release the particles, or (c) rotating a trough containing grains until movement forms a slope (Van Burkalow, 1945; Allen, 1969; Carrigy, 1970). The rotating trough in particular reveals the existence of two distinct critical angles rather than one. The slope can be slowly increased by rotation until it reaches the critical angle for avalanching, Φ_a , at which point the grains begin to flow, reducing the overall slope to the true angle of repose, Φ_r , the slope after avalanching has ceased. In a similar fashion, when piled to form a cone, the grains accumulate to the angle Φ_a , the mass then slumps to form a new surface at the repose angle Φ_r . The difference between these two angles is typically only 2° to 5°. However, in some cases the difference can be large, especially when moisture introduces surface tension that holds the grains together, acting to increase the angle needed for avalanching, while having little effect on the post-avalanche repose angle.

The studies agree that of the many factors that determine the angle of repose, particle shape has the greatest effect. For example, experiments by Carrigy (1970) comparing spherical glass beads and crushed angular quartz having nearly the same grain sizes revealed that Φ_r is about 10° greater for the angular quartz grains than for the smooth spheres, and when there is a mixture of the two, Φ_r is directly dependent on the proportions of rounded versus angular grains; the commonly observed repose angle of 33° in natural sands occurred when the mixture was about 80% crushed quartz. These results are what one might expect in that the angular grains provide more interlocking surfaces, thereby resisting slippage until a larger avalanche angle is reached, and then coming to rest at a higher angle of repose. Experiments such as these illustrate the fact that the angle of repose represents a measure of the internal friction of the granular material, the degree of friction or interlocking between grains.

The experiments of Carrigy (1970) and others also indicate that slightly different values are obtained for the avalanche angle when the grains are immersed in water rather than in air, while the repose angles are about the same. It had been suggested that the angle of repose should be less in water than in air, and therefore one could use measurements of maximum dips angles of cross-bedding strata to establish whether a sandstone had been deposited subaerially or under water. However, cross-bedding should mainly reflect the angle of repose, and the uniformity of Φ_r in water and air does not support such an interpretation. In addition, Carrigy made measurements on thirty different sands from various natural environments, and found that Φ_r was the same (within measurement error), but that the Φ_a avalanche angles were without exception greater in air than in water. This was due largely to the effects of surface moisture which tends to bind the grains together in air, a binding effect that is lost when immersed in water. Carrigy demonstrated for one sand sample that the avalanche angle increased from 35.6° when oven dried to 43.4° when 0.95% moisture by weight is present, although the angles of repose following avalanching were nearly the same. When moisture contents are greater than 1%, the sample ceased to behave as a loose granular material, even being able to maintain a vertical escarpment. Static-electricity charges on grain surfaces can have a similar effect in binding the grains.

ANHYDRITE AND GYPSUM

Anhydrite (CaSO_4) and gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) are the two most abundant minerals of ancient marine evaporite deposits and are also common in non-marine evaporite deposits. Sedimentary gypsum forms by direct precipitation out of evaporating seawater under arid climatic conditions in hydrologically restricted marine and marginal marine environments (e.g., tidal flats, coastal lagoons, “inland seas”, etc.). In non-marine, arid closed basin systems, gypsum precipitates from evaporating meteoric waters with chemical compositions dependent on the bedrock types and their proportions in the drainage areas. In contrast, at temperatures and pressures typical of sedimentary environments, anhydrite does not precipitate directly from evaporating waters but, as discussed in the next section, forms by dehydration of precursor gypsum precipitates. Sedimentary anhydrite is, in essence, a diagenetic mineral.

Stability fields of anhydrite and gypsum

In modern arid sedimentary environments gypsum readily precipitates directly from evaporating waters that carry calcium and sulfate ions, a phenomenon that is easily reproduced in the laboratory. In contrast, at typical Earth surface and shallow burial temperatures anhydrite can only be formed experimentally by dehydration of gypsum, a mechanism of formation of anhydrite that appears to operate in modern evaporite environments (e.g., Hardie and Shinn, 1986, p. 49). At higher temperatures, anhydrite nucleates directly from hydrothermal solutions such as the hot brines venting on the modern seafloor beneath mid-ocean ridges. Primary anhydrite precipitates are typical components of ancient hydrothermal Pb-Zn deposits.

Since anhydrite will not precipitate directly from aqueous solutions at sedimentary temperatures, the stability fields of gypsum and anhydrite cannot be accurately determined by classic solubility measurements (Hardie, 1967, pp. 185–188). However, the gypsum-anhydrite transition has been determined via gypsum-anhydrite conversion experiments (Hardie, 1967). For the reversible reaction $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}_{(s)} = \text{CaSO}_{4(s)} + 2\text{H}_2\text{O}_{(l)}$ at any given temperature and pressure, the following thermodynamic relationship must be true:

$$K_{P,T} = a_{\text{CaSO}_4} \cdot a_{\text{H}_2\text{O}}^2 / a_{\text{CaSO}_4 \cdot 2\text{H}_2\text{O}}$$

where K is the equilibrium constant at a given P and T , and a is the activity of each component in the reaction. Since the standard states for gypsum and anhydrite are the pure solids, which by definition have activities equal to unity, then the above relationship simplifies to:

$$K_{P,T} = a_{\text{H}_2\text{O}}^2$$

It follows that the gypsum-anhydrite transition at any given P and T is a function only of the activity of H_2O in the solution phase. Reversible experiments in which gypsum was converted to anhydrite and anhydrite converted to gypsum in solutions with fixed activities of H_2O allowed the construction of a T - $a_{\text{H}_2\text{O}}$ diagram that predicts the gypsum-anhydrite transition temperature in any aqueous solution of known activity of H_2O (Figure A7).

This experimental study underscores the role of kinetics in the behavior of gypsum and anhydrite. *At surface temperatures and pressures, gypsum will nucleate directly from supersaturated aqueous solutions but anhydrite will not.* In the anhydrite stability field (Figure A7), gypsum will be the initial (but metastable) precipitate. With time this metastable gypsum will convert to anhydrite (Hardie, 1967, pp.183–184).

Depositional features of sedimentary gypsum and anhydrite

In modern and ancient sedimentary deposits, both gypsum and anhydrite are found in the form of (1) beds, (2) as isolated crystals or clusters of crystals embedded in carbonate or siliciclastic sediments, and (3) as nodules or clusters of nodules embedded in carbonate or siliciclastic sediments.

Bedded gypsum

There are three main environments in which bedded gypsum can accumulate: ephemeral, shallow perennial, and deep perennial. In these settings bedded gypsum may be found as (1) *chemically precipitated layers*, as settle-out of gypsum crystals nucleated at the brine surface and/or as vertically-oriented crystals grown on the bottom by syntaxial overgrowth, and as (2) *detrital layers* made of sand and gravel size crystals and crystal fragments eroded from primary gypsum sources and redeposited in other parts of the depositional basin.

The distinction between ephemeral and shallow perennial marine environments in which bedded gypsum can accumulate is a narrow, but critical, one. In marginal marine systems, it is the distinction between a supratidal and a shallow subtidal setting. In both settings, bedded gypsum is deposited under subaqueous conditions, conditions that produce identical bottom syntaxial growth fabrics. However, in arid supratidal settings gypsum layers are deposited subaqueously in shallow, ephemeral seawater “lakes” (gypsum pans, see *Sabkha, Salt Flat, Salina*) formed by storm-driven flooding of the tidal flat. As such a “lake” shrinks with progressive evaporative concentration, the newly formed bed of crystalline gypsum is exposed to the air. This leads to evaporative pumping of brine from the shallow brine table, up through the vadose zone to the now dry pan surface. The subaqueously deposited gypsum bed becomes overprinted by penecontemporaneous vadose diagenetic processes, such as vadose cementation, that leads to the formation of enterolithic folds, tepees and diapiric structures (see under *Sabkha, Salt Flat, Salina*). However, there is an

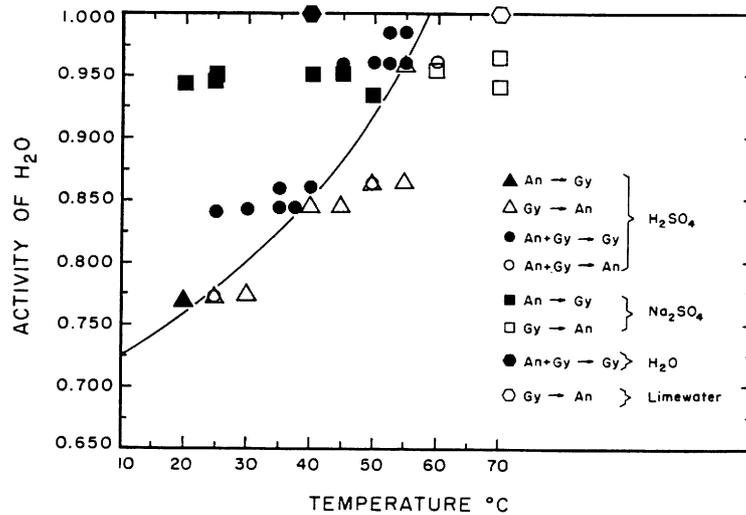

Figure A7 The stability of gypsum and anhydrite determined experimentally as a function of temperature and activity of H_2O at atmospheric pressure (from Hardie, 1967, Figure A8).

additional set of penecontemporaneous diagenetic modifications that are produced during the next flooding stage when gypsum-undersaturated seawater partly dissolves and erodes the exposed gypsum crystals. But during the subsequent evaporative concentration stage syntaxial overgrowth can “repair” the partly dissolved crystals (e.g., Demicco and Hardie, 1994, Figure 154C) and gypsum cements can fill or partly fill the intercrystalline cavities.

The absence (or rarity) of dissolution and syntaxial repair features in beds of vertically oriented gypsum crystals points unerringly to a *shallow perennial* subaqueous depositional environment, such as a coastal, back-barrier lagoon, as exemplified by the bedded gypsum of the Upper Miocene Solfifera Series of Sicily (Hardie and Eugster, 1971, Figures 4–7; Demicco and Hardie, 1994, Figure 154B). This Solfifera Series also carries bedded gypsum in the form of mm-scale lamination composed of couplets of calcite and finely crystalline gypsum laminae (so-called “balatino”, Hardie and Eugster, 1971, Figures 8, 10), planar and cross-laminated gypsum-calcite sandstones, and gypsum crystal conglomerates (Hardie and Eugster, 1971, Figures 12, 13, 14, 16).

Figure A8 shows a hypothetical comparison of the position and characteristics of bedded gypsum in (1) a marginal marine sabkha setting in which the cap of layered gypsum was deposited in an ephemeral supratidal pan, and (2) shallow restricted subtidal lagoon which developed into a closed ephemeral salt pan.

Bedded gypsum can form and accumulate in *deep water evaporite environments*. The clearest modern example is provided by the modern Dead Sea (Warren, 1989, pp. 140–145). Before 1979 the Dead Sea (maximum depth 400 m) was stratified and only tiny needles of aragonite and polygonal plates of gypsum were precipitated from the Upper Water Mass (UWM, 40 m thick), which was undersaturated with respect to halite (Neev and Emery, 1967). These mud-sized aragonite and gypsum crystals slowly sank to the bottom of the Dead Sea where they collected as well-defined laminae. The laminae are not annual deposits; as of 1967 only 15–20 laminae had been deposited in the previous 70 years. The gypsiferous laminae

were particularly well preserved where the Dead Sea floor was shallower than about 40 m. In 1979 the salinity of the UWM had increased to the point of overturn, and mixing with the underlying Lower Water Mass ensued. Since then halite, nucleated at the water–air interface, has been added to the saline mineral accumulation on the floor of the Dead Sea (Garber *et al.*, 1987).

A well-documented example of an ancient deep water gypsum deposit is the Miocene of the Periadriatic trough. For this gypsum deposit Parea and Ricchi Lucchi (1972) made a convincing case for transportation (“resedimentation”) of shallow water gypsum sediment into a deep water basin by turbidity currents and mass flow slope processes (for other examples, see Warren, 1989, pp. 150–163).

Bedded anhydrite

As discussed above, the evidence from experimental work as well from observations of modern active evaporite settings points overwhelmingly to the inability of anhydrite to nucleate as a primary mineral at normal Earth surface temperatures and pressures. Therefore, we must conclude that *beds of anhydrite, both modern and ancient, are formed by diagenetic alteration (dehydration) of primary gypsum*. The conversion of gypsum to anhydrite can be penecontemporaneous or it can take place at any stage during burial. The depositional environment recorded by bedded anhydrite, then, must be that of its bedded gypsum precursor. The criteria used to interpret the depositional setting of bedded gypsum, whether ephemeral, shallow perennial or deep perennial, should be applied to the bedded anhydrite.

Nodular and “chicken wire” gypsum and anhydrite: origin and significance

Individual ovoid to irregular shaped nodules (mm to cm scale) made of a fine felted mass of anhydrite laths (~100 microns long) embedded in carbonate or siliciclastic host sedimentary

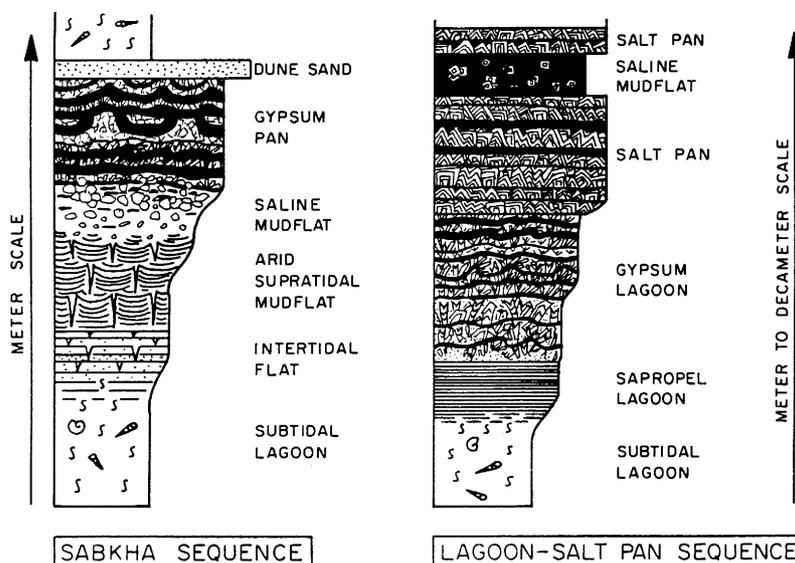

Figure A8 Hypothetical shallowing-upward successions comparing a lagoon-sabkha cycle to a lagoon-salt pan cycle (from Hardie and Shinn, 1986, Figure 69).

rocks have been described from many Phanerozoic evaporite-bearing deposits. Other nodular fabrics observed in anhydrite have been called “chicken wire lattice structure” (Imlay, 1940), “flaser” anhydrite (Jung, 1958) and “mosaic” anhydrite (Riley and Burne, 1961) (see also Bebout and Maiklem, 1973). Of these latter fabrics, the most commonly encountered is “chicken wire” anhydrite, which is a mosaic of irregular nodules separated by very thin, dark, wavy remnants of the sediment in which the nodules grew. The wavy boundaries in many cases have a distinct stylolitic character suggestive of modification by pressure solution. Both “chicken wire” anhydrite (Butler, 1970) and “chicken wire” gypsum (Ali and West, 1983) have been found in modern sabkha environments.

As discussed in the preceding sections, at typical Earth surface temperatures and pressures anhydrite nodules form by the conversion of a precursor gypsum crystal or cluster of crystals. Based on the discovery of nodular anhydrite in the modern tidal flat sediments of the Persian Gulf sabkhas (e.g., Butler, 1970), it is common practice to assign a sabkha environment to any ancient sedimentary rock that carries any type of nodular anhydrite or gypsum. Some workers have suggested that nodules with morphologies similar to those of modern anhydrite but composed of chert, mega-quartz, calcite, dolomite or celestite found embedded in ancient carbonate rocks are pseudomorphs after sabkha anhydrite. However, *the presence of gypsum or anhydrite with nodular or chicken wire fabrics is not, on its own, sufficient evidence to assign a sabkha origin to the host sedimentary rocks.* This follows because anhydrite nodules can form under a variety of conditions, the most unusual being the nodules of anhydrite found in cores of seafloor sediments under 2 km of water in the Atlantis II Deep of the Red Sea, a site of upwelling hydrothermal brines (Degens and Ross, 1969, pp. 366–367). Clearly, modern nodular anhydrite is not unique to sabkha settings. Instead, the common factor is the process of replacement of gypsum by anhydrite, that is, single crystals of gypsum are altered to a mass of tiny anhydrite laths plus liquid water, a rather cohesionless mixture easily deformed by the

weight of the enclosing sediment. The observed tendency is for the anhydrite mass to change toward a spherical or ovoid shape. Dehydration of clusters of gypsum crystals or layers of crystalline (or detrital) gypsum would yield “chicken wire” anhydrite. The *timing* of the formation of the nodular anhydrite would depend on the P, T and activity of H₂O of the pore fluids. Anhydritization could have taken place at the surface contemporaneously with sedimentation or much later during burial. Nodular and “chicken wire” gypsum is likely to have had a more complex history, one in which primary gypsum crystals were first replaced by a felted aggregate of anhydrite laths which in turn were later rehydrated to a mass of small gypsum crystals. In this regard, Murray (1964) has pointed out that gypsum formed at the surface will inevitably dehydrate to anhydrite on burial (depth of conversion dependent on the prevailing T, P and groundwater salinity). In turn, on uplift and contact with dilute groundwaters, anhydrite will rehydrate to gypsum.

In conclusion, gypsum and anhydrite nodular fabrics are at best ambiguous criteria for determining depositional environment. Nodules composed of other minerals such as calcite, chert or other non-sulfate mineral presumed to be pseudomorphous replacements of anhydrite or gypsum must carry even less weight. Instead, reliance can only be placed on the vertical succession of subfacies and their internal primary sedimentary structures and fabrics, fossils assemblages, etc., in diagnosing the depositional settings of ancient gypsum/anhydrite deposits (e.g., Figure A8)

ANKERITE (IN SEDIMENTS)

Ankerite is a frequent but usually minor burial diagenetic phase in sandstones. It can also be present in early diagenetic mudrock-hosted concretions, and rarely as a replacive or void filling burial precipitate in limestones. Ankerite precipitation may result from local (bed-scale) to regional mass transfer, particularly during interaction of compositionally and thermally distinct subsurface fluids.

Mineralogy and chemistry

Ankerite has a general formula $\text{Ca}(\text{Mg}, \text{Fe}^{2+}, \text{Mn})(\text{CO}_3)_2$ and is part of a solid solution series resulting from substitution of Fe^{2+} (\pm subordinate Mn^{2+}) for Mg^{2+} in the dolomite lattice. It is usually defined as having a $\text{Mg}^{2+} : \text{Fe}^{2+}$ ratio of $\leq 4 : 1$, and diagenetic ankerite typically contains 10–25 percent FeCO_3 . Ankerite in sedimentary rocks commonly contains up to 10 mol percent excess CaCO_3 , particularly where it has

replaced calcite. Ankerite is more stable than both calcite and dolomite in many iron-rich fluids, even if they have relatively high $\text{Ca}^{2+}/\text{Mg}^{2+}$ ratios.

Chemical analysis is usually required to distinguish ankerite from ferroan dolomite, although ankerite may be discriminated from pure dolomite by X-ray diffractometry. It is identical to dolomite in thin section, and gives a turquoise color with alizarin red-S and potassium ferricyanide mixed stain (see “Stains”). Ankerite is black in cathodoluminescence, but may display complex compositional zonation when imaged with backscatter scanning electron microscopy. It sometimes has curved crystal faces comparable the high-temperature “baroque” form of dolomite (e.g., Spötl *et al.*, 1996).

Ankerite in sedimentary rocks is commonly investigated using stable isotope geochemistry. However, O isotope fractionation between water and ankerite at diagenetic temperatures is poorly constrained. Many studies extrapolate experimental high temperature fractionation factors, or assume an “average” +3 percent difference between cogenetic calcite and dolomite/ankerite (e.g., Dutton and Land, 1988). Theoretical considerations based on crystal structure, chemical composition and cation-oxygen bond strengths suggest that the ankerite-calcite fractionation may actually be less than 3 percent in low-temperature situations (Zheng, 1999). Valid interpretations of ankerite geochemistry critically require evaluation of its replacive or pore-filling nature, which can be difficult in sandstones.

Occurrence of ankerite in sedimentary rocks

Sandstones

Disseminated ankerite and ferroan dolomite are very common diagenetic precipitates in both marine and continental sandstones, albeit rarely amounting to >10 percent of the mineral assemblage. Ankerite commonly overgrows earlier dolomite and/or replaces bioclastic or authigenic calcite. Quartz grains enveloped by ankerite cements are corroded, and partial to complete replacement of feldspars is also common. Many examples are described from the Mesozoic North Sea (e.g., Kantorowicz, 1985), Gulf Coast and Eastern Texas (e.g., Land and Fisher, 1987) and Alberta Basin. Ankerite is also recorded from Permo-Triassic continental sandstones in a variety of locations, and from a number of Paleozoic sandstones, notably in the southern USA. Pervasive cementation by ankerite is rare, although m-dm sized concretions have been described from deeply buried (>5 km) Jurassic sandstones of the Central North Sea (Hendry *et al.*, 2000).

Ankerite in sandstones tends to be paragenetically late, strongly depleted in ^{18}O and variably depleted in ^{13}C . This suggests formation at elevated temperatures (deep burial) with a proportion of the carbon derived by thermal decarboxylation of organic matter and the remainder remobilized from bioclasts and early cements or from adjacent limestones. Radiogenic $^{87}\text{Sr}/^{86}\text{Sr}$ values commonly indicate ankerite formation after a substantial amount of silicate diagenesis. Mudrocks are commonly believed to be principal sources of Mg^{2+} and Fe^{2+} , and ankerite formation has been causally related to mobilization of these cations following illitization of smectite and thermal reduction of ferric oxides (e.g., Boles, 1978). This interpretation has been questioned because Cenozoic strata in the Gulf Coast contain very little ankerite despite large volumes of illitized mudrock, and because much of the Fe^{2+}

Figure A9 High contrast backscatter electron photomicrograph of compositionally zoned ankerite—ferroan dolomite in Upper Jurassic sandstones, Central Graben, North Sea. Quartz grains and porosity appear black, K-feldspars are bright.

and Mg^{2+} produced in mudrocks can be consumed by *in situ* mineral authigenesis. An alternative source of Fe^{2+} and Mg^{2+} may be volcanoclastic materials within sandstones (Morad *et al.*, 1996). However, mudrocks appear to be the only viable Fe^{2+} and Mg^{2+} source for ankerite formation in many sandstones.

A variety of models have been proposed for fluid and mass transfer related to ankerite formation in sandstones. Variable ankerite compositions and/or concentration in close proximity to intercalated mudrocks suggest local solute transfer in stagnant pore fluids (e.g., Macaulay *et al.*, 1993). Other ankerites yield isotopic and fluid inclusion data that require long distance and/or cross-formational fluid flow. Ankerite associated with sulfate-sulfide mineralization in sandstones has been linked to mixing of hypersaline fluids derived from juxtaposed evaporites and metaliferous hot fluids transmitted up faults from source rocks deeper in the basin (Burley *et al.*, 1989).

Limestones

Ankerite and ferroan dolomite do not constitute major replacive phases in limestones except where stratigraphically associated with mudrocks that released Fe^{2+} ($\pm Mg^{2+}$) during burial diagenesis (e.g., Hendry, 2002; Taylor and Sibley, 1986). Minor ^{18}O -depleted ankerite may form late stage vug and fracture cements in some limestone hydrocarbon reservoirs (e.g., Woronick and Land, 1985). Such cements have variably negative ^{13}C values depending on mass balance of carbon derived from organic matter oxidation in source rocks versus local remobilization of $CaCO_3$. Ankerite may form localized replacive and void filling precipitates in some limestones influenced by volcanic or tectonically driven hydrothermal fluid circulation (e.g., Searl, 1992), as well as being present as gangue cements associated with epigenetic Fe-Pb-Zn ore deposits.

Mudrocks and coals

Ankerite has been recorded from a variety of marine mudrocks, both as disseminated crystals, grain replacements

and as concretionary cement. Stable isotopic data suggest that it formed at shallow to intermediate burial depths (10's–100's m) with carbon sourced by bacterial fermentation or thermal decarboxylation of organic matter and Fe^{2+} from reduction of detrital ferric oxides (e.g., Irwin, 1980). A limited supply of Mg^{2+} from residual seawater might explain why such ankerite is usually calcian. Ankerite does not typically form in the shallower sulfate reduction zone because pyrite is a more effective sink for Fe^{2+} .

Ankerite is less common than siderite and calcite in non-marine mudrocks because of a paucity of Mg^{2+} . Nevertheless, it can be a significant diagenetic precipitate in siltstones and mudrocks of coal measures as well as replacing authigenic siderite in coal seams. High concentrations of ferric oxides and hydroxides were eroded from lateritic soils and deposited in anaerobic coastal plain lagoons and swamps. Pore fluid mixing during marine inundation and/or between intercalated brackish and marine facies during shallow burial introduced Mg^{2+} and Fe^{2+} into the non-marine strata allowing ankerite to form (Matsumoto and Iijima, 1981).

Summary

Ankerite exists in sedimentary rocks as a late diagenetic cement or replacement of pre-existing carbonate. It can be formed in a number of ways, provided an adequate supply of Fe^{2+} and Mg^{2+} relative to Ca^{2+} . The iron is mostly derived from ferric oxides deposited in mudrocks, but sources of Mg^{2+} are more varied and can be difficult to constrain in individual cases. Ankerite can be formed as a response to basin-scale fluid flow or by localized mass transfer between juxtaposed porous sediments and mudrocks. Ankerite cements may also precipitate during early diagenesis given sufficient Mg^{2+} in pore fluids and provided that pyrite formation did not exhaust the local supply of labile iron.

ARMOR

The term ‘armor’ (or ‘armour’ in English usage outside the US) refers to clastic deposits in which the surface layer is coarser than the substrate. The phenomenon is widespread in gravel-bed rivers, also occurs in stony deserts (where it is usually referred to as ‘desert pavement’), and has occasionally been reported from pebbly beaches. The existence of armor is generally obvious if surface clasts are removed from a small area, and the degree of armoring can be quantified by comparing surface and subsurface grain-size distributions.

The commonest explanation for armoring is that it develops when a poorly-sorted noncohesive sediment is eroded by water or wind. The smaller clasts are more easily removed so the larger ones become concentrated on the surface as it is lowered. Thus many desert pavements are regarded as deflation lag deposits, and fluvial armor was originally recognized in degrading rivers below dams. However, as discussed below, fluvial armor can form without degradation and several alternative explanations have been proposed for desert pavement.

No matter how an armor develops, the word itself hints at a key consequence of the phenomenon: a greatly reduced rate of entrainment from the bed surface, compared to an unarmored

arrangement of the same bulk mixture of grain sizes. Armoring is therefore associated with a low rate of sediment transport, and provides a link between local sedimentology and larger-scale sediment flux.

Fluvial armor

The wide range of grain sizes present in gravel-bed rivers allows the possibility of size sorting and segregation through selective transport and deposition. From this perspective the development of a coarse surface layer is a kind of vertical sorting, and is almost as prevalent as the downstream- or downbar-fining trends that reflect spatial sorting (see Powell, 1998, for a useful review of armoring in this wider context). Fine material (sand and/or granules) is usually visible only in the sheltered lee of large clasts, but fills a substantial proportion of the subsurface voids in the gravel framework. The maximum surface and subsurface grain sizes may be similar, but the respective median diameters typically differ by one to two phi units.

Gravel armor can form in more than one way. The traditional explanation is preferential winnowing of finer sediment from the surface during degradation, for example, below dams which cut off the gravel flux from upstream so that the river erodes its bed to regain a capacity load. This degradation is self-limiting (Gessler, 1970) because, as the surface coarsens, the transport capacity of the flow declines (to zero immediately below the dam) and the coarser grains (if not the whole bed) become immobile. This sequence of events has been investigated in flume experiments with no sediment feed and has been modeled mathematically (see Sutherland, 1987, for a good review of both approaches). It can occur in sand-bed rivers that contain a little gravel, which becomes concentrated on the surface as a stable lag deposit.

In the 1980s fluvial scientists recognized that coarse surface layers also exist in many unregulated rivers with an ongoing sediment supply and peak flows which can transport all sizes of bed material. These surfaces were termed ‘pavements’ at first but ‘mobile armor’ has come to be preferred, as distinct from the ‘static’ armor just described. This terminology is not yet standard, though, and some workers restrict ‘armor’ to what is here termed static armor. Mobile armor allows a gravel-bed river reach to be in equilibrium (neither degrading nor aggrading, neither coarsening nor fining) despite the size-selective nature of bed-load transport. Without armor the annual bed-load flux would be finer-grained than the bed surface, since shear stresses in gravel-bed rivers are very rarely high enough for all sizes to be equally mobile. Armoring makes the intrinsically less mobile coarse fractions preferentially available for transport, whereas the more mobile fine fractions are mainly hidden in the subsurface (Parker and Klingeman, 1982). The armor forms by vertical winnowing during active bed-load transport. Entrainment of coarse clasts during floods creates gaps which are filled mainly by finer grains, in much the same way that the smallest bits of breakfast cereal end up at the bottom of the packet. Extreme floods may wash out the armor, but it re-forms during intermediate flows in most environments. However, in ephemeral streams there are no such flows and armoring is generally absent (Larone *et al.*, 1994).

The two types of fluvial armor were initially treated separately but, following Dietrich *et al.* (1989) and Parker and Sutherland (1990), they have come to be seen as members of a continuum. In this view some degree of armoring is the response to any reduction in sediment supply rate below the

capacity transport rate for an unarmored bed. Transport capacity depends on excess shear stress over a threshold for movement which, in turn, depends on the median diameter of the surface. Armoring raises the threshold and reduces the transport rate. In this view static armor is simply the limiting case as the bed-load flux vanishes, and different degrees of armoring represent channel self-adjustment to equalize bed-load capacity with supply (Dietrich *et al.*, 1989). Parker and Sutherland (1990) developed the concept by inverting transport equations for size mixtures and successfully retrodicted armor composition from measured bed-load flux and substrate size distribution.

Armoring can involve changes in grain packing as well as grain size distribution, and these may be at least as important in increasing resistance to entrainment and thus regulating sediment flux (Church *et al.*, 1998). The development of static armor is accompanied by progressively stronger imbrication and interlocking of the coarser clasts, as illustrated in Sutherland (1987), and this further increases the threshold stress. Additional structures form in streams with a mobile armor: pebble clusters, irregular reticulate stone cells, and transverse boulder steps in steep headwater streams. Surface structures associated with armoring are therefore important in understanding fluvial processes and the role of the bed surface in responding to, and regulating, sediment flux.

Desert pavement

Stony deserts are sufficiently extensive to have acquired local names (e.g., reg in Africa, gibber in Australia). One widely-held view about their origin is essentially the same as for static armor in a river: winnowing of finer material by wind, leaving a coarse lag. Sediment flux tends to zero over a fully-developed deflation lag surface, though in the early stages it may increase slightly because of enhanced elastic rebound of saltating grains (e.g., Nickling and Neuman, 1995). Pavement formation by deflation is inhibited by vegetation which reduces near-ground windspeed, and by surface crusting, so it is probably most likely in hyperarid conditions.

In semi-arid environments pavements can form through dislodgment of finer material by rainsplash followed by removal in sheetwash (e.g., Cooke, 1970), or stones can be forced upward through a clayey soil horizon by wetting and drying cycles (Jessup, 1960). More radically, McFadden *et al.* (1987) proposed that desert pavement can form during depositional episodes through a combination of eolian dust deposition and pedogenic processes beneath an evolving armor initiated by rock weathering.

Beach armor

Cobble beaches and spits are common on coasts with high wave energy, and coastal sedimentologists regard armoring as a fairly widespread phenomenon. Most interpretations emphasize clast sorting into shore-parallel bands under the action of wave swash and backwash. Shape as well as size sorting is involved (Bluck, 1967; Isla, 1993), with the most spherical clasts overpassing to higher up the beach. In certain instances gravel berms high on a beach may become armored by eolian deflation, with the sand winnowed out to accumulate in coastal dunes (Bascom, 1951).

ATTERBERG LIMITS

Atterberg Limits are the water contents which define transitions between the solid, plastic, and liquid states of a given soil material. The tests are restricted to cohesive soils with appreciable silt or clay fraction, and cannot be conducted readily on either sands or silts with a high sand fraction. Detailed mineralogical studies of cohesive soils have shown that Atterberg Limits are strongly related to both clay content and clay mineral species, and hence ultimately to the climatic and geologic conditions prevailing in the environment of deposition and during the post-depositional weathering cycle.

The modern test procedures for Atterberg Limits were formalized by engineers in the first half of the 20th century, and are described in most modern soil mechanics texts (Craig, 1997). Although the tests yield simple index numbers of soil behavior at various water contents, an important focus of

Table A1 Atterberg Limits of selected soils and associated engineering properties

Φ'_r = residual angle of shearing resistance.

modern soils engineering research has been to establish correlations between Atterberg Limits and more complex soil properties, such as shear strength.

Atterberg Limits tests require the preparation of an air-dried sample through a 425 μm screen, followed by mixing with distilled water to form a soil paste. In each test, the water content, w , is calculated as the mass percentage of water per mass of oven dry soil. The Liquid Limit, w_L , defines the boundary between the plastic solid and liquid states, and is traditionally measured in the Casagrande device. A 5.4 cm radius brass cup is partially filled with wetted soil paste to a depth of about 1 cm. A grooving tool is then used to scribe the center of the soil pat. An eccentric cam attached to a crank handle is used to raise and drop the cup twice per second through a 1 cm vertical distance onto a hard rubber base plate. The number of blows required to close the base of the groove over a distance of one-half inch (12 mm) is noted, and this failing soil is sampled, weighed and oven dried. The test is repeated at least three times at different water contents to obtain a semi-logarithmic plot of number of blows (log axis) versus water content. The water content interpolated at 25 blows is then the Liquid Limit.

The procedure described above requires some technical experience to obtain consistent results, and an operationally simpler drop-cone test is now used in many soils laboratories. The drop cone, with a mass 80 g and cone angle of 30°, is lowered until its tip just contacts the sample surface. The cone is then released for 5 s and the depth of penetration is noted. The penetration depths at various water contents are noted, with the Liquid Limit defined as the water content interpolated at a cone penetration of 20 mm.

The Plastic Limit, w_P , is the water content below which the soil becomes brittle, and cracks when remolded. Traditionally, the Plastic Limit is determined by rolling of a soil worm on a ground glass plate, using the heel of the hand, to a thickness of 0.125 inches (3 mm). At the Plastic Limit, the soil worm can no longer be thinned by rolling, and cracking and breakage occurs. The sample is then weighed and oven dried. Three more tests are conducted to ensure consistent results. By the drop-cone method, w_P is the water content at which the cone penetrates the sample approximately 3 mm.

The Shrinkage Limit, w_S , is determined by filling a brass, semi-circular conduit, 12.5 mm in radius and 140 mm in length,

with remolded soil paste, then allowing it to air dry. Linear shrinkage of the sample is monitored, with w_S defined as the water content at which no further volume decrease occurs.

Various indices of soil behavior can be derived from basic Atterberg Limits data. The Plasticity Index, $I_P = (w_L - w_P)$, represents the range of water contents between the solid and liquid states. An engineering convention is to construct a plasticity chart by plotting I_P as ordinate versus Liquid Limit, w_L . The plasticity chart provides a valuable summary of the geotechnical properties of a large number of soil samples, and allows a rapid separation of low plasticity silty materials of relatively high frictional strength from highly plastic clays, the latter usually associated with high swelling potential and lower shear strength.

The Liquidity Index, $I_L = (w - w_P)/(w_L - w_P)$, where w is the natural field water content. I_L is a measure of field moisture content normalized by plasticity, since I_P is denominator. I_L values above 1.0 indicate a field water content above the Liquid Limit, a condition common in soft unconsolidated clays (Lefebvre, 1996). These soils tend to liquefy when disturbed. Conversely, negative I_L values indicate moisture values below the Plastic Limit, which is common in stiff clays and shales in drier climates. Such soils exhibit much higher shear strength. I_L is therefore a useful hydrotechnical index of the relative stability of various earth materials.

The Activity Index, $I_A = I_P/\%$ clay, and measures soil plasticity normalized by clay content. Activity values are strongly correlated with clay mineral type. Values above 2 indicate expanding montmorillonite clays; values closer to 0.5 are typical of kaolinite clay soils. High I_A values generally indicate soils of low strength, high plasticity and high swell-shrink potential, thus indicating potential slope stability and foundation engineering problems.

Table A1 summarizes typical values of Atterberg Limits and associated indices for a range of soil materials. The very large ranges in values emphasize the importance of both clay mineral species and clay content as controls. Of particular note is the contrast between very high plasticity, montmorillonite clay soils (e.g., Mexico City volcanogenic lacustrine clay and Pierre Shale marine clay-shale), in comparison with very low plasticity silts and silty-clay soils (e.g., glaciolacustrine silts and glaciomarine Leda Clay). In the latter two deposits, much of the clay-sized fraction typically is not true phyllosilicate but

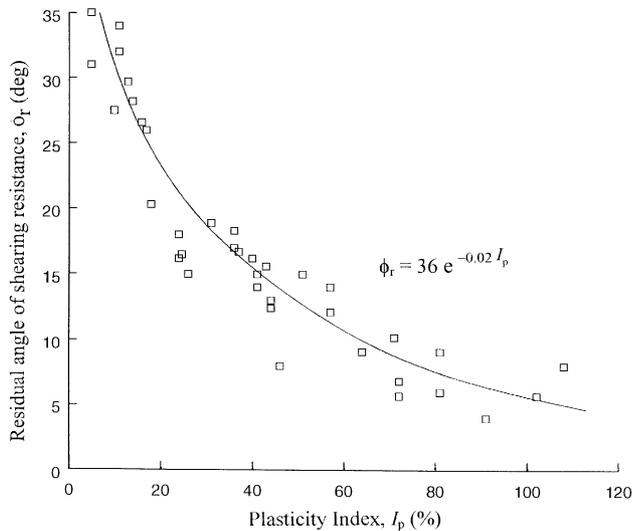

Figure A10 Relation between plasticity index and residual angle of shearing resistance. Data points are derived from Voight (1973), Kanji (1974) and the author's files.

instead quartz-feldspar rock flour derived from glacial abrasion. Average values of residual friction angle are also given for each soil type. Residual strength refers to the lowest value obtainable from large-displacement, drained shear tests. Strong inverse relations exist between ϕ'_r and I_p (Figure A10) and I_A , as previously noted by Voight (1973), Kanji (1974), and Wroth and Wood (1979).

ATTRITION (ABRASION), FLUVIAL

Fluvial attrition is generally understood to refer to any process of mechanical grain wear leading to grain size reduction in the course of sediment transport through rivers. Fluvial abrasion is generally accepted as an equivalent term, though it might also be interpreted to mean modification of the stream bed or banks. Mikos (1993) has presented a modern treatise on the subject of fluvial attrition of clastic grains.

“Abrasion” in the present context specifically implies surface wear caused by the relative motion of two surfaces in frictional contact, especially when one surface is harder than the other (“grinding”, when one of the grains is at rest, is sometimes distinguished). Additional processes that have been invoked as contributing to fluvial “abrasion” include impact or percussive effects (e.g., chipping, splitting and sandblasting), and crushing, when the impact of a larger rock causes a small grain to disintegrate. Weathering and solution have also been invoked, but this appears to confuse preparatory processes with mechanical destructive mechanisms. In rivers, abrasion appears mainly to affect pebble and larger sizes.

The characteristic downstream reduction in size, hence weight, of fluvial gravels was formulated by Sternberg (1875) into a “law” of weight loss—“the wear of a grain is proportional to its submerged weight (W) and the distance (L) it has travelled”. Mathematically, $dW/dL = -\alpha W$, in which α is the weight loss rate coefficient. The statement integrates to the familiar result

$$W = W_0 e^{-\alpha L}$$

in which W_0 is the initial grain weight before travel. Since $W \propto D^3$, grain diameter, the rule can be interpreted as a size reduction rule, in which $\alpha_D = \alpha_W/3$. Sternberg’s result has been abundantly confirmed empirically and, since river engineers supposed for a long time that abrasion was the chief source of the effect, it became known as the law of fluvial abrasion.

However, experimental measurements of abrasion nearly always return rate coefficients much smaller than ones inferred from field data (Adams, 1978 provides a list of experimentally derived abrasion coefficients for a wide range of lithologies). It has consequently been recognized that size-selective transport (e.g., Plumley, 1948; Bradley *et al.*, 1972) and weathering of grains during storage in bars and floodplains (Bradley, 1970) represent additional mechanisms for gravel size reduction along rivers.

Adams (1979) investigated the wear of weathered grains recruited into river headwaters. He found that the size reduction coefficient (α) itself changes with distance downstream, at a declining rate, so that the rate of change of grain size with distance follows a power law, rather than the exponential rule of Sternberg. He also showed convincingly that the result was due to wear and interpreted it to reflect the rapid destruction of weathered material. Farther downstream, the Sternberg rule applies to the remaining, competent material. However, Jones

and Humphrey (1997) demonstrated rapid changes in the wearing coefficient of material liberated from long-term storage in fluvial deposits, where substantial weathering again occurs. At the other extreme, Rice and Church (1998) demonstrated dramatic changes in grain size over reach-scale distances far too short for appreciable particle wear to occur, indicating the efficacy of size-selective transport. Both processes occur simultaneously, particularly in the presence of multiple lithologies, when less resistant lithologies may be consumed by abrasion whilst the size of the more resistant ones varies mainly by selective transport. Recent work has sought to examine the relative significance of and interaction between abrasion and selective transport of grains (e.g., Parker, 1991a,b).

There remain significant complexities in the problem of determining wear and its relation to grain size variation downstream. Mikos (1993) criticized tumbling mill experiments, in which many experimental abrasion coefficients have been determined, and showed (also in Mikos, 1995) that, when grain size is established on a weight basis (e.g., by customary sieve analysis), the relation between size loss and weight loss of measured aggregations of grains depends upon whether or not abrasion products are preserved in the analysis and also upon the measurement principle used in the analysis.

Grain Threshold
Sediment Transport by Unidirectional Water Flows

ATTRITION (ABRASION), MARINE

Marine attrition is the mechanical wearing down of rock particles and minerals by wave action both longshore and shore-normal, leading to increasing textural and compositional maturity. The term textural maturity describes the prevalence of finer and better rounded grains, compositional maturity comprises the extinction of less resistant rock particles or minerals. Well-rounded fine-grained quartz sand theoretically represents the final stage of maturity.

The role of sphericity as a measure of marine attrition is debated, as is the effect of sorting or selective transportation. Because of their differing settling velocities, particles of different size or weight, of different sphericity and different roundness behave differently during marine transportation both longshore and shore-normal, leading possibly to similar results as attrition. The same is true for longshore fining of the particles.

Marine attrition of sand

Literature dealing with marine attrition of sand is extremely scarce. Experiments demonstrate that rounding and thus attrition of quartz sand is extremely low or practically negligible (Thiel, 1940; Kuenen, 1960; Schubert, 1964). The relative smoothness of foreshore grains due to marine attrition is discussed by Lee and Osborne (1995), the creation of a more mature heavy mineral suite of beach placers in southeastern Australia by Roy (1999). Most modifications of quartz sand or heavy mineral suites along beaches are assumed to be the result of sorting or selective transportation (Bascom, 1951; McBride *et al.*, 1996; Trenhaile *et al.*, 1996).

Marine attrition of pebbles

Weight loss and the modification of petrographic composition

Matthews (1983) put up to 76 tonnes of limestone pebbles into the surf of Palliser Bay, New Zealand, at three sites. A weight loss of 41 percent per year due to rounding of the pebbles was found at the most exposed site and 15 percent or 7 percent at the two other sites. Bartholomä *et al.* (1998) investigated the 8 km Bianco Beach in Calabria, southern Italy, a tide-less, wave dominated high energy beach, sampling the beach-parallel profile and the beach-normal profiles (back-, fore- and offshore). This beach is fed by a fluvial delta at its southern end. Thirty nine samples comprise a total of 2.6×10^3 kg with grain sizes between 16 mm and 63 mm. The beach sediment contains, among others, two reference groups of rocks, a granitic group (more or less isotropic granites, pegmatites and vein quartz) and a gneiss group (more or less anisotropic strongly foliated gneisses, schists and phyllites). The granites are obviously more resistant to abrasion than the gneisses. In all fractions and beach zones the proportion of gneiss clasts decreases in the direction of net transport from 56 percent to 31 percent, corresponding to a mean reduction of 3 percent per kilometer (Figure A11(1), the zero value corresponds to the fluvial input), indicating strong marine attrition.

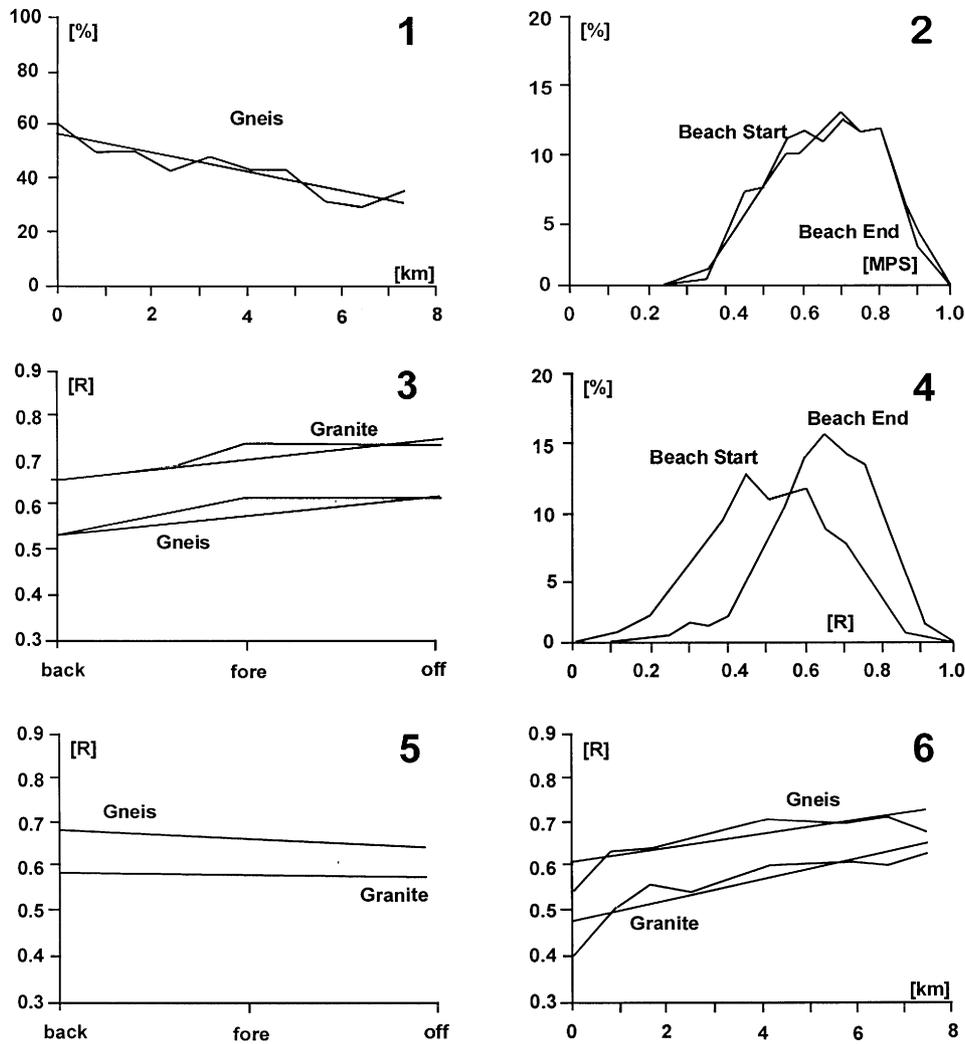

Figure A11 (1) Reduction of less resistant gneiss clasts longshore, measurements and trend; (2) Sphericity frequency distributions of the gravel populations at beach start and beach end. (From Bartholomä *et al.*, 1998, printed with permission of SEPM (Society for Sedimentary Research).

Sphericity

Dobkins and Folk (1970) grouped authors into “sorters” who believe that disc-shaped gravels remain high on the beach where geologists can easily find them, whereas rods and equants selectively roll back to the foot of the beach and are lost from sight, and “abraders”, who believe that surf mechanics develops discs by attrition, presumably by sliding the gravel back and forth. Dobkins and Folk (1970) defined themselves as abraders: the production of discs on the beaches is predominantly a result of attrition caused by pebbles sliding over sand or small pebbles in the surf zone. In contrast, Kuenen (1964) states that pebbles were flattened very little by

sliding. The flatness of beach pebbles as compared to fluvial ones must be a matter of selection. Also Bluck (1967) demonstrated that particle shapes are not so much made as used on these beaches, and that discs are not produced by a special feature of marine attrition. The most oblate discs are found in areas least worked on by the sea. Even according to Bartholomä *et al.* (1998) sphericity fails as an appropriate indicator of marine attrition. The sphericity frequency distribution of more than 20,000 clasts is almost identical comparing beach start and beach end (Figure A11 (2)). There is a slight increase of sphericity of both granites and gneisses in the foreshore zone (Figure A11 (3)), but roundness is equal when the three beach environments are compared (Figure A11 (5)),

indicating that this increase in sphericity is caused by sorting rather than attrition.

Roundness

Roundness values of older articles are hard to compare, because only printed roundness images of the Krumbein tables (1941) were used. Bartholomä *et al.* (1998) determined the roundness values of the entire data set via Fourier analysis (Diepenbroek *et al.*, 1992) and found a remarkable difference between beach start and beach end (Figure A11 (4)). Because the roundness-profile crossing the beach does not show any trend (Figure A11 (5)), the foreshore zone is ruled out as a locus of forced marine abrasion. The authors show, that the uniform roundness along the cross-shore profiles and the increasing alongshore roundness in the direction of net transport (Figure A11 (6)) can only be interpreted as the result of sporadic high energy events, which cause the entire set of pebbles to migrate offshore. The cross-shore profile of the beach then is uniform and very flat, being composed entirely of coarse sand. All pebble grain-sizes and all rock types are abraded and rounded simultaneously. This means that during rounding due to attrition the proportions of the axes of both anisotropic gneiss clasts and isotropic granite clasts remain preserved, and no change of sphericity takes place.

Longshore fining

The loss of weight due to rounding and the extinction of less resistant rock types certainly go hand in hand with a longshore fining of the clasts. It is not possible, however, to discriminate this effect from longshore sorting and selective transportation.

Summary

Increasing roundness and decreasing percentages of less resistant rock types or minerals are the main indicators of marine attrition. The meaning of sphericity is uncertain, but the majority of the authors tend to negate sphericity as an useful tool in examining marine attrition. Longshore fining can be the product of both marine attrition and selective transportation or sorting, and as a result it fails as an indicator of marine attrition alone.

AUTHIGENESIS

Overview

Authigenesis refers to processes by which minerals form, *in place*, within sediments and sedimentary rocks. Such minerals are referred to as *authigenic minerals*. In contrast, *detrital* minerals are erosion products deposited in the depositional environment. Diagenesis refers to the physical and chemical changes that occur in sediments after they are deposited (or precipitated). All authigenic minerals form within this context. The formation of authigenic minerals is a result of the presence of unstable mineral grains, biological modification of the sediment, grain deformation and fracturing, flux of various fluids through the sediment, and changing burial conditions. The intrinsic value of most sediments is their ability to hold fluid such as water and hydrocarbons. From an economic viewpoint, authigenesis is important because it influences the *porosity* (void volume in the rock) and *permeability* of the rock (ability of the rock to transmit fluid).

Authigenic minerals can reveal clues to the conditions the sediment has been subjected to after deposition. For example, petrographic thin sections reveal sequences of authigenic minerals, which allows a reconstruction of the relative timing or *paragenesis* of events. Early formed authigenic minerals are characterized by euhedral terminating crystal faces indicating growth into open pore space. Later pore-filling cements or grain replacements are characteristically anhedral crystals. Trace elements, isotopic, and fluid inclusion data can reveal the source of authigenic mineral components, temperatures of crystallization, and the type of water with which the sediment has interacted (e.g., Schultz *et al.*, 1989; Stallard and Boles, 1989; Thyne and Boles, 1989). In some cases, quantitative crystallization ages can be obtained from authigenic minerals using isotopic dating methods (e.g., Lee *et al.*, 1985).

Cause of authigenesis

Authigenic minerals form because sedimentary particles are not in thermodynamic equilibrium with the fluid composition, pressure, and temperature conditions at the time of deposition. Biological activity is common near the sediment-water interface. The organisms have the ability to control oxidation-reduction reactions and the generation of methane or carbon dioxide. Initially, the sediment is deposited with high porosity and permeability, which implies that large fluid volumes can easily move through the sediment. While the sediment resides near the surface, salinity and water composition may change drastically by changes in sea level, changes in hydrologic drainage, and evaporation. As a result, early authigenesis may be controlled by biological activity and changing fluid composition in an open system. Over time the sediment loses pore space and permeability is reduced (due to compaction and cementation); thus fluid composition becomes a less important control on the formation of authigenic minerals.

As the sediment becomes buried, pressure and temperature increases, causing further mineralogical (and physical changes) to the sediment. Typically, temperature increases 25–35°C per kilometer of burial. This causes mineral-solution reaction rates to increase by a factor of 10 for every kilometer of burial (Krauskopf and Bird, 1995). As a result of increased reaction rates, authigenic mineral replacement of pre-existing minerals becomes more common at higher temperature. From a thermodynamic viewpoint, reactions sensitive to temperature involve net changes in entropy (or degree of disorder). Thus, dehydration reactions occur at elevated temperatures due to the higher entropy associated with water released from hydrated minerals.

Pressure typically increases between 11.3 MPa/km (hydrostatic gradient) and 22.6 MPa/km (lithostatic gradient) during burial. Pressure has a less marked effect on the formation of authigenic minerals. From a thermodynamic perspective, mineral changes (reactions) which are pressure dependent involve an overall net volume reduction.

Eventually, conditions of pressure and temperature at deep burial become so extreme that we refer to the processes as *metamorphic* and the rocks as metamorphic rocks. This transition is not recognized by nature and many authigenic minerals span the boundary between diagenesis and metamorphism. In general though, most petrologist would agree that 200–250°C would be the upper temperature limit of what would be called authigenic minerals.

Examples of authigenesis

Authigenic minerals forming at shallow depths

Shallow sediment can be subjected to marked chemical changes and/or high flux of pore water. As a result, large volumes of early cements can form such as carbonate concretions of calcite, siderite, dolomite, or pyrite (e.g., Curtis *et al.*, 1986; Hayes and Boles, 1993). High fluid flux can result in leaching of detrital aluminosilicate grains from the rock, leaving a residue of authigenic kaolinite (e.g., Hayes and Boles, 1992). One of the earliest consequences of seawater being present within the sediment is biogenic reduction of the sulfate to sulfide and precipitation of authigenic pyrite. Further evidence of biological activity in shallow buried sediment is the production of ammonium, which can substitute for potassium in authigenic

feldspar (Ramseyer *et al.*, 1992). In many cases, grains in clastic sediments show early coatings of authigenic iron oxides or clay minerals, including hematite, smectite, illite or chlorite (e.g., Heald and Larese, 1974).

Volcanic glass is an unstable component in volcanoclastic sediments and it is rarely preserved. During shallow burial, the main reaction products are authigenic clay minerals (smectite) and zeolites (Mumpton, 1981). Zeolite producing reactions are widely dispersed in deep sea pelagic sediments including formation of phillipsite, usually found in young sediments and clinoptilolite, found in older sediment. Saline alkaline lakes have abundant altered ash beds including the zeolites phillipsite, clinoptilolite, mordenite and analcime. Diagenetic K-feldspar is found in the most concentrated pore waters of these lacustrine environments.

Authigenic minerals forming during burial

Calcite, dolomite, and ankerite cements can form in clastic sediments at burial depths as deep as 4–5 km (e.g., Boles and Franks, 1979). The source of calcium for these cements may include clay minerals and feldspars, and carbon derived from organic matter (e.g., Boles, 1998).

Clays and silts undergo mineral transformations, which are largely a response to temperature increase during burial. One of the most studied reactions is the dehydration of detrital smectite to illite (Hower *et al.*, 1976). Most smectite has some interlayering of illite and observations show that the proportion of illite layers increases with increasing burial or temperature. This transition occurs at about 100°C in many sedimentary basins. The source of the potassium is typically detrital K-feldspar or in some cases potassium micas. The smectite-illite transformation releases Si, Mg, and Fe, which forms cements of quartz, carbonates, and clays (Boles and Franks, 1979). Other clay mineral changes that occur are the transition of kaolinite to chlorite or illite (Boles and Franks, 1979; Bjorlykke and Agaard, 1992).

Authigenic quartz cements commonly form euhedral overgrowths on detrital quartz grains. Most recent work has shown that quartz cements are controlled largely by the kinetics of quartz precipitation. Thus, at temperatures of 90–100°C quartz cement becomes significant in many sedimentary basins (Walderhaug, 1996).

Biogenic siliceous sediment is deposited as opal or amorphous silica. Opal is an unstable component of sediments and it becomes progressively altered from cristobalite to chert composed of quartz (Murata and Larson, 1975; Pisciotto, 1980). The opal-cristobalite transition occurs at about 35–55°C and the cristobalite-quartz transition occurs from about 55°C to 110°C.

Albitization of plagioclase is widely recognized in deeply buried sediments (e.g., Coombs, 1954; Land and Milliken, 1981). To a lesser extent K-feldspar becomes albitized during burial. The albitization of plagioclase usually starts at about 100°C in sedimentary sequences and most calcium plagioclase has been altered to albite by about 150°C (Boles, 1982). Albitization consumes sodium and releases calcium to the pore water. Thus, if the rock has very low permeability the reaction is inhibited due to the inability of material to be transported (Boles and Ramseyer, 1988). Authigenic products of feldspar dissolution and albitization are clay minerals (kaolinite or chlorite) and calcite or laumontite (Boles and Coombs, 1975).

Early formed zeolites are eventually replaced in a series of dehydration reactions by laumontite, albite, K-feldspar, and chlorite (Boles and Coombs, 1977) or other minerals such as prehnite or pumpellyite with increasing age and burial depth. Laumontite requires a minimum temperature of about 70°C but is stable beyond 200°C and is considered by many as a transition to conventional metamorphism.

Summary

In summary, authigenic mineral reactions are initially controlled by fluid dominated open systems and later by rock-dominated relatively closed system. Although we have a good descriptive understanding of the type of authigenic mineral reactions that occur, there remains much to be done to quantify these processes. Present and future research trends are interdisciplinary studies to understand the mineral/fluid interface, the role of organisms in mineralization, the rates of authigenesis, the role of faulting as pathways and barriers to fluid flow, and interpreting early authigenic minerals in terms of sea level and climate/atmospheric changes.

AUTOSUSPENSION

Definition

An autosuspension current may be defined as a particle-driven gravity flow that can persist indefinitely, without any external supply of energy. The ultimate criterion for autosuspension must, therefore, be lack of net deposition. This criterion is reinforced if the current is also capable of erosion.

Theoretical development

Daly (1936) and Kuenen (1938) both realized the possibility of the process now called “autosuspension”, although the first analysis of this phenomenon was made by Knapp (1938). He realized that the gravitational energy expended by a particle-driven gravity flow must be at least equal to that needed to maintain the suspended load, and derived a simple criterion for this situation: $US/v_s > 1$, where U is the velocity, S is the bed slope (small), and v_s is the settling velocity of the sediment particles.

The same concept was discovered independently, and considerably extended, by Bagnold (1962). He was apparently the first to use the term “auto-suspension”. Bagnold recognized that although $US/v_s > 1$ was a necessary condition for this phenomenon, it was not sufficient, and he placed additional restrictions on the occurrence of autosuspension.

More extensive analyzes were carried out independently by Pantin (1979) and Parker (1982), both of whom described time-developing currents that could either erode or deposit, depending on the initial velocity and sediment content (both depth-averaged). The bed slope and other parameters were assumed constant. Eventually, a given current would either collapse and deposit all of its load, or enter a state in which erosion would occur (i.e., autosuspension), accompanied by a progressive increase in both velocity and sediment content. Both of the foregoing models used coupled differential equations to express changes in volume, sediment content, and momentum (Pantin) or mean-flow energy (Parker), but neither explicitly accounted for the turbulent energy balance. Parker (1982) named the erosive currents “ignitive”, by analogy with the ignition and continued burning of combustible material, and predicted “catastrophic equilibrium”, a state in which increasing sediment concentration eventually imposes a limit to further sediment entrainment, and thus to further acceleration of an ignitive current. These two models showed that autosuspension is promoted by large flow thickness, high bottom gradient, and a low sediment-settling velocity, as well as high initial current velocity and sediment concentration.

Further investigation (Fukushima *et al.*, 1985; Parker *et al.*, 1986) showed that the above “three-equation” models made physically-impossible demands on the available energy, and that an equation for turbulent energy balance would have to be included. This resulted in a “four-equation” model, which kept the energy requirement within appropriate limits, and predicted autosuspension under physically reasonable conditions. The process of ignitive autosuspension may be regarded as a positive-feedback loop, and is shown diagrammatically in Figure A12.

Other models that predicted autosuspension soon followed. Stacey and Bowen (1988) and Eidsvik and Brørs (1989)

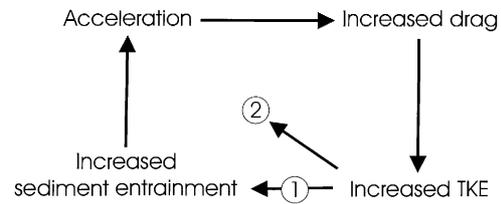

Figure A12 The positive-feedback loop in ignitive autosuspension. TKE = turbulent kinetic energy; (1) = portion of TKE expended on the entrainment of new sediment; (2) = portion of TKE expended on viscous dissipation, maintaining the existing sediment load, and thickening of the flow by water entrainment (see Parker *et al.*, 1986, Eq. 8). Continuation of the loop may lead to “catastrophic equilibrium” (see text). Failure of the loop will result in deceleration, decrease in drag and TKE, and deposition of sediment.

considered the problems of stratified flows; Pantin (1986) studied the generation of autosuspension by a periodic forcing process, and later (1991) developed an autosuspension model for underflows with a light interstitial fluid. These models, like all of those described earlier, were two-dimensional Cartesian, and did not allow for lateral changes.

Emms (1999) advanced the autosuspension concept further, by developing models that included the Coriolis parameter. In addition, his “four-equation” and “five-equation” models allowed for lateral spread, and could thus be applied to the open slope.

Autosuspension in natural systems

There is widespread indirect evidence that autosuspension occurs in natural systems, including storms in submarine canyons (Inman *et al.*, 1976, interpreted by Fukushima *et al.*, 1985 and by Pantin, 1986); flooded rivers in fiords (Prior *et al.*, 1987, interpreted by Pantin, 1991); and earthquake-induced failure on the continental slope (Hughes Clarke *et al.*, 1990). Prior *et al.* (1986) have described channeling due to erosion by high-density flows entering bodies of lower density fluid (hyperpycnal flows), a phenomenon entirely consistent with autosuspension. There is also good evidence of autosuspension in powder-snow avalanches (Fukushima and Parker, 1990), while the severe erosion reported from some pyroclastic flows (Sparks *et al.*, 1997) may well involve autosuspension.

Autosuspension can also help to explain some of the main features of the turbidite beds that occur widely in stratigraphic sequences. These beds evidently represent major, time-discontinuous events associated with high sediment transport rates and strong currents; they can be interpreted as the product of turbidity currents, initially in autosuspension, generated periodically under exceptionally severe conditions (e.g., storms, floods, or submarine landslides). These currents would deposit their load when, inevitably, they reached the base of the slope or a closed basin, and encountered bottom gradients too low to sustain the autosuspension process (Komar, 1977; Pantin, 1979).

Experimental work

Until very recently, there have been no successful attempts to produce unequivocal evidence of autosuspension in the laboratory. Neither Southard and Mackintosh (1981) nor

Parker *et al.* (1987) succeeded in producing autosuspension. However, Pantin (2001), using specially designed equipment, was able to obtain clear evidence of autosuspension in a series of experimental flows. The method consisted of running a suspension of 20 μm silica through a sloping 5 cm Perspex tube with special inserts, over a test bed of the same material (stained blue), and measuring the increase in flow velocity, together with the proportion of test bed entrained.

Deliberate attempts to generate turbidity currents in submarine canyons (Buffington, 1961; Dill, 1964) have met with little success; fortunately for the operators, perhaps, they did not meet the conditions necessary for triggering an autosuspension current.

AVALANCHE AND ROCK FALL

Avalanche and rock fall are slope movement processes by which masses are detached from jointed rock outcrops and accelerate by self weight to lower elevations by a combination of sliding, rolling, and flow. Since the sedimentological record imprinted by snow avalanches is very localized and transient, this article is restricted to rock-slope instability processes.

Rock avalanche

General attributes

Rock avalanche is a large-scale mass movement process involving the disintegration of a rock slide failure to form a rapidly flowing, granular mass. Many of the largest rock avalanches are known to have been triggered by either volcano collapse or seismic shock. Rock avalanches attain their largest size and destructive potential in high mountain areas and have been recorded on virtually every rock type. The avalanche attributes of high volume (10^6 – 10^{10} m³), high velocity (20–50 ms⁻¹), long running distance (3–20 km), and extensive deposits (hundreds of km² for the largest events) distinguish them as the most hazardous and destructive geomorphic events on Earth. Some deposits are extensive enough to warrant the status of stratigraphic formations. Very large events, estimated to lie in the range 10^{10} – 10^{14} m³, have also been identified on Mars and the Moon.

Slope failures derived from unconsolidated colluvial, glacial, and volcanic materials, termed *debris avalanches*, and are mechanically similar to rock avalanches. Debris avalanches derived from the failure of colluvial and glacial materials are generally small by comparison (typically 10^3 – 10^5 m³); however,

debris avalanches derived from stratovolcanic collapse are among the largest slope failures on Earth. The world record is presently held by the 300–360 ka event from Mt. Shasta, California, having an estimated volume of $2.6 \times 10^{10} \text{ m}^3$ and a deposit surface area of 450 km^2 .

Sedimentology and morphology of rock avalanche deposits

Rock avalanche deposits are diamictons comprising mainly angular, poorly sorted rock debris of local provenance, ranging in size from very large boulders, tens of meters in diameter, to fine silt and clay-sized fractions. The wide spectrum of sizes is produced in part by fracture and kinetic comminution of rock material as it moves downslope from the avalanche detachment zone, and partly by entrainment of water-saturated fine materials from the valley floor overridden by the avalanche. The vertical grading of rock avalanche deposits is highly variable, though some show slight inverse grading, caused by upward migration of large boulders by dispersive pressure (Middleton and Wilcock, 1994). Inverse grading may also develop from kinetic sieving, in which a preferential downward movement of finer material occurs through voids between larger clasts.

Rock avalanches discharging into lowland areas produce extensive, spatulate, hummocky sheets of rubbly diamicton, tens of meters thick and kilometers in extent. Longitudinal grooves and ridges commonly occur sub-parallel to the flow direction, with pressure ridges developed transverse to the flow near its terminus (Shreve, 1968). Avalanches exhibit a range of morphologies depending on their mobility. Relatively dry avalanches, moving orthogonal to the valley axis, have lower mobility through expending much energy by collision with the adverse valley wall. Major landslide dams impounding lakes are common in these cases (Costa and Schuster, 1988). Avalanches discharging along a valley axis are more likely to en-

train water and saturated valley floor materials. This in turn causes high basal water pressure and a reduction of internal friction, leading to a high velocity, streaming type of motion. Avalanche running distances exceeding 5 km are common. Rock avalanches confined by valley walls often exhibit evidence of run-up and superelevation against obstacles and valley side slopes, allowing estimates to be made of avalanche flow velocity (Hung, 1995).

Rock avalanche mechanics

A long-standing problem in rock avalanche mechanics is their high mobility on relatively low slope angles. Figure A13 shows a plot of avalanche volume, V , against angle of reach, defined by the quotient of fall height, H , and avalanche travel distance, L . H/L defines the running slope, f , of the avalanche, which approximates the average friction angle mobilized by the moving debris (Middleton and Wilcock, 1994, p.107). The inverse relation between V and f is the well documented 'size effect' (Hsü, 1975). A range of mechanisms has been proposed to account for this relation. Basal water pressure is a possibility, given that many avalanches traverse low-lying areas where saturated, fine grained materials are readily entrained. Very long-running volcanogenic debris avalanches or *lahars* (Reid *et al.*, 2001) result from the incorporation of melting snow and ice. Fluid-escape craters and fine debris cones on the surfaces of some rock and debris avalanches demonstrate that high fluid pressures prevailed during the motion. In the fully geostatic case, where total overburden pressure equals fluid pressure, effective stress would be close to zero, and frictional resistance in the Mohr-Coulomb sense would be lost. The avalanche size effect due to water pressure could then be accounted for by the longer fluid drainage paths required in larger, thicker avalanches, which would favor a longer retention of excess fluid pressures.

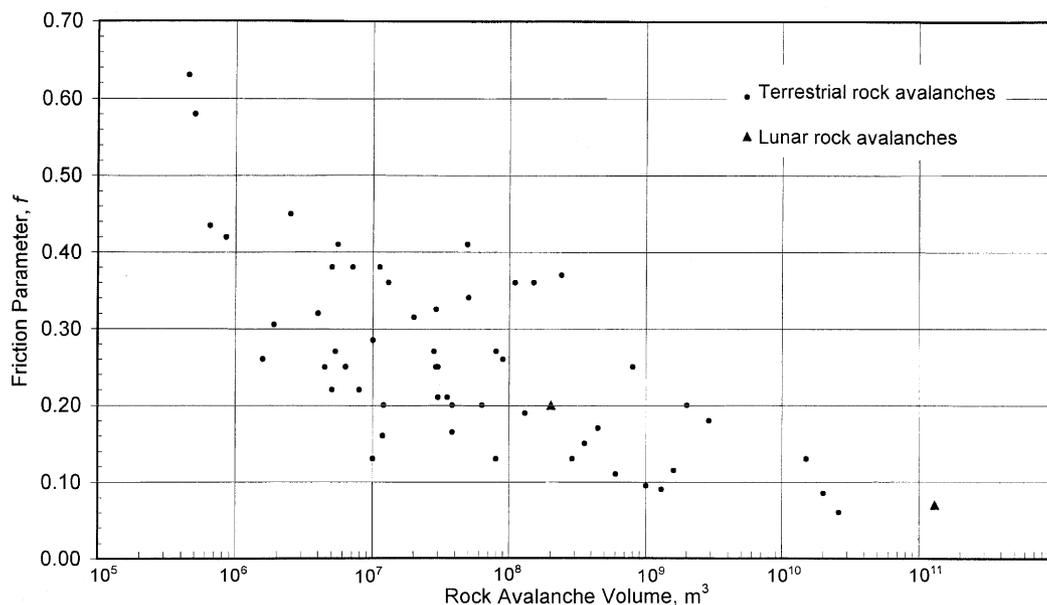

Figure A13 Rock avalanche volume versus avalanche friction parameter, f . Data are derived from Hsü (1975) and Evans *et al.* (1989).

The 'air-layer lubrication' theory (Shreve, 1968) requires that avalanches be air launched at some point along their path, followed by the avalanche running on a cushion of compressed air. This is a less appealing mechanism given the high compressibility of air. Acoustic fluidization (Melosh, 1987) requires propagation through the moving mass of acoustical energy with wavelengths longer than the average particle diameter. Wave propagation creates grain zones in compression, which move with little internal deformation, and zones of rarefaction where slip is possible. The result is a lesser dissipation of energy than would occur if all grain zones experienced shear strain. Finally, the 'self-lubrication' mechanism (Campbell, 1989) is based on the development of a relatively low-density, rapidly sheared zone at the base of an avalanche, upon which the bulk of the mass is efficiently transported with significantly less internal deformation. The size effect is then explained by the greater length of time required to dissipate the greater kinetic energy of very large avalanches.

Rock fall

General attributes

Rock fall is a generally small-scale mass movement process involving the detachment of individual rock particles, or relatively small groups of particles, from cliffs and other bedrock outcrops. The total volume of material detached by a rockfall event is generally $10\text{--}10^4\text{ m}^3$, which is several orders of magnitude smaller than volumes delivered by rock avalanches. Detachment of individual rockfall blocks from a rock face typically occurs along pre-existing planes of weakness such as joints, bedding, and foliation, with most failures occurring by either sliding or toppling. Downslope movement typically occurs by a combination of sliding, free-fall, saltation, and rolling. Rock fall is especially active during episodes of multiple freeze-thaw cycles in autumn and spring periods, or whenever high water pressure exists along joints. Rocks with closely spaced joints are most prone to production of rockfall debris, yielding a high frequency of blocks in the range $0.01\text{--}10\text{ m}^3$. However, in sparsely jointed massive rocks, rock fall is a less frequent though sometime catastrophic process. Huge monoliths totaling several thousands of cubic meters may topple or fall (Schumm and Chorley, 1964).

Rock fall deposits

The prolonged operation of rock fall at a site leads to cone-shaped accumulations of angular rubble known as talus. Most talus slopes produced by rock fall develop characteristic angles of rest in the range $34^\circ\text{--}36^\circ$, the so-called angle of repose of the rubble material (Carson, 1977). Somewhat steeper angles can develop when talus is built slowly by small-scale rock fall. Angles significantly flatter than 35° indicate that other processes, notably snow avalanche, rock avalanche, or debris flow, have reworked talus material (Luckman, 1988), implying that some talus deposits are composite features. It is common to find finer material interbedded with coarse-grained rockfall deposits, so the surface rubble layer is often not indicative of the texture of the entire deposit.

Rock fall mechanics

The loss of potential energy by a falling particle must be balanced by the sum of its kinetic energy gain and energy losses caused by friction with, and deformation of, the talus surface underlying the moving particle. The total travel distance of a particle across a talus slope is a function of its initial angle of impact, its initial velocity, and its size relative to that of material comprising the talus slope. Particle impact angle on the talus slope is a critical factor, since more than 80 percent of kinetic energy can be dissipated by cratering work at the first impact. A transition from bouncing to rolling eventually occurs, since progressively less of the particle's remaining momentum is directed normal to the slope during successive impacts. Once rolling has commenced, larger particles tend to run further by virtue of their lower rolling-friction angles. Over time, the talus slope develops a basal concave section with larger blocks deposited in the "shadow" zone, well beyond the base of the main talus deposit (Evans and Hungr, 1993). A distinct fall-sorted texture thus evolves comprising a progressive downslope increase in mean particle size.

Because of the sporadic nature of the rock fall process, and the difficulty of measuring its effects in remote areas, some of the most detailed process studies have been conducted along highways and railways where rock fall poses a hazard (Hungr *et al.*, 1999). Computer simulations, corroborated by field studies, are now routinely used in determining rockfall risk assessments wherever public safety is a concern (Evans and Hungr, 1993).

AVULSION

Avulsion is the process in which river (or other) flows are diverted out of an established channel into a new course at a lower elevation on the adjacent surface. Although the term usually refers to major discharge diversions that result in new channels, it is sometime used in reference to short-term flow switching within braided channels. Avulsions may be *full*, in which all flow is transferred out of the parent channel, or *partial*, in which only a portion of the flow is transferred. Full avulsions result in abandonment of the parent channel downstream of the diversion site, whereas partial avulsions lead to new channels that coexist with the parent channel. Partial avulsion is a principal mechanism that forms anastomosing channels (if the channels rejoin) and distributary channels (if the channels do not rejoin), the latter a common feature of alluvial fans and deltas. Avulsions may be abrupt or gradual. For example, in 1855 the Yellow River (China) breached one of its levees during a large flood, and within a single day, all flow had diverted through the breach into the floodplain (Qian, 1990). In contrast, full avulsions in the Meuse-Rhine delta often require several centuries to complete, and durations of up to 1250 years have been measured (Stouthamer and Berendsen, 2001).

Avulsions are features of aggrading river systems and should not be expected in actively incising stream valleys. They are not restricted to any particular channel form or size and will recur in any river system for as long as aggradation continues. Frequency of avulsion recurrence varies widely among the few modern rivers for which such data exists, ranging from as low as 28 years for the Kosi River (India) up to 1400 years for the Mississippi (see Table 4.2 in Stouthamer and Berendsen, 2001). Data from the geologic record suggest that much larger intervals between avulsions have existed (e.g., Kraus and Aslan, 1993). By forcing large-scale repositioning of stream channels, avulsion is a dominant mechanism for constructing river floodplains, deltas, and alluvial fans and for generating laterally extensive sedimentary deposits in the stratigraphic record.

Causes of avulsion

Two basic conditions are required for avulsion: (1) a long-term “setup” in which the channel gradually increases its

susceptibility to avulsion, and (2) a short-term “trigger” event which initiates the flow diversion. The setup requirement is attained by the tendency for a channel belt to rise above the level of the adjacent floodplain under conditions of net aggradation. Such *superelevation* of the channel belt develops because overbank deposition rates tend to be greatest near the channel (forming levees) and to decrease exponentially away from the channel across the floodplain. Such elevated channel belts are known as *alluvial ridges*. With continued aggradation and elevation differentiation, this topology becomes increasingly unstable and is eventually relieved by avulsion when a sufficiently large trigger event occurs. Such events are typically floods, but also include such processes as abrupt neotectonic movements, ice jams, log jams, vegetative blockages, debris dams, or bank failures (see Jones and Schumm, 1999, for review).

Implicit with the setup requirement is the presumption that some critical value of channel-to-floodplain slope must be exceeded before avulsion can take place. Mackey and Bridge (1995), for example, consider the probability of avulsion occurring at a particular site as a product of the ratio of cross-valley to down-channel slope and the return period of flood discharge in excess of some threshold value. Note that the slope ratio can be increased by either increasing cross-valley slope or decreasing down-channel slope. The former is readily attained by increasing the elevation of the channel belt relative to the floodplain, whereas down-channel slope may be reduced by increasing sinuosity or, in the case of prograding deltas, by channel lengthening. Cross-valley or down-channel slope can also be altered by tectonic tilting. As an alternative to channel-to-floodplain slope, Mohrig *et al.* (2000) argue that elevation difference between the channel water surface and the lowest areas of the floodplain exerts the primary control on avulsion setup. In either case, continuing elevation of the alluvial ridge relative to the rest of the floodplain eventually makes avulsion inevitable.

When general setup conditions are sufficient to permit avulsion, the site at which the avulsion takes place is likely to be opportunistic and determined by such local factors as channel geometry, bank stability, or topography. For example, avulsion sites commonly occur at the outer banks of meander bends where flow velocities are high, confining levees are narrow, and flood flows impinge the banks at high angles. Floods continually test weaknesses in the channel banks, and local areas of relative instability, for example, intersected sand bodies of former channels, are potential locations for avulsion (Chrzaszowski *et al.*, 1994; Smith *et al.*, 1998). Avulsion sites commonly begin as crevasses that enlarge until flow is permanently diverted from the parent channel. Many crevasse channels, however, become plugged with sediment and do not result in permanent flow transfer. Modeling results (Slingerland and Smith, 1998) suggest that whether a crevasse-channel plugs, runs to full avulsion, or reaches a steady state of partial avulsion depends on the ratio of crevasse to main-channel bed slope, ratio of crevasse to main channel depth, and bed grain size. For fine to medium sand sizes, crevasse-channel slopes greater than about 5 to 8 times main-channel slope are predicted to develop into full avulsions regardless of initial crevasse size. Lower crevasse-channel slopes will more likely become plugged or sustain partially diverted flows for long periods.

Styles of avulsion

It is generally presumed that the initial pathways of newly diverted flow will follow the direction of greatest slope or

maximum flow efficiency away from the parent channel. The extent of avulsive flooding and nature of channel patterns that subsequently develop are then governed in large part by the character of the floodplain surface, for example, its gradient, relief, vegetative cover, presence of existing channels (active or abandoned), elevation of water table, and floodplain width. Abandoned alluvial ridges and narrow valley walls, for example, limit the lateral extent of avulsive flow normal to the parent channel and redirect it downvalley. Dense vegetation covers, low floodplain gradients, and high water tables (associated with shallow floodplain lakes and marshy wetlands) promote slow runoff, leading to ponding and deposition of fine sediment. Rapid runoff is enhanced by high gradients, low water tables, and sparse vegetative covers.

Three broadly different styles of floodplain response to avulsion have been recognized: (1) appropriation or reoccupation of preexisting channels, (2) creation of new channels by incision, and (3) deposition of multichanneled progradational sediment wedges. (1) Appropriation of active floodplain channels or reoccupation of abandoned channels is a common avulsion style that results from the tendency for the diverted flow to seek pathways of maximum transport efficiency. If the annexed channel is large enough to accommodate the diverted flow, little floodplain modification takes place. Commonly, however, the annexed channel is too small for the newly captured flow; deepening and/or widening of the channel usually follows, sometimes accompanied by extensive crevassing and deposition of crevasse splays (Pérez-Arlucea and Smith, 1999). (2) Incision of new channels is most likely to occur in well-drained floodplains where avulsive floodwaters run off quickly and little sediment deposition takes place (Mohrig *et al.*, 2000). Such incisional channels may form by downstream extension from the initial avulsion site or upstream migration of a knickpoint from the site where the diverted flows reenter the parent channel or tributary (Schumm *et al.*, 1996). (3) Deposition and down-floodplain progradation of multichanneled sediment wedges is a dominant avulsion style in poorly drained marshy floodplains (Smith *et al.*, 1989; Tye and Coleman, 1989). Scales of progradation range from small crevasse splays to regional-scale complexes of coalesced splays and lacustrine deltas. The active margins of the progradational wedge are supplied by many small, often interconnected, channels which later are succeeded by a single large channel as the avulsion evolves to completion. In cases of regional-scale full avulsions, this final channel becomes the new parent channel for the next avulsion.

Avulsion deposits

Because avulsions are expectable consequences of aggradation and the principal mechanisms by which laterally extensive alluvial deposits are formed, we should expect abundant evidence of avulsion in alluvial stratigraphic successions. As yet, however, only a few studies of ancient river sediments have drawn specific attention to avulsion processes or deposits. Evidence for avulsion is often straightforward but indirect. For example, the mere presence of a well-developed paleosol within an alluvial succession suggests that avulsion resituated the contemporaneous river channel to a location too distant to flood the paleosol site with fine sediment.

Direct evidence of avulsions can be found in the character of their deposits. Avulsion involving channel reoccupation can be inferred by well-defined, multistoried, often stepped, sand bodies within a single channel-fill succession, or different stratigraphic levels of levee deposits associated with the same channel-fill. Avulsion dominated by incisions of new channels may be manifested by abundant ribbon (low width/thickness ratio) sand bodies encased in fine floodplain sediments and defined by sharp erosional contacts (Mohrig *et al.*, 2000). Deposits of progradational avulsions tend to be the most heterogeneous. They include ribbon sands formed by anastomosing distributary networks, sheet sands formed by crevasse splays and channel-mouth bars, and a variety of fine-grained sediments deposited in interchannel lows and in ponded or otherwise slow-moving water bodies formed by the avulsion (Smith *et al.*, 1989). Because the avulsive sediment wedge is predominantly progradational in character, upward-coarsening successions, with thicknesses scaled to water depth, are typical (Pérez-Arlucea and Smith, 1999). Sedimentary successions formed by progradational avulsions are likely to be capped by paleosols or fine-grained flood deposits of succeeding channel belts. Ancient examples are described by Kraus (1996) and Kraus and Wells (1999).

B

BACTERIA IN SEDIMENTS

Epibenthic bacteria forming biofilms and microbial mats

Bacteria live in an extremely wide range of habitats, and their occurrence is only restricted by the requirement for water and the physicochemical stability limits of biomolecules (Knoll and Bauld, 1989). In sediments, epibenthic bacteria attach firmly to the surfaces of mineral particles by their adhesive and mucous, 'extracellular polymeric substances (EPS)' often more abundant than the cell material itself (Decho, 1990 for overview and introduction; Decho, 2000). The mucilaginous substances aid the microbes to sequester nutrients, to protect themselves against osmotic pressure caused by changing salinities, and to maintain an optimal chemical microenvironment for activities of extracellular enzymes (Decho, 1990). These coatings, composed of single cells and their mucilages enveloping mineral particles are known as biofilms (Marshall, 1984; Charaklis and Wilderer, 1989; compare also Stolz, 2000). Further biomass enrichment leads to the formation of discrete, tissue-like organic layers, microbial mats, that cover extensive areas of the seafloor (definition of term see Krumbein, 1983; Cohen and Rosenberg, 1989; Stal and Caumette, 1994; Stolz, 2000; brief historic outline included in Stal, 2000). Microbial mats are biologically stratified communities. Different bacterial populations organize in horizontal layers in dependence to intrasedimentary, chemical gradients (Stolz, 2000, and references therein). Their highly active metabolic cycles are in steady interaction with chemical parameters of their surroundings, and thus the microbes powerfully influence their environment (Stal, 2000). This bacterially mediated element transfer causes diverse intrasedimentary mineral deposits and structures of high preservation potential (Krumbein, 1986). In consolidated rocks, occurrences of the minerals permit conclusions on the biology of ancient microbiota, and on the environmental conditions of the past.

Epibenthic bacterial populations as 'bioreactors'

Epibenthic microorganisms and their slimy secretions contribute to a high porosity of the surface sediments, and their intensive metabolic and catalysatory activities raise the amount of chemical reactions substantially. The transfer capacity of a multi-layered microbial mat is even greater, because the different metabolic cycles interlock with each other. Therefore a microbial mat was compared with an intrasedimentary 'bioreactor' (Hanselmann, 1989; compare also model of 'bioid' by Krumbein, 1986). Within the stratified community of a microbial mat (Figure B1), each population depends on the metabolic products of the other below or above (Cohen and Rosenberg, 1989; Hanselmann, 1989; Stal and Caumette, 1994; Ehrlich, 1996; Nealson, 1997; Stal, 2000; Stolz, 2000; Nisbet and Sleep, 2001). In the photic zone, primary producers, mainly cyanobacteria (and diatoms), build up biomass by oxygenic or anoxygenic photosynthesis. Below the cyanobacteria, a layer of purple sulfur bacteria may establish (depending on the relative depth gradients of light and oxygen). Their purely anaerobic photosynthesis makes use of lower light intensities than cyanobacteria. Sulfur bacteria require sulfide, which is provided by sulfate-reducing bacteria colonizing deeper parts of the sediments. Here, a great variety of heterotrophic bacteria decompose the primary organic material. With the aid of their highly effective enzymes, they degrade polysaccharides, lipids, or proteins, of the primary biomass, and release monomers. These are further decomposed by sulfate reducing and methanogenic bacteria to carbon dioxide, hydrogen sulfide, methane, and inorganic nutrients.

Chemical processes as a consequence of decomposition and mineralization of organic material lead to precipitation of sulfides, carbonates, silicates, and many other minerals (Krumbein, 1986). This will be outlined in the following.

Decomposition of organic material causing precipitation of minerals

In microscopic scale, the cell walls of bacteria are composed of macromolecules that give an overall electro-negative charge to

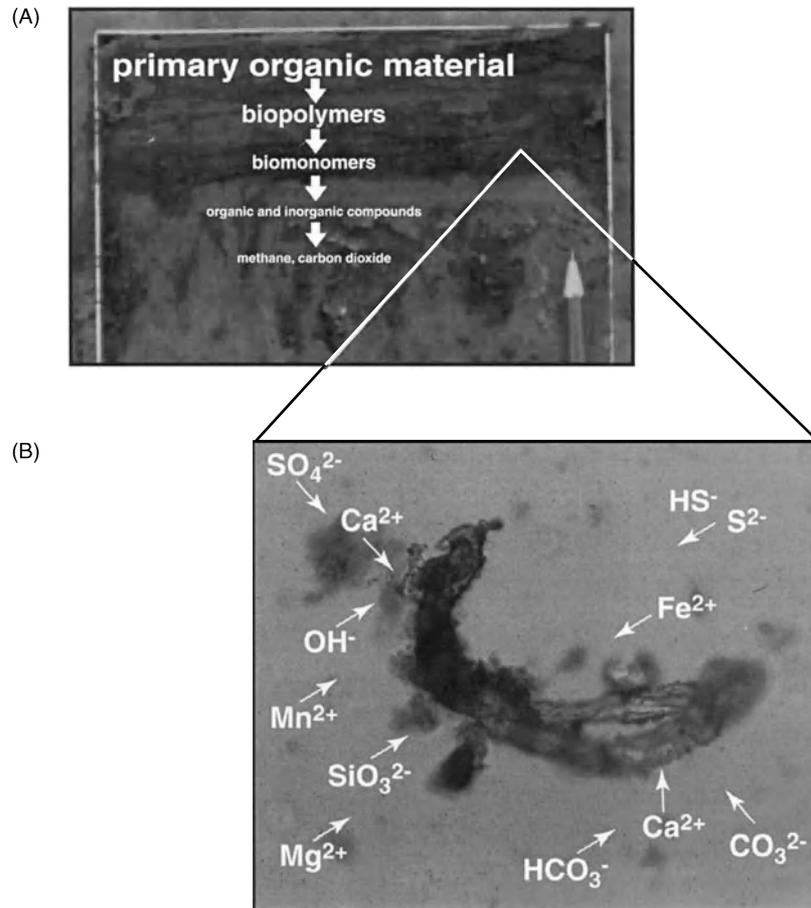

Figure B1 Bacterial decomposition of organic material leads to precipitation of sulfides, carbonates, silicates, and other minerals. (A) Within microbial mats, primary organic material is decomposed in several steps until inorganic nutrients are formed. (B) In microscale, ions dissolved in the surroundings react with reactive chemical groups along the outer cell wall. This might induce mineral precipitation. Photo shows initial precipitates (? pyrite) along cyanobacterial filament.

the outer cell walls (Beveridge, 1989; Beveridge and Doyle, 1989; Schulze-Lam *et al.*, 1996). The reactive chemical groups of the cell wall project into the surrounding environment, but protons released through the cell membrane in course of ATP-generation of the living cell occupy the negatively charged sites. Additionally, the heterogeneously charged microsites of the cell wall adsorb water molecules (that have bipolar chemical structure), and as a consequence a film of water permanently envelopes and buffers the cells (Schulze-Lam *et al.*, 1996). It is assumed that after bacterial cells die, the increasingly electro-negative charge of the cell surfaces react with electro-positive metal ions dissolved in the seawater. In laboratory experiments, the first metal ions serve as nucleus for further metal enrichment, and counter-ions are attracted (Beveridge, 1989; Beveridge and Doyle, 1989; Schulze-Lam *et al.*, 1996; Douglas and Beveridge, 1998; Ferris, 2000). Because of the water molecules enveloping bacterial cells, initial precipitates are hydrated and amorphous (Beveridge, 1989; early steps of aragonite formation on cell envelopes are documented by Krumbein, 1979a; see also Schulze-Lam *et al.*, 1996). Over time, dehydration of the precipitates leads to a crystalline mineral phase, and during this diagenetic alteration

for example, aragonite changes to calcite (Beveridge, 1989). Depending on microenvironmental geochemistry induced by decomposing heterotroph bacteria, counter ions like sulfate, carbonate, or sulfide ions determine formation of specific minerals, (Figure B1). For example, pyrite is formed in presence of Fe²⁺ and HS⁻ or S²⁻ ions, and often can be found intimately related to carbonate layers in subrecent, decaying microbial mats (Gerdes *et al.*, 2000).

Microbial ecosystems are ancient and nearly as old as the earliest geological record, so knowledge of bacterially induced chemical processes provides important clues on the biological and environmental evolution of Earth and other planets.

BALL-AND-PILLOW (PILLOW) STRUCTURE

Definition and description

Ball-and-pillow structure is a soft-sediment deformation structure comprising rounded masses of clastic sediment

(pseudonodules, q.v.) set in similar or finer grained matrix, that are vertically stacked within one horizon (Figure B2(A), (B)). Much of the discussion in the entry for pseudonodules, relating to their description and their origin through loading processes related to variations in gravitational potential energy, is relevant to ball-and-pillow structure. Distinctive features of ball-and-pillow structure include: the pseudonodules are commonly contorted into spiral or zig zag shapes; there may be very little matrix between the pseudonodules; and some ball-and-pillow horizons are consistently underlain by convolute stratification and overlain by dish structure.

Historical development

Ball-and-pillow structure is usually traced back to Smith (1916), in a paper entitled 'Ball or pillow-form structures in sandstones'. The term 'ball-and-pillow structure' was introduced by Potter and Pettijohn (1963), who mistakenly cited Smith's (1916) title as 'Ball- or pillow-form structure', although Smith (1916) clearly did not intend 'ball' and 'pillow' to be part of a single name, referring instead to 'pillow-form

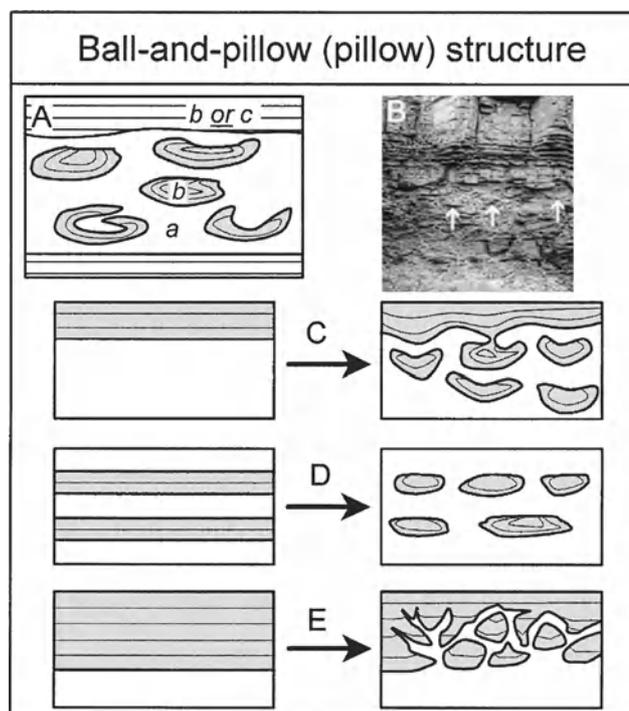

Figure B2 Definition and interpretation of ball-and-pillow structure. For simplicity, stratification is not shown in the lower, less dense layer. (A) Definition diagram for ball-and-pillow structure, where a, b and c are distinct sedimentation units. (B) Ball-and-pillow structure from an Upper Carboniferous delta front sequence at Amroth, west Wales, UK. Arrows point to individual pseudonodules. The section illustrated is 3 m thick. (C) Formation by repeated detachment from the base of a layer undergoing load deformation. (D) Formation by the simultaneous loading of several couplets of denser and less dense sediment. (E) Formation by a process of sedimentary stoping in which mobile sediment rises through an essentially passive layer.

or ball structures'. The structures described by Smith (1916) and Potter and Pettijohn (1963) are very similar to those that have subsequently been described as both ball-and-pillow structure and pseudonodules (or pseudo-nodules). The history and use of these terms are inextricably entwined, and are discussed fully in the entry for pseudonodules.

Interpretation

Examples of deformation pathways that lead to ball-and-pillow structure are shown in Figure B2. Some ball-and-pillow horizons represent isolated fold noses formed by downslope slumping, but most result from loading processes related to variations in gravitational potential energy and driven by variations in bulk density. Factors that favor the development of pseudonodules, in contrast to load casts that affect the base of a laterally continuous bed, include a driving force of large magnitude, a combination of driving forces, a very weak lower layer, or a long duration of deformation. Loading processes that can result in ball-and-pillow structure include: lateral drift of pseudonodules as they sink (e.g., Kuenen, 1958: Plate I); repeated detachment of masses from the base of a 'source layer' (Figure B2(C)); simultaneous liquidization and loading of several couplets of denser and less dense sediment (Figure B2(D)); and a process of 'sedimentary stoping', in which liquidized sediment (usually fluidized sand) rises through an essentially passive upper layer (Figure B2(E)). Criteria need to be developed to characterize the products of each of these pathways. For example, in ball-and-pillow horizons formed by sedimentary stoping, the pseudonodules are unlikely to have flat upper surfaces, they are likely to be relatively undeformed internally, and the upper surface of the ball-and-pillow horizon may be highly irregular.

Summary

Ball-and-pillow structure represents an extreme form of load structure. It can form as the end product of several soft-sediment deformation pathways. Further studies are needed to develop criteria that differentiate these various pathways.

BAR, LITTORAL

Introduction

Ridges of unconsolidated sediment, which characterize the upper shoreface of littoral zones dominated by waves, and are generally larger than bedforms are termed *wave-formed bars* (e.g., see Figure B3). They were recognized as early as 1845 on the marine coasts of Europe, by 1851 in the Great Lakes of North America and subsequently on marine and lacustrine coasts worldwide (see Zenkovich, 1967). Confusion surrounds the term *bar* because: (a) it is used for similar forms in other environments (see Bar, Fluvial); (b) bars occur within the littoral zone with a wide range of size, shape, location and orientation relative to the shoreline, and within a wide range of littoral environments; (c) no single classification system has proved satisfactory (e.g., Greenwood and Davidson-Arnott, 1975; Wright and Short, 1984; Lippmann and Holman, 1990); (d) explanation of the origin(s) and dynamics of *wave-formed bars* is far from complete. Detailed reviews of the origin, form and dynamics of bars are given in van Rijn (1998) and Greenwood (2002, in press).

Origin

The boundary conditions for bar formation depend upon the bed material (mineralogy, size, etc.), the bathymetric setting, and the geographic location, which controls the wave climate, tidal regime, etc. In general, barred profiles are associated with large values of wave steepness and wave height-to-grain size ratios; however, the degree of wave energy reflection or dissipation is an important control and thus shoreface slope is critical. A number of hypotheses have been proposed for bar formation: (i) *break point hypotheses* relate bars to a seaward transport of sediment entrained by roller or helical vortices under plunging or spilling breakers, or a convergence of sediment at the breakpoint through onshore transport associated with wave asymmetry and skewness, and offshore transport through set up induced undertow; (ii) *infragravity wave hypotheses* propose that low frequency waves generated within the surf zone or offshore and reflected, produce a convergent pattern of drift velocities, which interact with large incident short waves to induce a range of forms from simple 2-dimensional to 3-dimensional crescentic forms; (iii) *self-organization hypotheses* suggest that processes associated with the complex, non-linear feedback between the hydrodynamics and the sand bed give rise to a range of topographic forms. Alongshore and offshore sediment transport was proposed for bar formation: (a) under meandering or cellular nearshore circulations produced by the instability of longshore flows; (b) a coupling between morphodynamic instability and mean flows; and (c) a non-linear action between shoaling waves and the bed.

Morphology and morphodynamics

Modern *wave-formed bars* are near symmetrical, to strongly asymmetrical undulations in the upper shoreface profile (Figure B3). They occur both intertidally and subtidally, as well as in nontidal areas, and may range in number from 1 to >30, covering a belt up to 1.5 km wide. In plan view, they form

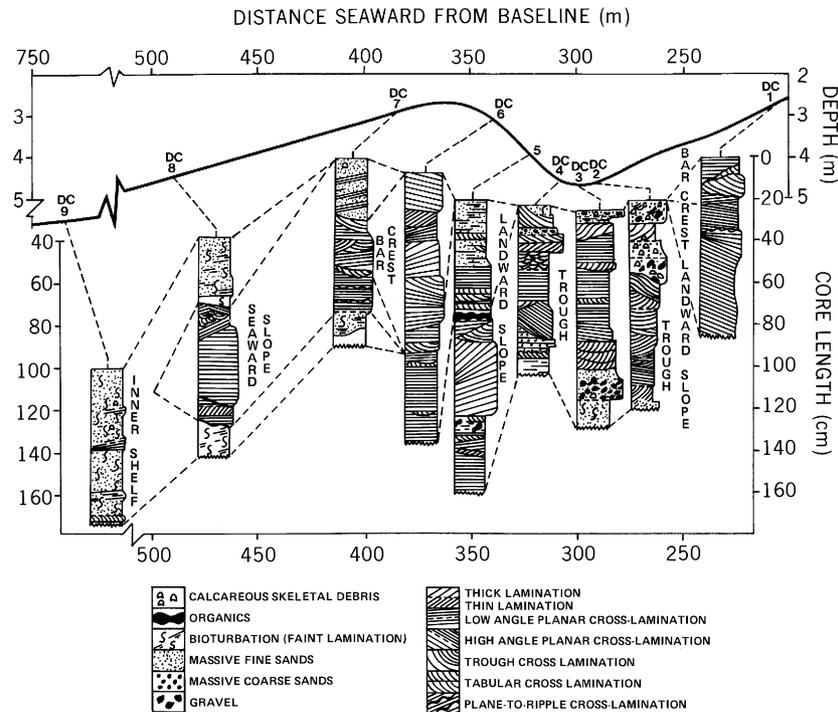

Figure B3 Typical barred profile from a marine environment in the southern Gulf of St. Lawrence, Canada. Note: the structures shown are from a series of nine tube cores taken across the bar; the lateral correlation of facies is shown by the dotted lines (modified after Greenwood and Mittler, 1985).

continuous or compartmentalized, linear, sinuous, or crescentic ridges, and range in orientation from shore-normal, often producing periodic or rhythmic forms, both alongshore and cross-shore. Bars increase in size and spacing in the offshore direction, range from a few decimeters to more than 4.75 m in height (Greenwood and Mittler, 1979), and may stretch alongshore for tens of kilometers. Shepard (1950), Hands (1976) and others present detailed morphometry based on topographic surveys. Recently, analysis of video imagery has given new insights on bar morphodynamics during storm events and over long (decadal) time periods (e.g., Lippmann and Holman, 1990; Reussink *et al.*, 2000). Van Rijn (1998) summarizes much of the vast literature on bar dynamics.

Texture

The vast majority of *wave-formed bars* consist of sand-size materials, although they have been recorded in sands mixed with small gravels; the associated troughs often contain gravels plus silt and clay-sized sediments. A distinct size fractionation is associated with the bar form, which is superimposed on the expected coarsening of sediments shoreward across the shoreface. Crest sediments are better sorted than those of the associated trough, but may be finer or coarser depending upon whether the latter are erosional lags or suspension deposits from quiescent periods (Mothersill, 1969; Greenwood and Davidson-Arnott, 1972; Keranen, 1985). In general sediments are negatively (coarse) skewed, although this is not universal (see Fraser *et al.*, 1991). Sizes vary significantly with wave energy levels (Mulrennan, 1992; Stauble and Cialone, 1996).

Bedforms and internal stratification

Bed shear over nearshore bars is controlled by the complex, non-linear interactions within combined wave-current boundary layers. Sediment transport (Osborne and Greenwood, 1992), bedform development (Greenwood and Sherman, 1986) and internal stratification (Greenwood and Mittler, 1985) depend on the relative importance of a spectrum of oscillatory flows and any superimposed quasi-steady flow (Table B1). A number of studies document the bedforms that occur over bar topographies (Hunter *et al.*, 1979; Dabrio and Polo, 1981; Shipp, 1984; Short, 1984; Ollerhead and Greenwood, 1992) and Clifton (1976) and Clifton and Dingler (1984) provide conceptual models for analyzing modern and ancient littoral systems. The internal structures of bars have been described by several authors (Howard and Reineck, 1972; Reineck and Singh, 1973; Davidson-Arnott and Greenwood, 1974, 1976; Hunter *et al.*, 1979; Greenwood and Mittler 1979, 1985; Shipp, 1984), and summarized in Allen (1982). Stratification depends on position (see Figure B3): (a) *offshore slope*: couplets of small-scale trough (occasionally chevron) cross-lamination and low-angle parallel lamination; (b) *bar crest*: sub-horizontal, parallel lamination is most common, with medium-to-large scale trough cross-lamination dipping onshore (most common) and offshore; (c) *landward slope*: similar structures to those on the seaward slope except the parallel lamination dips onshore; (d) *trough*: parallel bedding and small-to-medium-scale trough cross-lamination; dips are highly variable reflecting both waves and bidirectional longshore currents; (e) *rip channel*: offshore-dipping, small-to-medium-scale units of tabular and trough cross-bedding occur in association with

Table B1 Flow regimes, bedform sequences and structural assemblages in littoral bars

quasi-steady rip currents. Rapid bar migration in shallow water produces medium-to-large-scale sets of onshore dipping tabular cross-lamination by avalanching on the bar front (Davidson-Arnott and Greenwood, 1974; Fraser *et al.*, 1991). Bioturbation is controlled by the degree of sediment reworking by the hydraulic regime and therefore is greatest on the lower offshore slope.

Facies models

The vertical and lateral sequences of stratification which occur with bar migration/accretion are described by Howard and Reineck (1972), Shipp (1984) and Greenwood and Mittler (1985) and models have been proposed by several authors (Davidson-Arnott and Greenwood, 1976; Hunter *et al.*, 1979; Shipp, 1984). Preservation potential depends upon the rate and direction of bar migration, the rate of sediment supply and water level change (Hunter *et al.*, 1979). For subaqueous bars, the most likely facies to be preserved are those of the trough, lower seaward slope and inner shelf. In bars that weld to the beach face, seaward progradation may preserve the large-scale tabular sets associated with the migrating slip face (van den Berg, 1977). However, the likelihood of preservation is generally small and conclusive evidence of wave-formed bars is lacking (see Ly, 1982, for one possible example).

BARRIER ISLANDS

Introduction

Barrier islands are wave-built accumulations of sediment that accrete vertically due to wave action and wind processes and are separated from adjacent barriers or headlands by tidal inlets. Most are linear features that tend to parallel the coast, generally occurring in groups or chains. Barriers are separated from the mainland by a region termed the *backbarrier* consisting of tidal flats, shallow bays, lagoons and/or marsh systems. Barrier islands may be less than 100 m wide or more than several kilometers in width. Likewise, they range in length

from several hundred meters to certain barriers along open coasts that extend for more than 100 km. Generally, barrier islands are wide where the supply of sediment has been abundant and relatively narrow where erosion rates are high or where the sediment was scarce during their formation. Their length is partly a function of sediment supply but is also strongly influenced by wave versus tidal energy of the region.

Coastal barriers consist of many different types of sediment depending on their geological setting. Sand, which is the most common constituent, comes from a variety of sources including rivers, deltaic and glacial deposits, eroding cliffs, and biogenic material. The major components of land-derived sand are the minerals quartz and feldspar. In northern latitudes where glaciers have shaped the landscape, gravel is a common constituent of barriers, whereas, in southern latitudes carbonate material, including shells and coral debris, may comprise a major portion of the barrier sands. Along the southeast coast of Iceland, as well as parts of Alaska and Hawaii, the barriers are composed of black volcanic sands derived from upland volcanic rocks.

Global distribution

Barriers comprise approximately 15 percent of the world's coastline. They are found along every continent except Antarctica, in every type of geological setting, and in every kind of climate. Tectonically, they are most common along Amero-trailing edge coasts where low gradient continental margins provide ideal settings for barrier formation (Inman and Nordstrom, 1971). They are also best developed in microtidal to mesotidal regimes and in mid- to low-latitudes (Hayes, 1979). Climatic conditions control the vegetation on the barriers and in backbarrier regions, the type of sediment on beaches, and in some regions such as the Arctic, the formation and modification of barriers themselves. The disappearance of barriers toward the very low energy northwest ("Big Bend") coast of Florida in the Gulf of Mexico attests to the requirement of wave energy in the formation of barriers.

Low-relief coastal plains and continental shelves provide a platform upon which barriers can form and migrate landward during periods of eustatic sea-level rise. The longest barrier chains in the world coincide with Amero-trailing edges and include the east coast of the United States (3,100 km) and the Gulf of Mexico coast (1,600 km). There are also sizable barrier chains along the east coast of South America (960 km), east coast of Indian coast (680 km), North Sea coast of Europe (560 km), eastern Siberia (300 km), and the North Slope of Alaska (900 km).

Barrier island sub-environments

Many sub-environments make up a barrier and their arrangement differs from location to location reflecting the type of barrier and the physical setting of the region. Generally, most barriers can be divided in three zones: the beach, the barrier interior, and the landward margin (Figure B4). Some barrier systems, such as those along the Mississippi coast, have active beaches on their landward sides due to expansive adjacent bays. The continual sediment reworking by wind, waves, and tides, establishes the beach as the most dynamic part of the barrier. Beaches exhibit a wide range of morphologies depending upon a number of factors including the sediment grain size and abundance, and the influence of storms.

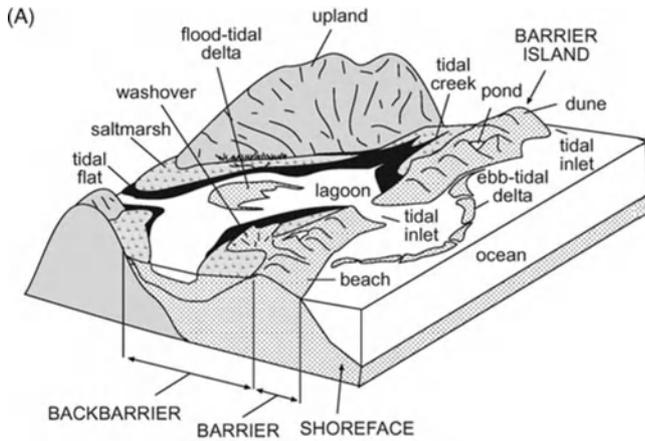

Figure B4 (A) Barrier island sub-environments, (B) Oblique aerial photograph of highly retrogradational barrier island, showing extensive washovers, Masonboro Island, North Carolina.

Sediment is removed from the beach during storms and returned during more tranquil wave conditions. During the storm and post-storm period, the form of the beach evolves in a predictable fashion. Along sandy barriers, the beach is backed by a frontal dune ridge (*foredune*) which may extend almost uninterrupted along the length of the barrier provided the supply of sediment is adequate and storms have not incised the dune ridge. The frontal dune ridge is the first line of defense in protecting the interior of the barrier from the effects of storms. Landward of this region are the secondary dunes which have a variety of forms depending on the historical

development of the barrier and subsequent modification by wind processes. The low areas between individual beach ridges, called *swales*, commonly extend below the water table and are the sites of fresh and brackish water ponds or salt marshes.

Along the backside of many barriers the dunes diminish in stature and the low relief of the barrier gradually changes to an intertidal sand or mud flat or a salt marsh. In other instances, the landward margin of the barrier abuts an open water area of a lagoon, bay, tidal creek, or coastal lake. Along coasts where the barrier is migrating onshore, the landward margin may be dominated by aprons of sand that have overwashed the barrier during periods of storms (Leatherman, 1979; Figure B4). In time, these sandy deposits may be colonized by salt grasses producing arcuate-shaped marshes. In still other regions, the backside of a barrier may be fronted by a sandy beach bordering a lagoon or bay. In this setting, wind-blown sand from the beach may form a rear-dune ridge outlining the landward margin of the barrier. The ends of the barrier island abutting tidal inlets are usually the most dynamic regions due to the effects of inlet migration and associated sediment transport patterns.

Origin of barrier islands

The widespread distribution of barrier islands along the world's coastlines and their occurrence in many different environmental settings has led numerous scientists to speculate on their origin for more than 150 years (Schwartz, 1973). The different explanations of barrier island formation can be grouped into three major theories: (1) *Offshore bar theory* (de Beaumont-Johnson), (2) *Spit accretion theory* (Gilbert-Fisher), and (3) *Submergence theory* (McGee-Hoyt) (Figure B5).

Elie de Beaumont believed that waves moving into shallow water churned up sand which was deposited in the form of a submarine bar when the waves broke and lost much of their energy. As the bars accreted vertically, they gradually built above sea level forming barrier islands (Figure B5). de Beaumont's idea that barriers were formed from offshore sand sources was countered by G.K. Gilbert, who argued that the barrier sediments came from alongshore sources. Gilbert proposed that sediment moving in the breaker zone through agitation by waves would construct spits extending from headlands parallel to the coast. The subsequent breaching of spits by storm waves would form barrier islands (Figure B5). Before the end of the nineteenth century, a third barrier island theory was published by W.D. McGee in 1890. He believed that during submergence, coastal ridges were separated from the mainland forming lagoons behind the ridges. In 1919, D.W. Johnson re-investigated the various theories and studied the shore-normal profile of barrier coasts. He reasoned that if barriers had formed from spits, then the offshore profile should intersect the mainland at the edge of the lagoon.

Hoyt (1967) correctly argued that if barrier islands had developed from offshore bars or through the breaching of spits, then open-ocean conditions would have existed along the mainland prior to barrier formation. Before becoming sheltered, breaking waves and onshore winds would have formed beaches and dune systems at these locations. Hoyt was able to show that for most barrier systems an open-ocean coast never existed along the present mainland coast. In situations where rising sea level and marsh development has led to an encroachment of lagoonal deposits onto the mainland, sediment cores from these regions have showed no evidence

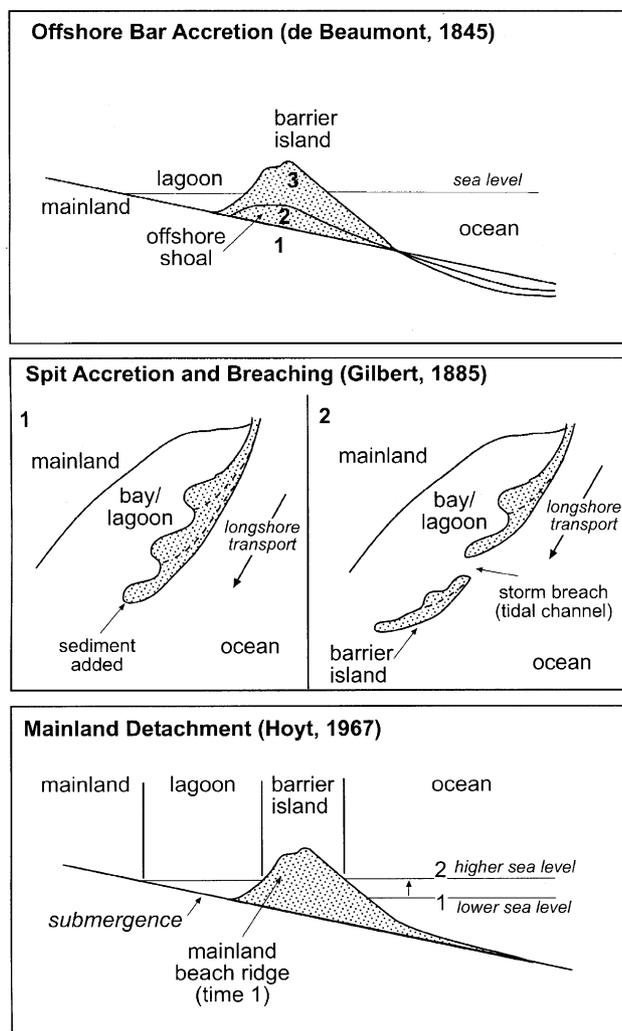

Figure B5 Models of barrier island formation (modified after Penland and Boyd, 1985).

of beach and nearshore sediments or the shells of organisms that are commonly inhabit the nearshore region. Armed with sedimentologic data, Hoyt (1967) had made a compelling case for barrier islands forming by submergence of coastal dunes or beach ridges due to rising sea level (Figure B5). However, in 1968, John Fisher produced a critical review of the submergence theory pointing out that long, straight, and continuous dune ridges would not occur along a coast being inundated by rising sea level. In light of these observations, Fisher became a strong proponent of Gilbert's spit accretion theory.

Recent barrier island research

Since the late-1960s there have been many studies of barrier islands aimed at determining the sedimentary layers making up the barrier and deciphering the manner in which these layers were deposited. This research has been aided by the radiometric dating of organic material contained within the barriers sediments, such as shells, peat, and wood, thereby providing a

chronology of barrier construction (Davis, 1994). In addition to traditional stratigraphic techniques, ground-penetrating radar (GPR) is also employed to study barriers (Jol *et al.*, 1996; van Heteren *et al.*, 1998). Sediment cores are taken in conjunction with the GPR surveys to determine the composition of the sediment layers and the environment in which they were deposited. Additional information concerning former barriers and their associated tidal inlets and lagoons has been gathered from the inner continental shelf using high-resolution shallow seismic surveys, a technology similar in principle to GPR. These advancements have provided new insights about the formation of coastal barrier systems.

Scientists are beginning to accept the idea that barriers can form by a number of different mechanisms. In considering the formation of barrier islands, it is important to recognize that almost all the world's barriers are less than 6,500 years old and most are younger than 4,000 years old. Most barriers formed in a regime of rising sea level but during a time when the rate of rise began to slow. Sedimentological data from the inner continental shelves off the East Coast of the United States, in the North Sea, and in southeast Australia suggest that barriers once existed offshore and have migrated to their present positions.

Morphosedimentary barrier types

The overall form of barriers, their stability, and future erosional or depositional trends are related to the supply of sediment, the rate of sea-level rise, storm cycles, and the topography of the mainland. When a barrier builds in a seaward direction it is said to prograde and is called a *prograding* barrier. Prograding barriers form in a regime of abundant sand supply during a period of stable or slow rise in sea level. The sand to build these barriers may come from along the shore or from offshore sources. These conditions were met along much of the East Coast of the United States and many other regions of the world about 4,000 to 5,000 years ago when the rate of sea-level rise decreased and sediment was contributed to the shore from *eroding headlands* (examples: Provinceland Spit in northern Cape Cod, Massachusetts (FitzGerald *et al.*, 1994); Lawrencetown barrier along the Northeast Shore of Nova Scotia), from the *inner continental shelf* (examples: barrier system along Bogue Banks, North Carolina; Algarve barrier chain, in southern Portugal; Tuncurry barrier in southeast Australia (Roy *et al.*, 1994); East Friesian Islands along the German North Sea coast), and *directly from rivers* (examples: most barrier systems in northern New England; barrier chain situated north of the Columbia River along southern coast of Washington).

A *retrograding* barrier forms when the supply of sand is inadequate to keep pace with relative sea-level rise and/or with sediment losses (Moslow and Colquhoun, 1981). Stated in terms of a sediment budget, a barrier becomes retrogradational when the amount of sand contributed to the barrier is less than the volume transported away from the barrier. The sand may be lost offshore during storms, moved along shore in the littoral system, or transported across the barrier by overwash. *Overwash* is a cannibalistic process whereby storm waves transport sand from the beach through the dunes, depositing it along the landward margin of the barrier (Figure B4). In this way the barrier is preserved by retreating landward. Because these barriers have been migrating over various types of backbarrier settings, including lagoons and marshes, the

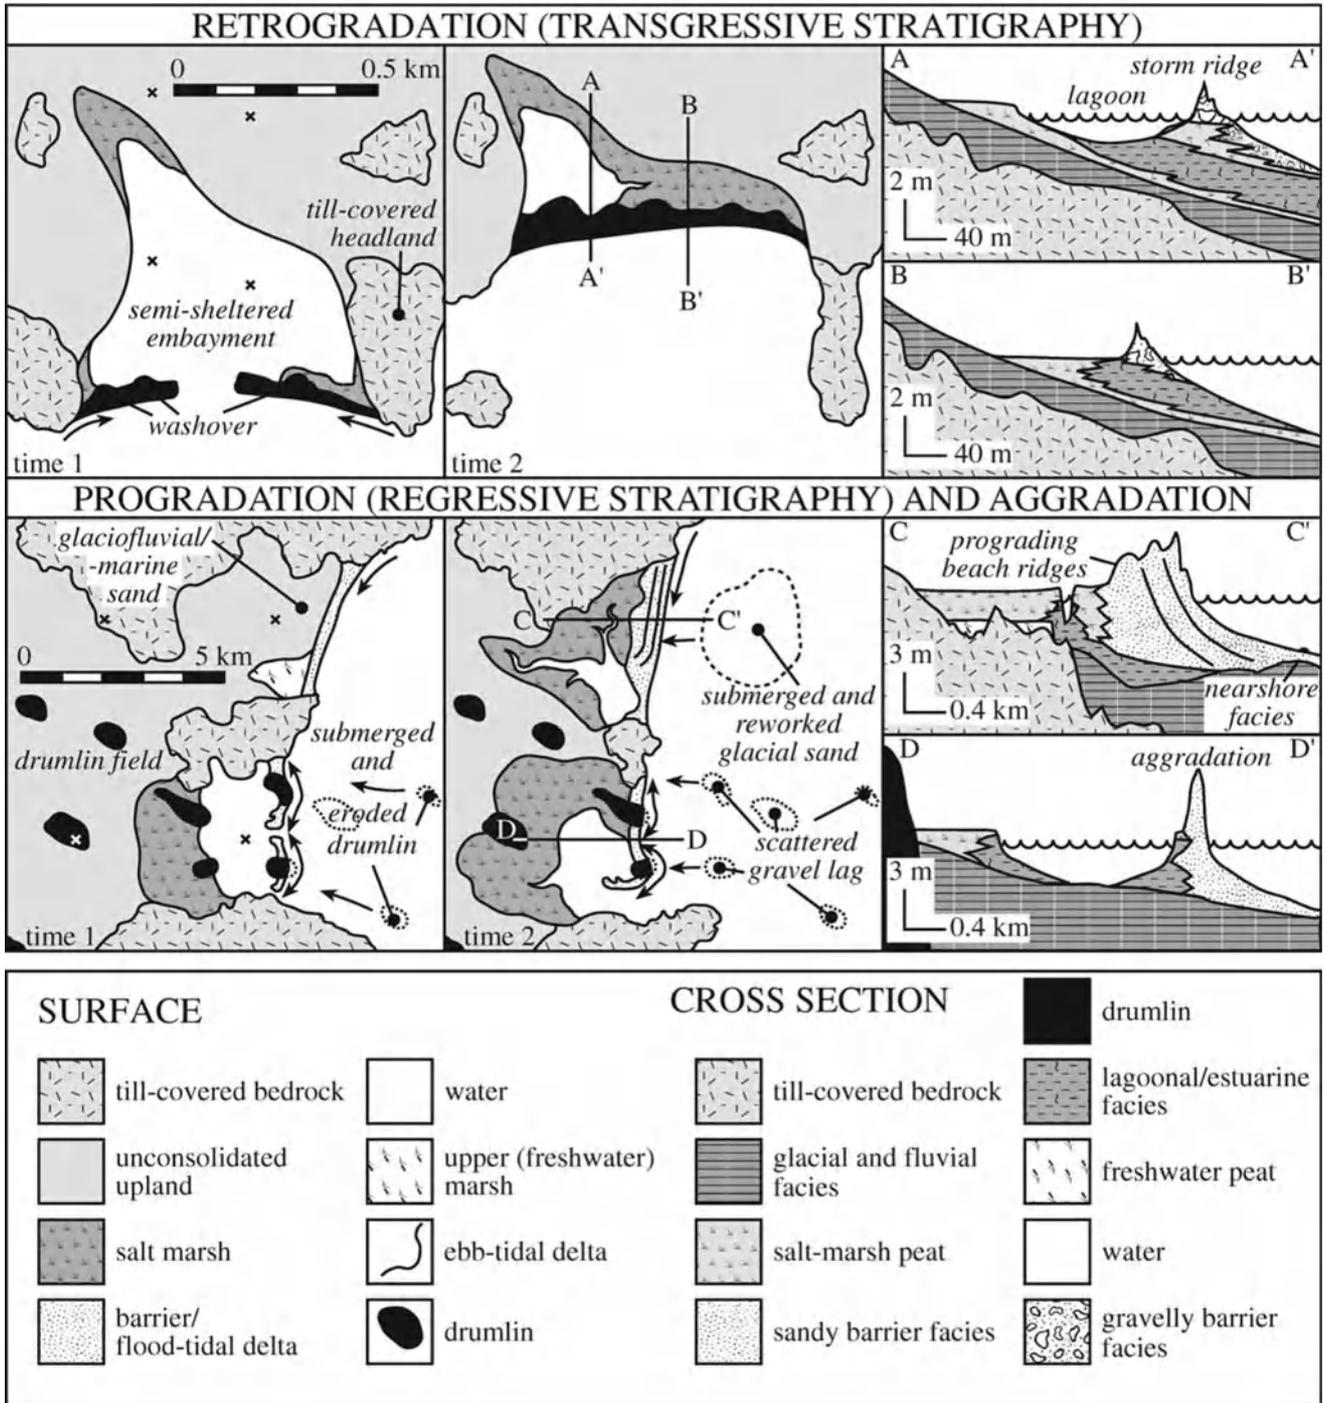

Figure B6 Barrier island stratigraphies as a function of different evolutionary styles (modified from FitzGerald and van Heteren, 1999).

sedimentary components comprising these environments (lagoonal muds, marsh peats, upland tree stumps) are commonly exposed along the front side of the barrier, usually in the intertidal zone.

If a barrier has built vertically through time in a regime of rising sea level and occupies approximately the same footprint

as it did when it first formed or stabilized, it is termed an *aggrading* barrier. These barriers are rare because it requires that the rate of sediment supply to the barrier exactly compensates for rising sea level. Too little sand and the barrier migrates onshore (retrograding) whereas too large a supply and the barrier builds seaward. Without subsurface

information they are difficult to recognize, because morphologically they may appear similar to non-beach ridge, prograding barrier or even a retrograding barrier that has stopped moving onshore.

Barrier island stratigraphy

Barriers exhibit a variety of architectures consisting of many different types of sedimentary sequences depending upon their evolutionary development. The stratigraphy of a barrier is defined by a set of grain size, mineralogical, and other characteristics of the layers comprising the barrier deposit. Factors such as sediment supply, rate of sea-level rise, wave and tidal energy, climate, and topography of the land dictate how a barrier develops and its resulting stratigraphy. Another important factor affecting barrier thickness is accommodation space which defines how much room is available for the accumulation of barrier sands.

Barrier sequences often contain tidal inlet deposits, especially along barrier coasts where tidal inlets open and close and/or where tidal inlet migration is an active process (Reinson, 1984, 1992). A tidal inlet migrates by eroding the downdrift side of its channel while at the same time sand is added to the updrift side of its channel. In this way, the updrift barrier elongates, the downdrift barrier retreats, and the migrating inlet leaves behind channel fill deposits underlying the updrift barrier. Independent studies along New Jersey and the Delmarva Peninsula, North Carolina, and South Carolina indicate that 20 percent to 40 percent of these barrier coasts are underlain by tidal inlet fill deposits (Moslow and Heron, 1978).

Each morphosedimentary barrier type has a diagnostic stratigraphy that reflects the manner in which it developed (Figure B6). Prograding barriers typically exhibit *regressive* stratigraphy. Because this type of barrier builds in a seaward direction, the barrier sequence is commonly thick (10–20 m) and overlies offshore deposits, usually composed of fine-grained sands and silts (Bernard *et al.*, 1970). The barrier sequence consists of nearshore sands, overlain by beach deposits, and topped by dune sands. The contacts between the units are gradational and for the most part the sedimentary sequence coarsens upward except for the uppermost fine-grained dune sands. The retrograding barrier type migrates in a landward direction over the marsh and lagoon by overwash processes, resulting in a *transgressive* stratigraphic sequence (Kraft and John, 1979). The Holocene sequence typically bottoms in lagoonal muds, however, if the barrier has retreated far enough landward, mainland deposits may be preserved forming the base of the sequence. In these instances, we may find tree stumps, soils, and other deposits. The mainland units are overlain by backbarrier sediments including a variety of units such as lagoonal silts and clays and marsh peats which had formed in intertidal areas. In the vicinity of tidal inlets, backbarrier deposits consist of channel and flood-tidal delta sands. Overlying the backbarrier deposits is the thin barrier sequence (<3 m to 4 m) consisting of washovers, beach deposits, and dune sediments if they are present. Aggrading barriers build upward in a regime of rising sea level and in an ideal case, the deposits from the same environmental setting are stacked vertically. In most cases, however, the barrier has shifted slightly landward and seaward through time due to changes in sediment supply and rates of sea-level rise. Therefore, most aggrading barriers exhibit some interstacking of various units. For example, in the rear of the barrier the

sequence may consist of washover and dune units inter-layered with marsh and lagoonal deposits. Aggrading barriers tend to be thick (10 m to 20 m) and for reasons stated previously, are uncommon.

BAUXITE

Introduction

Bauxite is found in many parts of the world, but more particularly in tropical areas. Bauxite is of supergene origin commonly produced by weathering and leaching of silica from aluminum bearing rocks. Bauxite may occur *in situ* as a direct result of weathering or it may be transported and deposited in sedimentary formation. Gibbsite $[\text{Al}(\text{OH})_3]$, boehmite and diaspore $[\text{AlO}(\text{OH})]$ are the three principal hydrates of aluminum and form the main constituents of bauxite and laterites with gibbsite often being the predominant mineral. Gibbsite or hydrargillite, bayerite and nordstrandite are all polytypes of aluminum trihydroxide. Diaspore is a dimorph of boehmite. Australian soils often contain gibbsite, particularly in the soils of hot humid climates where the topography is suitable for its accumulation as occurs in Northern Queensland. Gibbsite often occurs in association with kaolinite as exemplified by the Weipa deposits of North Queensland (Wilke and Schwertmann, 1977). Gibbsite is the end product of granitic weathering and is formed from the diagenetic sequence: plagioclase \Rightarrow amorphous or allophanic minerals \Rightarrow kaolinite \Rightarrow gibbsite. Such a sequence shows why the impurity in gibbsites is often kaolinite. Australian bauxites are predominantly composed of mixtures of gibbsite and boehmite with no diaspore. Impurities include hematite, kaolinite, quartz, and other derived minerals. The Weipa bauxite composition varies from 70 percent to 95 percent gibbsite and from 25 percent to 5 percent boehmite.

Thermal transformations

Bauxites are a complex admixture of minerals with a number of alumina phases present in any mix. Figure B7 summarizes the

thermal transformations of the components of bauxite. These transformations are dependent upon the particle size, the rate of heating and the vapor pressure above the bauxite. In principle if gibbsite is heated it alters structure to form Chi-alumina, then kappa-alumina and at temperatures above 1100°C alpha-alumina. Boehmite on the other hand transforms to gamma-, delta-, theta- and then alpha-alumina. Bayerite, which is not commonly found in bauxites either, transforms to boehmite or to eta-alumina. Diaspore transforms directly to alpha-alumina. Such complex phase relations affect the way in which bauxite is processed for aluminum production.

Thermal analysis

The thermal transformations of the bauxitic minerals may be studied by a number of techniques including thermal analysis. The use of thermal techniques to study the dehydration and dehydroxylation of bauxite has been widely documented (Lodding, 1969). It is clear that many variables must be taken into account when using techniques such as DTA, DSC, TGA, CRTA and quasi-isothermal TGA and isobaric TGA (Frost *et al.*, 1999a,b,c; Ruan *et al.*, 2001a,b). Such variables include heating rate, external pressure, water vapor pressure, sample particle size and even thickness of sample size in the DTA crucible (Paulik *et al.*, 1983; Naumann *et al.*, 1983). Figure B8 illustrates the thermal analysis patterns of gibbsite bauxites. It has been shown that boehmite and gamma-alumina were formed under the dehydration of gibbsite. The initial step in the thermal decomposition of gibbsite is the diffusion of protons and the reaction with hydroxyl ions to form water (Frost *et al.*, 1999a). This process removes the binding forces between the layers of the gibbsite structure and causes changes in the chemical composition and density within the layers. Published DTA patterns of a coarse-grained gibbsite show an endotherm centered on 230°C followed by a second at 280°C (Frost *et al.*, 1999a,b,c). This latter endotherm is attributed to

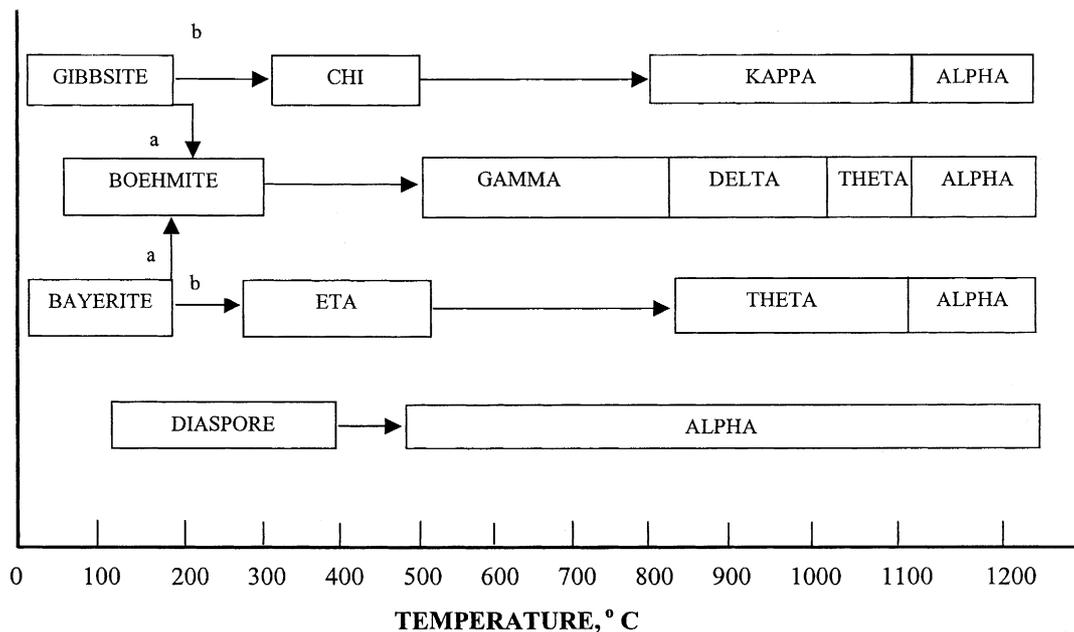

Figure B7 Relationship between the oxo(hydroxy) phases of aluminium.

the formation of boehmite by hydrothermal conditions due to the retardation diffusion of water out of the larger grains. This exothermic reaction does not occur in the DTA patterns of finely grained gibbsite. A shallow endotherm may be observed between 500°C and 550°C and is attributed to the formation of boehmite. There is general agreement that boehmite and a disordered transition alumina are formed upon the thermal treatment of coarse gibbsite up to 400°C. When fine-grained gibbsite is heated rapidly, an X-ray amorphous product labeled rho-alumina is obtained.

Spectroscopic characterization of bauxites

One valuable suite of techniques that are suited for the characterization of bauxites are based upon vibrational spectroscopic techniques. These techniques include those of infrared including near-IR (NIR), far-IR, DRIFT spectroscopic techniques. Raman spectroscopy is also useful in the characterization of the bauxitic phases.

Raman spectroscopy

Raman spectroscopy has the advantage that it is a scattering technique, does not require sample preparation and is not sensitive to the presence of water. The Raman spectrum of gibbsite shows four strong, sharp bands at 3617, 3522, 3433 and 3364 cm^{-1} . The spectrum of bayerite shows seven bands at 3664, 3652, 3552, 3542, 3450, 3438, and 3420 cm^{-1} in the hydroxyl-stretching region. Five broad bands at 3445, 3363, 3226, 3119, and 2936 cm^{-1} and four broad and weak bands at 3371, 3220, 3085, and 2989 cm^{-1} are present in the Raman spectrum of the hydroxyl-stretching region of diaspore and boehmite, respectively. The hydroxyl-stretching bands are related to the surface structure of the minerals. The Raman spectra of bayerite, gibbsite, and diaspore are complex while the Raman spectrum of boehmite only shows four bands in the low wavenumber region. These bands are assigned to deformation and translational modes of the alumina phases. A comparison of the Raman spectrum of bauxite with those of boehmite and gibbsite shows the possibility of using Raman spectroscopy for online processing of bauxites.

Near infrared spectroscopy

Another most useful technique for studying bauxites and their phase components is the reflectance technique of NIR spectroscopy. NIR is known as the spectroscopy of protons as so as a consequence all phases containing water or hydroxyl units can be measured by NIR. This means that NIR is also most useful in the online processing of bauxites. Figure B9 displays the first overtone of the fundamental vibrations of the hydroxyl stretching vibrations.

NIR spectroscopy distinguishes between alumina oxo and hydroxy phases. Two NIR spectral regions are identified for this function: (a) the high frequency region between 6400 cm^{-1} and 7400 cm^{-1} , attributed to the first overtone of the hydroxyl stretching mode, and (b) the 4000–4800 cm^{-1} region attributed to the combination of the stretching and deformation modes of the AIOH units. NIR spectroscopy allows the study and differentiation of the hydroxy and oxo(hydroxy) alumina phases, since each phase has its own characteristic spectrum. The spectrum of bayerite resembles that of gibbsite whereas the spectrum of boehmite is similar to that of diaspore. Bayerite has four characteristic NIR bands at 7218, 7128, 6996, and 6895 cm^{-1} . Gibbsite shows five major bands at 7151, 7052, 6958, 6898, and 6845 cm^{-1} . Boehmite displays three NIR bands at 7152, 7065, and 6960 cm^{-1} . Diaspore shows a prominent band at around 7176 cm^{-1} . The use of NIR reflectance spectroscopy to study alumina surfaces has wide application, particularly with thin films and surfaces. The technique is rapid and accurate. NIR, because of its sensitivity can be used in reflectance mode for the on-line processing of bauxitic minerals.

Infrared emission spectroscopy

Details of the experimental part of infrared emission spectroscopy have been detailed in a number of publications (Frost *et al.*, 1999a,b,c). The emission spectra were collected at intervals of 50°C over the range 200–750°C. The time between scans (while the temperature was raised to the next hold point) was approximately 100 seconds. It was considered that this was sufficient time for the heating block and the powdered

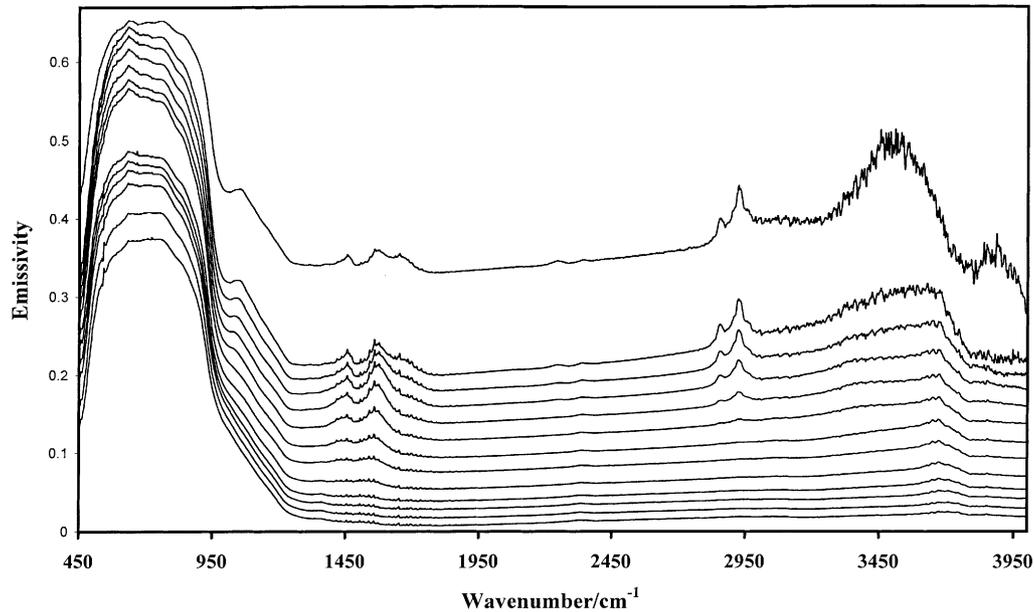

Figure B11 Infrared emission spectra of Weipa bauxite.

sample to reach temperature equilibrium. The spectra were acquired by coaddition of 64 scans for the whole temperature range (approximate scanning time 45 seconds), with a nominal resolution of 4 cm^{-1} . Good quality spectra can be obtained providing the sample thickness is not too large. If too large a sample is used then the spectra become difficult to interpret because of the presence of combination and overtone bands. Figure B11 displays a series of infrared emission spectra for a Weipa bauxite. The spectra clearly show the temperature at which the bauxite dehydrates and dehydroxylates. Phase changes may be observed through the loss of intensity in the OH deformation band at around 1020 cm^{-1} .

Summary

Modern techniques of analysis including NIR, infrared emission and Raman spectroscopy enable on-line and *in situ* studies of bauxites and its components to be studied. When these spectroscopic techniques are combined with modern thermal analysis, new and essential information to the understanding of bauxites is obtained. Such information is critical to aluminum processing. Normally the bauxite is dissolved in hot caustic at 100°C . In such processing the gibbsite component of the bauxite dissolves but not the boehmite and other components. To dissolve the boehmite, higher temperatures and pressures are required. It is useful to modify the bauxite surfaces to enhance this dissolution.

BEACHROCK

Beachrock is a sedimentary rock that results from rapid lithification of sand and/or gravel by calcium carbonate

cements in the intertidal zone. It occurs predominantly on tropical coasts, but is also found as far north and south as 60° latitude. In contrast to the implications of the name, beachrock outcrops are not restricted to beaches but some are found on tidal flats, in tidal channels, and on reef ridges. To date the origin of beachrock is not fully understood having been variously attributed to physicochemical precipitation, biologically induced cementation, or a combination of both.

Occurrence, composition, texture, and cements

Beachrock exposures are typically patchy with bedded layers that dip gently (<10°) toward the sea. Hopley (1986) suggested that the largely intertidal occurrence of beachrock makes its fossil occurrence a potential indicator of sea level. Problems with this approach include possible failure to recognize other deposits that might get cemented close to sea level such as dune calcarenite, eolianite, or cay sandstone (carbonate sand cemented by calcium carbonate from fresh water above high tide level on reef islands), especially when diagenetic environments frequently changed, and the fact that radiometric dating of beachrock can only produce an average age of the constituent particles and cements.

The composition of beachrock constituent particles is more or less similar to that of the adjacent consolidated sediment. Grain-size ranges from sand to gravel: sediments are moderate to very well sorted, with sorting usually better than that of the adjacent subtidal sediments.

Beachrock cements are dominated by aragonite and high-magnesium calcite. The aragonite cement includes isopachous fringes of needles that are up to 100 µm long, and often overlie a dark layer at their base that consists of aragonite platelets rich in iron and sulfur (Strasser *et al.*, 1989). Small aragonite (<10 µm long) needles may form "micritic" cement (e.g., Webb *et al.*, 1999). High-magnesium calcite cements often include microcrystalline ("micritic") cement with crystals less than 5 µm in diameter. Less common are cement fringes of high-magnesium calcite blades or scalenohedral crystals (up to 70 µm long). Peloidal cements with approximately 40 µm diameter peloids, and equant crystal crusts of high-magnesium calcite also occasionally occur. Cements indicative of the vadose diagenetic environment are encountered rarely and these result from cementation in the wave spray zone or during low tide exposure. In this case, typical meniscus or gravitational ("dripstone") cement fabrics are common. Detailed descriptions of beachrock cements are provided in Bricker (1971: 1–43), Moore (1973), Meyers (1987), Strasser *et al.* (1989), and Gischler and Lomando (1997) among others. Scoffin and Stoddart (1983) provided a comprehensive review on beachrock and intertidal cementation up to that time.

Origin

Early 19th century reports on beachrock confirm its rapid formation in the intertidal zone (e.g., Moresby, 1835). For example, natives to Indo-Pacific islands were known to harvest beachrock for building stone where new occurrences formed on the same beach within less than a year. High resolution radiometric dating of cements in coral reef slopes have shown that marine aragonite cements, comparable to those observed in beachrock, reach growth rates of 80–100 µm per year (Grammer *et al.*, 1993).

The mechanisms used to explain beachrock cementation include both physicochemical and biologically induced precipitation of calcium carbonate. Physicochemical models explain precipitation of carbonate cement by evaporation of seawater during low tide (e.g., Ginsburg, 1953; Hanor, 1978), and by degassing of CO₂ during falling tides (Meyers, 1987) or during higher tides (Pigott and Trumbly, 1985). Apart from CO₂ pore water saturation states, water agitation is probably another important factor in beachrock formation. A large scale study on Belize beachrock showed that the vast majority of beachrock exposures occurred on windward beaches of reef islands, suggesting that beachrock cementation only occurred where beaches experienced intensive and persistent flushing by seawater (Gischler and Lomando, 1997). Variations in pore water pressure during pumping of seawater through the beach may also lead to calcium carbonate precipitation. Beachrock formation in Grand Cayman island was interpreted by Moore (1973) to be largely a product of cementation under mixed meteoric-marine conditions. In contrast, Hanor (1978) used thermodynamic calculations to show that precipitation of beachrock cement cannot be induced by mixing of marine and meteoric water. Rather, these calculations favor CO₂ degassing as a means of supersaturating pore-water with calcium carbonate to the point of inducing cement precipitation.

There is also evidence suggesting the importance of biological processes in beachrock formation. Algal coatings may form on the beach, and stabilize grains so that they can be preferentially cemented (Davies and Kinsey, 1973). Withdrawal of CO₂ by photosynthesis may furthermore induce calcium carbonate precipitation. Krumbein (1979) noted the occurrence of high concentrations of organic matter during initial stages of beachrock formation in the Gulf of Aqaba and suggested that anaerobic and later aerobic decay processes were responsible for cement precipitation. Decay processes may include ammonification leading to higher pH, or sulfate reduction that elevates alkalinity, or hydrolysis of urea forming ammonium carbonate and eventually calcium carbonate. Further suggestions of a biological influence on beachrock formation are provided by Webb *et al.* (1999). These workers found microbial filaments in both beachrock cement and microbialites within beachrock cavities on Heron Island, Great Barrier Reef. They stressed the importance of acid organic macromolecules with Ca²⁺ binding carboxyl groups in biofilms in forming nucleation zones for cements. The common dark zones at the base of isopachous fringes of acicular aragonite beachrock cement may reflect the occurrence of organic mucus (Davies and Kinsey, 1973). According to the SEM study of Chafetz (1986), nuclei of marine peloids, which may also form beachrock cement, are composed of bacterial clumps.

Open questions remain with regard to the formation of beachrock. If physicochemical (inorganic) processes are sufficient to induce calcium carbonate cementation, why are beachrock outcrops so patchy in distribution, even on the windward beaches of reef islands? The same patchy distribution argues against organic processes as a pre-requisite for precipitation of CaCO₃ cement, unless and until it can be shown that specific organic processes are peculiar to beachrock formation and therefore are not ubiquitous in occurrence as is the presence of microbes. It would seem that aspects of both inorganic and organic processes have to be taken into account to explain the origin of beachrock. To date,

however, exclusively inorganic or exclusively organic models do not suffice to explain the distribution of intertidal marine cementation.

There are only very few reports on fossil, pre-Holocene occurrences of beachrock, which probably is to a large extent a consequence of its poor preservation potential. As soon as beachrock is exposed it becomes subject of intensive intertidal erosion, so only in cases of rapid burial would beachrock outcrops be preserved.

BEDDING AND INTERNAL STRUCTURES

Bedding

Bedding is the arrangement of sedimentary rocks in beds or layers of varying thickness and character. A bed (or stratum) is a relatively conformable succession of genetically related laminae or lamina-sets (Campbell, 1967) bounded by surfaces (called bedding surfaces) of erosion, nondeposition, or their correlative conformities.

The *bed* is the smallest formal lithostratigraphic unit of formal *stratigraphy*, and as such is defined solely on the basis of its lithology, including color, grain size, and thickness. A bed may range in thickness from a few millimeters to over 10 m. A key bed (or key horizon) is a well-defined, easily identifiable stratum or body of strata that can be easily distinguished from the overlying and underlying strata by sufficiently distinctive characteristics, such as lithology, thickness, texture or fossil content and their lateral gradients. These allow physical tracing and stratigraphic correlation of the key bed over long distances, up to several tens of km.

In *sedimentology*, the bed has a different, genetic connotation: in other words, it represents a distinctive depositional event, related to some processes or mechanisms of deposition. In this meaning, a bed may show a change of lithology from bottom to top, for example, from sand(stone) to mud(stone); this is the case for most turbidites, storm layers (tempestites), crevasse deposits, etc.

There exists a hierarchy of bedding in terms of scale, geometry and spatial relationships of physical surfaces. This hierarchy defines units of different rank, ranging from the individual lamina to the basin-fill complex, and temporally spans over a wide range of timescales (from 10⁻⁶ years to 10⁷ years). Not always is the hierarchical arrangement recognizable, especially where the main bedding surfaces (*master bedding*) are obscured by superposition of lower-rank surfaces. In this case, individual beds cannot be clearly identified and counted, and only the bedding style, or pattern, is described (e.g., cross-bedding, sand/mud interbedding, clinofolds, etc.), with a rough specification of scale (small, medium, large).

The *lamina* is the smallest sedimentation unit and is characterized more by being a part of a bed than by its thickness, although most laminae are in the submillimeter to centimeter range. A single set of conformable laminae (laminaset) may form a bed (solitary set and form-set of J.R.L. Allen) or be a part of it: it can be associated either with other laminasets in a wholly *laminated bed* or with structureless (massive, graded) portions in a partly laminated bed (see below, Bouma sequence). There exist also entirely structureless beds, which can be either emplaced by mass flows or have their original structures destroyed by bioturbation or liquefaction after deposition.

Bed packets or bundles distinct from those above and below in a stratigraphic succession are called bedsets by Campbell (1967); within a bedset, there can be a dominant facies (i.e., all beds are similar in terms of lithology, thickness, texture, structures) or a systematic vertical change corresponding to a *facies sequence* (coarsening- or fining-up, thickening- or thinning-up, etc.). Bedsets are delimited by set boundaries and form *sedimentary bodies* of simple or composite character.

Repetitive bedsets can be grouped in cosets separated by coset boundaries (base of the lowest set and top of the youngest).

The spatial arrangement of individual component bodies in a complex body is called *stacking pattern* or *architecture* (Miall, 1985). The term architecture is also applied to the *internal organization* of an individual body showing a hierarchy of volumes and surfaces: in this case, an *architectural element* is defined at each level of organization or rank. All such elements have a *facies* connotation, but the term *facies* is too often used quite loosely because there is a lack of agreed-upon rules; for the sake of clarity and communication, it is advisable to specify at which rank the *facies* is defined, this being left to the choice of the operator. After that, all smaller scale elements will be *sub-facies*, all larger scale elements will be *facies associations*. An example of *facies* can be a trough cross-bedded sand(stone), representing bar crest deposits in a deltaic depositional system. An example of *facies association* is a mouth bar, for example, including bar back, bar crest, bar front and distal bar *facies*.

When a *facies association* shows some kind of vertical order, it is usually called a *facies sequence*. Lateral *facies* changes are much less documented due to lack of sufficiently long exposures; lateral transitions are rather inferred than observed, with some notable exceptions (see *Facies Tracts* by Mutti, 1992).

Beds, bedsets, architectural elements, *facies*, *facies associations*, and stacking patterns are all three-dimensional units, but for most practical purposes they can be recognized (or at least inferred) and described in two (cross-sections), and even in one (vertical profiles, well logs). The hierarchical classification of depositional units and architectural scale concepts are thus useful for basin analysis and the petroleum industry, since reservoir geometry and internal heterogeneity may involve different ranks and physical scales.

Internal structures

These are sedimentary structures located within beds or layers and observable on surfaces cut at high angles to bedding planes, that is, in normal stratigraphic sections. In clastic deposits, most internal structures are physical, or purely mechanical in origin, with the exception of trace fossils and bioturbation (bio-mechanical). In carbonates, evaporites, cherts and other sedimentary rocks of chemical and biochemical origin, a color-compositional differentiation (e.g., color banding) or peculiar structures (e.g., stromatolites, birds eyes, structures related to crystal growth or dissolution) can be observed, but a detailed description of them is not given here (see *Diagenetic Structures*). Attention will be focused here on mechanical structures. They are subdivided into two main groups: those produced by transportation and deposition, and those resulting from deformation soon after deposition (soft-sediment deformation as contrasted with tectonic or structural deformation).

Structures related to transportation processes

Most of these structures consist in geometrical arrangements of laminae or kinds of *lamination*, and occur in sands and sandstones; they are also called *tractive structures*, traction referring to bed-load movement of sedimentary particles. Lamination can also be found in silty sediments, in which case resulting from differential settling from suspensions. Laminated or structureless mud(stone) can be associated in

alternating patterns with sand(stone); *draping* indicates a thin muddy cover, laterally continuous or discontinuous, on sand beds or an irregular topography. When traction is simultaneous with settling of silt and sand (which is put in suspension by highly turbulent flows, such as turbidity currents), *traction-plus-fallout* lamination forms (Jopling and Walker, 1968).

Local erosion is involved in the formation of tractive structures, producing truncation surfaces and discordances of various geometry and scale; some of them can be used for the hierarchical differentiation of bedding. Tractive structures may form when a current is in equilibrium (no net erosion or deposition) with its lower boundary (sedimentary interface), or in conditions of net deposition due to loss of carrying capacity. In the former case, the result is a diastem or a single, thin bed (solitary set, form-set with bedforms preserved on top: Allen) of tractive laminae due to either a fresh sand supply or *in situ* reworking of preexisting sand. Net deposition implies a higher preservation potential of laminated intervals, even if the flow is oscillating and some erosion is produced; continuous feeding of sand to the bottom not only buries previously deposited laminae, but can build up decimeters or even meters of laminated sediment (see the "Contessa" bed and other similar "megaturbidites" in the Apennines of Italy).

Unidirectional flows

Tractive currents produce bedforms of various scales: small (ripples), medium (subaqueous dunes), large (eolian dunes, subaqueous bars and sandwaves). A set thickness of 4–5 cm separates ripple from dune scale but no agreement exists for a boundary between medium and large structures. Bedforms can be extremely shallow or the bottom even and flat when the Froude number is in excess of or near unity. One can thus distinguish subcritical (lower flow regime) from supercritical tractive structures, and the distinction is applicable even at a small scale (e.g., core examination), because subcritical forms have a separation zone at their lee side, where gravity avalanching takes place developing *foreset laminae* inclined at the angle of repose of the sand (up to 30°–35°). Strata therefore exhibit, in sections cut at a small angle with the flow direction, *high angle lamination* with respect to their bedding planes. No flow separation, and hence *low angle lamination* (<10°) characterizes supercritical bedforms. Low angle laminae are not reliable indicators of current direction, whereas *foreset laminae* are.

In case of a flat bottom, horizontal or *plane-parallel lamination* occurs. A bed can part along weaker laminae showing *parting lineation* (or primary current lineation), that is, slightly terraced, shallow ridges formed by strips of sand grains aligned parallel to the flow. They are present also on low amplitude bedforms of upper flow regime, such as antidunes and humpback dunes.

At outcrop scale, the terms cross-bedding, cross-stratification and cross-lamination are used when laminasets are bound by nonparallel, intersecting surfaces; cross-bedding is the net result of local deposition and erosion related to the migration of bedforms (those of small and medium size are more commonly represented in subaqueous deposits).

Cross-bedding should be qualified by specifications, for example: (a) laminaset thickness as a scale indicator; (b) presence or absence of *foreset* (high-angle) laminae, which means lower or upper flow regime; (c) relation with master bedding or other evidence of an original flat bottom;

(d) morphology of set boundaries (erosional vs non-erosional; tabular vs concave or trough). Such characters can help, for instance, to distinguish subaqueous from eolian deposits (the latter show thick to very thick beds and lack ripple scale lamination) or bedforms grown on flat bottoms from those topping larger forms, such as ripples on dunes or dunes on sandwaves (typical of bars and sandwaves is the hierarchical organization in cross-bedded sets).

Backset laminae (dipping opposite to the flow) can form on the stoss side of so-called regressive antidunes (Allen, 1982), but are not usually preserved; the few examples reported in the literature for ancient deposits, especially turbidites, have been reinterpreted as regular foreset laminae left by inverted or reflected flows. Only in pyroclastic strata, in particular those deposited by turbulent surge flows, are backset laminae commonly found (Allen, 1982, figures 10–15), probably owing to the peculiar conditions (temperature/moisture, density contrast between solid particles and fluid). In general, tractive lamination is beautifully preserved in these deposits, and foreset laminae inclined at 20° or less can be observed in dune-like or dunoid (Ricci Lucchi, 1995a) bedforms. *Counter-flow ripples* are sometimes seen at the toe of large subaqueous structures, for example, tidal sandwaves; they are the product of recirculation in separation bubbles.

Sets and cosets of cross-laminae can show a *climbing* attitude of the corresponding bedforms (more commonly ripples, but also subaqueous dunes), with a variable angle of climb indicated by the stoss sides. This is a clear evidence of traction combined with fallout, and the cross-bedding style has been called *ripple-drift cross-lamination* (Jopling and Walker, 1968); three varieties (types A, B, and C) have been distinguished on the basis of relative amounts of erosion and deposition on the two sides of the bedforms. Climbing cross-bedding normally derives from decaying currents and shows bedform profiles preserved by a mud cover.

Low angle laminae occur in sets usually separated by low angle erosional surfaces, both planar and curved; resulting laminasets are wedge-shaped to sigmoidal. It is not easy, especially in limited outcrops, to decide whether they are related to a current, an oscillatory motion or a combination of the two (see below). Low angle lamination has been described in “proximal” sandy turbidites (Mutti and Ricci-Lucchi, 1972, facies B) and fluvial deposits (couplets of planar laminated sand and gravel are a common feature of sheetflood deposits within alluvial plain/alluvial fan depositional systems).

Oscillatory and combined flows

Two kinds of “short term” (non-geological) periodicity are recorded in sediments, that of wind waves and that of tidal waves.

Wind-generated waves may form within any body of water and exert traction below a critical depth referred to as the wave base. Wave orbits increase their ellipticity toward the bottom, where they culminate as straight lines representing to-and-fro motion. This motion results in grain movement by rolling and saltation on an initially plane sand bottom. Wave-formed ripples vary greatly in size, with h (height) commonly ranging between 0.003 m and 0.25 m, and λ (wavelength) between 0.009 m and 2 m. Their ripple index varies between 4 and 13.

Wave ripples are characterized by a symmetrical profile near wave base and tend to become more asymmetrical approaching the shoreline (steeper side facing landward). In

2D-sections, they display diagnostic internal features, such as inconsistency between ripple morphology and internal structure, structural dissimilarity between adjacent sets, presence of chevron and bundled upbuildings of foreset laminae, and irregular and undulating lower set boundaries (wave-truncated ripples of Campbell, 1967; de Raaf *et al.*, 1977). In plan view, wave ripples display straight to slightly sinuous crests, with characteristic bifurcations, that are uncommon in current ripples. Wave ripples are typically found within lower shoreface sands, but have also high preservation potential in shallow-water environments affected by oscillatory waves, such as lagoons and large lakes.

In intertidal environments, partial erosion of wave ripples at low tide conditions results in characteristic truncation of their tops. Actually, in very shallow water depths (foreshore deposits, swash/backwash zone) upper flow regime conditions prevail and planar surfaces, both erosional and depositional, are the dominant feature. Foreshore sands are thus characterized by the stacking of gently seaward-dipping sets of parallel laminated sand, formed during fair-weather conditions, separated by erosional surfaces related to storm events (wedge-shaped, low-angle cross-stratification).

While wave ripples are generated by fair-weather waves, storm waves tend to produce a structure of similar or greater size, called *hummocky cross-stratification* (HCS) by Harms *et al.*, (1975). More precisely, HCS is interpreted as the result of combined, waning unidirectional and oscillatory flows, but anyway a diagnostic feature of storm-dominated processes. Recently, however, sedimentary structures very similar to HCS have also been observed to characterize flood-dominated fan delta and river delta systems (Mutti *et al.*, 1996).

HCS consists of convex-up, large amplitude (1–5 m) and low-relief (10–50 cm), irregular domal features (hummocks), separated by broad troughs (swales). Gently undulating (5–15°) lamination is the most common internal feature, displaying a general concordance with the basal erosion surfaces and systematic lateral variations of laminae thickness (pinching and swelling of individual laminae). Where concave-up sets are well preserved, swaley cross-stratification (SCS) is developed (Leckie and Walker, 1982). HCS is generally restricted to coarse silt to fine sand, and is particularly abundant within lower shoreface deposits, in association with symmetrical wave ripples. SCS may be abundant in shallower (upper shoreface) and coarser grained deposits. Storm events in the offshore-transition area, above storm wave base, characteristically develop idealized sequences (Dott and Bourgeois, 1982) that rest on scoured surfaces, passing upward into HCS, and capped by flat lamination and symmetrical ripples at top of the sandy layers. The sequences are capped by bioturbated mudstone intervals.

In flood-generated delta-front sandstone lobes, large-scale HCS is developed within 3–15 m thick sandstone packets, separated by highly fossiliferous and bioturbated muddier deposits.

Tidal structures and bedding

Tidal currents regularly change direction from the flood tide current, which flows landward between the low and high tide, and the ebb tide current, which flows in the opposite direction as the water level returns to low tide. Bipolar cross-bedding, forming the characteristic herringbone cross-stratification, is the typical, expression of alternating tidal currents in

high-energy, subtidal settings. Herringbone cross-stratification, however, is not very common in the rock record, because of the fact that one half of the current generally is much stronger than the other, and ebb and flood currents may follow different paths. Bedforms migrating in one direction, under the influence of the dominant current, can be only slightly modified by the subordinate current. Diurnal changes in bedform migration controlled by asymmetrical tidal currents may thus result in discrete sets of unidirectional cross-strata (sand foresets form on the lee side of large bedforms), separated by gently sloping erosion surfaces, which are termed *reactivation surfaces*. This pattern of alternating unidirectional cross beds and reactivation surfaces is characteristic of large, linear bedforms (sand waves), with wavelengths of tens to hundreds of meters and heights exceeding 10 m, which are commonly observed in open-shelf environments.

Regular changes in magnitude and direction of tidal currents over the tidal cycle allow transport and deposition of sand at some stages and fallout of mud from suspension during periods of slack waters. Tidal structures resulting from this rhythmic alternation of traction and fallout processes are termed tidal rhythmites (Tessier, 1993) and generally characterize intertidal flats. Tidal rhythmites include sand layers, showing small-scale current ripples, alternating with mud drapes, reflecting deposition during stillstand phases.

Distinctive sedimentary structures of intertidal flat environments include flaser bedding, wavy bedding and lenticular bedding (Reineck and Wunderlich, 1968). *Flaser bedding* (see *Flaser*) is characterized by isolated thin drapes of mud amongst a cross-laminated sandy unit. In contrast, lenticular bedding is made up of isolated sand ripples within a mud-dominated deposit. Wavy bedding is intermediate between the two, consisting of approximately equal proportion of sand and mud.

In higher-energy, subtidal settings, a characteristic feature of tidal sedimentation at the scale of diurnal, ebb-flood tidal cycles is double mud drapes, formed during the two slack water stages of the tidal cycle. Double mud drapes, commonly a few mm thick, typically separate unidirectional, bipolar cross beds showing current reversals. These diagnostic tidal structures, forming a characteristic sigmoidal stratification, are referred to as *tidal bundles* (Visser, 1980), and are commonly developed in subtidal (estuarine) channels. In intertidal settings, the *tidal bundles* include just one mud drape. Cyclic variations in strength of tidal currents at the scale of neap-spring cycles result in cyclic variations in thickness of tidal bundles, forming characteristic tidal bundle sequences (Yang and Nio, 1985).

Internal structures in episodic (catastrophic) deposits

Episodic events include tsunami waves, seismic shocks, violent hurricanes, catastrophic flash floods, and sediment gravity-flows. Resulting beds are lenticular to tabular and internally disorganized (random arrangement of particles) to organized. Organization means size grading (graded bedding), grading in the lower part plus lamination in the upper portion of sandstone, or thoroughly laminated sandstone. Beds are commonly capped by mud, but can be separated by erosion surfaces ("amalgamated"). The different parts of organized beds are called *intervals* or *divisions*.

Gravity flows are moving dispersions (mixtures of solid particles and water) classified on the basis of the different

proportions of the two phases and the grain-support mechanisms. Following Middleton, Lowe, Postma and Mutti (see Mutti, 1992, for references), different flow types can be identified. In cohesive debris flows, the fluid has pseudoplastic characteristics and grain transport is a result of matrix strength, which is in many instances adequate to support large boulders. Coarser grains move to regions of lower shear, and are rafted on the top or edge of flow, resulting in inverse grading. In grain flows, shear stress is transmitted through the flow by a dispersive pressure resulting from intergranular collisions. Frictional freezing, which occurs when the applied shear can no longer overcome the flow strength, is the dominant depositional mechanism from both cohesive debris flows and grain flows.

Debris flow deposits are characteristically very poorly sorted and lack almost any internal structure (the preponderance of plug flow hampers the development of shear fabric or sorting). When large clasts are present, they are randomly distributed (the bed has a chaotic aspect) or concentrated near the top, locally protruding. A rough development of inverse grading can thus be observed throughout the bed or at the base, combined with lack of significant basal scours.

Debris flows show marked downslope transformations, as they decelerate and mix with ambient waters; such transformations are reflected in internal fabric and structures. A high-density, inertia-driven mixture of sediment and water that moves downslope under conditions of high pore-fluid pressure is termed *hyperconcentrated flow*. The typical structureless debris flow deposits may thus be replaced in a downcurrent direction by deposits from hyperconcentrated flows; these are characterized by deep basal scours, large rip-up mudstone clasts, a coarser grained matrix, and tendency of larger clasts to concentrate in the lower part of the bed. Deposits from hyperconcentrated flows may also include evidence for tractional bedforms.

Traction carpets, resulting from a combination of fluid turbulence, hindered settling, and dispersive pressure produced by grain collision, may develop in the basal portion of high-density flows, and are a relatively common feature of grain flows. Traction carpets, which are commonly followed by *en-masse* deposition, display characteristic, inversely graded stratification bands and show upward transition to ungraded, crudely graded or well-graded beds.

At modest levels of sediment concentration, the flow is cohesionless and may be internally turbulent. In fluidized and liquefied flows, escaping pore fluid provides a full or partial supporting mechanism, respectively. In low-density turbidity currents, particles are supported by the flow turbulence, and sediment deposition occurs through grain settling and traction-plus-fallout processes. The typical pattern of grain size change within a bed which is formed from a decelerating flow is referred to as *normal grading*. Larger particles achieve a higher terminal velocity and settle out of suspension faster than smaller grains. Two types of grading have been distinguished in turbidites (Middleton, 1967): distribution and coarse-tail. The first type is shown by all size classes, the second one by coarser particles only. Grading may pass upward into, and/or be superimposed by, tractive lamination, as observed since the thirties of last century by geologists in the Apennines looking for way-up criteria in zone of vertical and overturned beds. Later Bouma (1962) formalized a vertical sequence of internal structures, the now familiar "Bouma sequence".

The *Bouma sequence* includes, from base to top: normally graded, structureless medium to fine sand, with frequent dewatering pipes and dish-and-pillar structures (division a); planar laminated to undulating fine sand, with parting lineations and inversely graded stratification (division b); small-scale cross-laminated very fine sand, with abundant climbing ripples (division c); current-laminated coarse silts and interlaminated silts and mud (division d). The succession is capped by a homogeneous and massive mudstone (division e), actually a pelitic bed or parting. The transition from thoroughly current-laminated sand to structureless mud is more or less gradual and marks the passage from traction-plus-fallout processes to pure grain settling from suspension. In more proximal turbidites, richer in sand, Lowe (1982) defined different varieties of structure sequences, but they seem to have a less universal application.

Sharp-based layers with distinctive internal fining-upward tendencies, being the expression of decelerating, waning turbulent flows, are not exclusive of submarine gravity flows, but may be commonly encountered in different depositional environments, such as lakes, river deltas (hyperpycnal plumes related to river floods) and shallow-marine realms (storm-generated currents).

Intraformational mud clasts, referred to usually as clay chips and a variety of other terms, and deriving from intrabasinal sources, are a common feature of debris flow, hyperconcentrated flow and structureless to graded portions of turbidity flow deposits. They are typically embedded in sand and occur: a) concentrated at or near the base of the bed; b) scattered throughout; c) aligned (and relatively sorted) in the uppermost structureless or graded sandstone, often at the transition with tractive laminae. These situations reflect different distances of travel within the flow and a marked tendency to buoyancy. This should be considered a fabric more than a structure; the same applies to *clast imbrication* (see *Imbrication*), showing in both massive and selective (e.g., beach) deposits. Flattened clasts are inclined to the horizontal, so that the plane formed by the long and intermediate axis of the clasts dips up-current, according to the most stable position. Imbrication represents a very useful paleocurrent indicator and is a characteristic feature of gravel-bed rivers and gravel beaches (where dip is seaward). It indicates a transport of pebbles in temporary, or intermittent, suspension.

Internal scours may be found in gravity flow and other episodic deposits, owing to flow pulsations or bottom irregularities during deposition; care should be taken, however, not to mistake such local features with parts of larger erosion or amalgamation surfaces separating distinct beds (events).

Internal structures and facies sequences

The “Bouma sequence” just described represents an example of a *genetic package*, or association, of structures, that is, a systematic vertical succession of structures consistent with a specific mechanism evolving in time (decaying suspension flow). In this case, the time is short (hours, days) being the duration of a single depositional event of episodic nature. Similar genetic packages can be found in multilayer sedimentary bodies, built up by several events, and in normal or selective deposits. The best known case is that of the fining-upward sequence displayed by fluvial and tidal point bars formed by lateral accretion (Allen, 1982, his figures 2–23).

Notice that Allen uses the term structure not only for the cross-bedding, parallel lamination, etc., inside the body, but also for its overall geometry (“lateral accretion structure”). Alternatively the same object can be described as a facies sequence, a facies association or an architectural element.

The following description summarizes that of Allen (1982): in tidal flats, mud-sand interbedded point bars form the inner bank of small meandering gullies. They are rarely thicker than 1.5 m and consist of curved, sigmoidal layers, from parallel-laminated to current rippled, both ebb and flood directions often being preserved. The base of the bar is an irregular erosional surface, generally overlain by gravel of bivalve and other shells mixed with pebbles of muddy sediment derived from cut banks.

River point bars, in intermediate to large sand-bedded rivers, where the secondary [transversal] flow is fully developed, have also a basal, diachronous erosion surface, with flutings, pot-holes and other scours. Sediments in the lateral accretion deposit fine upward in general but interfinger in detail, and internal sedimentary structures appear upward in order of declining flow power, an arrangement which reflects the distribution of bedforms over the bar surface, in turn revealing the inward decline of current strength. Curved bedding surfaces, generally sigmoidal in radial profile, define the *lateral accretion structure* [= master bedding].

Structures related to deformational processes

Primary sedimentary structures are subjected to disturbances by fluid movement, compaction and gravitational instability if the sediment remains soft and deformable. *Soft sediment deformation* is the general term for changes to the fabric and layering of a bed of unconsolidated sediment. It affects most commonly multilayer deposits, especially sand-mud alternations, and can be diffused in the whole packet or concentrated along bedding planes or within individual beds. No systematic classification exists, apart from a broad subdivision into structures characterized by vertical movement and structures showing a lateral component of motion (gravitational or current shearing). For nomenclature, see Table B2.

Concerning the first group, trapping of water induced by rapidly deposited sediment may lead to disruption of previous structures within a bed (more commonly sand) or a bedset. This may occur due to shocks by earthquakes or oscillations in water pressure, which may temporarily liquefy the sediment. Beside liquefaction, deformation can result from sediment contraction (e.g., desiccation) or dilatation, unequal loading, upward injection of fluid or paste-like material, downward injection in fractures, compaction, downslope movements, current or ice drag or combined effects.

Sedimentary structures formed by liquefaction, injection, etc. are often associated with deposits from high-density turbidity currents and subaqueous slumps; those that can be related to earthquakes may be called *seismites*, but this attribution is often conjectural.

Sand volcanoes are formed by the violent expulsion from the subsurface of sand and water mixtures. Dewatering (fluid-escape) structures result from forceful expulsion of water from a consolidating fluidized bed, due to loading or a shock. The water moves upward, disrupting overlying layers and forming *dish-and-pillar* structures. Dishes are subhorizontal, gently concave-upward clay or organic-rich laminae, deformed at their margins by upward flow. Pillars are near-vertical

Table B2 Soft-sediment deformation structures reported in modern and ancient sediments. For references, see Ricci Lucchi (1995b)

Modern	Ancient
Liquefaction structures	Ball-and-pillow structure (Smith, 1961; Pettijohn and Potter, 1964)
Sand boil	Load structures
Sand volcano, sand-vented volcano (Obermeier <i>et al.</i> , 1986)	Flame structure (Cooper, 1943)
Sand blow (Sieh, 1978; Doig, 1990)	Injection structures, diapiric structures
Sand slough (Fuller, 1914; Rascoe, 1975)	Flow rolls (Pepper <i>et al.</i> , 1954)
Sand slough (Fuller, 1914; Rascoe, 1975)	Pseudonodule (Macar, 1948)
Patterned ground (Washburn, 1950)	Convolute lamination (Kuenen, 1953)
Mima mounds (Fuller, 1914; Arkley and Brown, 1954; Berg, 1990)*	Cycloid (Hempton and Dewey, 1983)
Patterned ground (Washburn, 1950)	Dish structure (Wentworth, 1967; Lowe and Lo Piccolo, 1974)
	Pillar structure, or dish-and-pillar structure (Lowe and Lo Piccolo, 1974)
	Water escape structures
	Sand volcano
	Sandstone dike
	Sandstone pipe
	Clastic (sedimentary) sill
	Clastic (sedimentary) dike
	Slump ball (Kuenen, 1948)
	Slump structures
	Boudinage
	Pull-apart (Natland and Kuenen, 1950)
	Ice-shear (ice-push) structures
	Glaciotectonic structures
	Drag fold
	Hydroplastic deformation
	Wrinkle marks (Häntzschel and Reineck, 1968; Allen, 1985)

* Fuller (1912) regarded this structure as aseismic, Berg (1990) reinterpreted it as seismic

dewatering pipes, interrupting the dishes and made up of structureless sand. Dishes are found in both massive and crudely laminated sandstones and are related to horizontal movements of water or liquidized sand. In the dark laminae, preexisting (semipermeable membranes?) or newly formed, fine particles are concentrated by elutriation.

Convolute laminations are deformational structures developed in rapidly deposited fine-grained sands and silts, and commonly associated to water-escape structures and climbing ripple cross-lamination in turbidites and river flood deposits. They are either symmetrical about a vertical plane or leaning and asymmetrical, and usually exhibit narrow vertical upturned laminae, often truncated at the top, separated by broader synclinal downfolds, with wavelengths of a few centimeters or decimeters. Some convolutions are associated with water-escape dishes, pillars, etc.

Many explanations have been offered for the origin of this structure; the asymmetrical varieties involve shearing, probably caused by an overflowing dense current. Downslope movement (slumping) seems to be excluded by the common occurrence in basinal sediments, especially turbidites, and the dying out of the folds both upward and downward into flat surfaces, without any evidence of *décollement*. Liquefaction or hydroplasticity of some or all laminae involved (which contain variable amounts of organic material or clay) and density instability are the most invoked mechanisms. Timing of formation can be during bed deposition (syndepositional type of Allen, 1982), just before or immediately after deposition ceases (metadepositional), or definitely after (postdepositional).

Load casts are the commonest type of deformation of sand-mud interfaces and “represent the instability of discontinuous

layered systems” (Allen, 1982) due to inverted density gradients (Dzulynski, 1966). The structure consists of lobes of sagging sand alternating laterally with sharp-crested diaphragms (“flames”), projecting from a mud that was quite fluid when it was loaded. Load casts can be found at various scales ranging from millimeters to decameters (in outcrops).

Similar to load casts, but more deformed and complex in shape and internal structure are *pseudonodules* or *ball-and-pillow* structures. In this case, sand is pierced or completely disrupted and detached from the “mother bed” and embedded in the underlying mud (something analogous to stoping in magmas). Internal laminae follow the curvature of the outer surfaces, indicating that they are formed by viscous shearing within the ball or pillow during its descent. The most plausible explanation is again the physical state of the materials (Rayleigh-Taylor instability of sand-mud interbeds) combined with an external perturbation, that is, seismic shocks. Downslope movements are not necessarily implied, even though the pillows may end up in slumped masses.

Deformations in slump sheets is best observed where sliding materials are heterolithic and/or in different state of compaction and cohesion. A variety of geometries is thus displayed, from disharmonic folds, cascade folds, box folds, concentric folds, isolated hinges, shear planes, slabs and blocks, brecciation and even, in most conspicuous slump sheets (tens of meters thick), cleavage in mudstones (Ricci Lucchi, 1995b). Sand volcanoes, other fluid-escape structures and burrows may occur at the top. Axial surfaces vary from steeply inclined to flat-lying, and axes tend to be parallel to depositional strike, but with a wide dispersion of orientation.

Structures related to advancing ice or sand bodies are shown by layered muds in the form of folding, crumpling and contortion,

at places extremely “baroque” (complicated). Antiform folds can be arranged *en echelon*, more or less parallel to the edge of the encroaching body, and may be associated with shear planes. These structures are the combined effect of differential loading and drag.

Sedimentary dykes can be produced at various scales by both forceful injection of fluid or hydroplastic sediment from below and infilling of open cracks from above. Ptygmatic folds can develop in dykes owing to subsequent compaction or to increasing resistance encountered by the injection.

Smaller injected dykes are indistinguishable from the pillars associated to dishes in sandstones; larger structures are called pseudodiapirs, mudlumps, etc., and originate in multilayered successions rich in mud. Infilled dykes range from desiccation cracks to large fissures and fractures formed in lithified sediments, especially limestone, subjected to extensional stresses (“neptunian dikes”).

Deformed cross-bedding has various aspects. It can affect either the topmost part of foreset laminae, overturning or disharmonically folding them, or the mid-lower portions, where small folds, discordant slabs, small normal (gravity) faults or patches of vaguely laminated or structureless sediment appear (Allen, 1982). Fluid drag on subaqueous or subaerial, water-saturated sediment is generally held responsible for the first case, whereas in the other, some form of gravity induced downslope slip is more plausible. The lee side of eolian dunes, for example, is prone to sliding when wet. Detachment and sliding of slightly cohesive sand laminasets can occur without internal deformation.

BEDSET AND LAMINASET

According to McKee and Weir (1953), a *bed* is a sedimentary stratum greater than 10 mm thick, whereas a *lamina* is less than 10 mm thick. The divide at 10 mm is arbitrary, and not

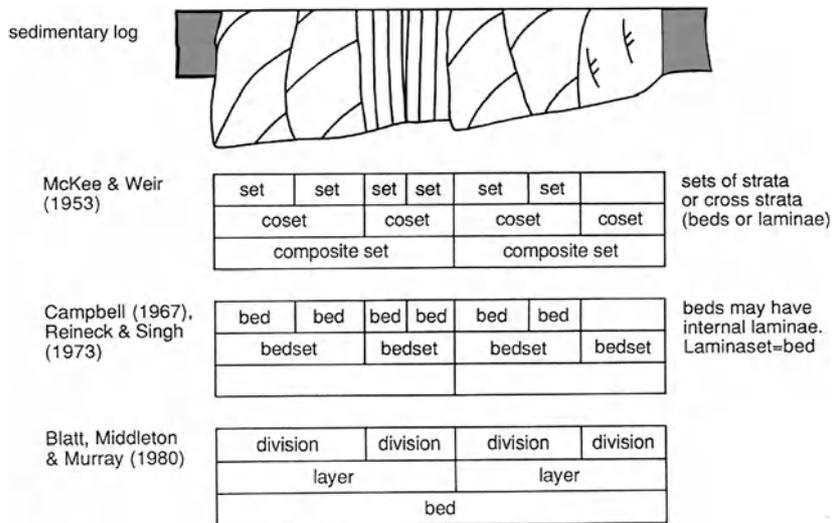

Figure B12 Comparison of terminology for describing stratification (from Bridge, 1993).

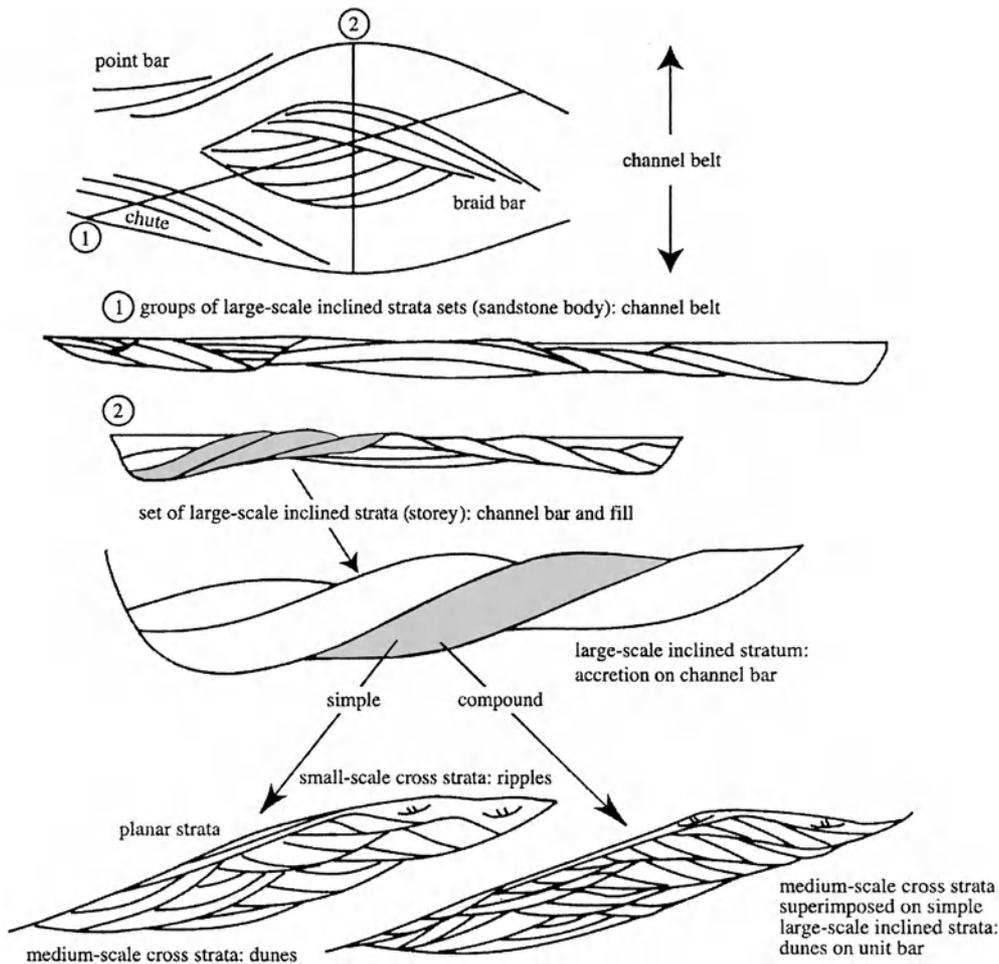

Figure B13 Proposed terminology for the case of superimposed scales of strata, using river channel deposits as an example (modified from Bridge, 1993).

based on objective statistical analysis of stratal thickness, nor on any genetic implication. Beds and laminae are recognized on the basis of changes in sediment texture and/or composition within or between them. Beds and laminae generally occur in sets (*bedsets*, *laminasets*) that are distinctive in terms of the orientation, texture and composition of beds or laminae within the set (Figure B12). If the beds or laminae within a set are inclined at more than a few degrees relative to the set boundaries, the beds or laminae are given the prefix *cross* or *inclined* (e.g., set of cross laminae, or cross-lamina set). Bedsets or laminasets also occur in sets. For example, a set of similar cross-lamina sets or cross-bed sets is referred to as a simple set or *coset* (Figure B12), according to McKee and Weir (1953). A set or different types of bedsets or laminasets is called a *composite set* (Figure B12).

This terminology for defining beds, laminae, bedsets, and laminasets is widely used but is not without its problems and detractors. Modifications to the terminology shown in Figure B12 suggest that there was a desire to use the term bed for a larger scale of stratum than that defined by McKee and Weir (1953). The term bed may therefore refer to a set of strata rather than a single stratum with no internal subdivision. Another problem with McKee and Weir's terminology is that both laminae and beds may occur in the same set of strata. This problem arises because of the arbitrary division of strata into beds and laminae. A single stratset containing beds and laminae could logically be called a composite set, but this term has already been used for a set of different sets rather than a set of different strata. Perhaps the greatest difficulty with all of the different methods for defining strata and sets of strata is that there is no consistent use of terms for referring to the many different superimposed scales of strata and sets of strata in sedimentary basins. The terms used for the smaller stratsets (bedset, laminaset) have not been applied to the larger-scale stratsets. Instead, poorly defined, inexplicit terms such as *storey*, *architecturalelement* and *parasequence* have been used.

Bridge (1993) argued that, in order to describe hierarchies of different-scale strata, it is desirable to use a reasonably small number of explicit terms consistently irrespective of scale, and to use qualifying terms to describe relative scale of strata. Figure B13 shows an example of this approach applied to river deposits, and includes interpretation as well as descriptive terminology. An alternative method of describing hierarchies of strata of different scale is by numerically ordering their bounding surfaces (e.g., Brookfield, 1977; Allen, 1983; Miall, 1996). As discussed by Bridge (1993), this approach is difficult to use in practice.

BENTONITES AND TONSTEINS

Definition

Bentonites are thin, widespread clay-altered ash layers that are commonly dominated by smectite (Fisher and Schminke, 1984). This is the definition used by sedimentologists. Knight (1898) first used the name bentonite for an unusual clay in the Benton Shale of Cretaceous age in Wyoming. The absorbent properties and swelling nature of this and similar clays were later shown to be due to the presence of the smectite group of minerals (*q.v.*) of which montmorillonite is the most common. In the definition of bentonite the emphasis on the origin is generally attributed to Ross and Shannon (1926). They noted that the clay was a product of the “alteration of a glassy igneous material, usually a tuff or volcanic ash” and the resultant clay “is usually the mineral montmorillonite, but less often beidellite” (a member of the smectite group). Smectite-rich bentonites are valuable raw materials and some authors would restrict the bentonite definition to smectite-rich deposits irrespective of origin (Grim and Guven, 1978; Roen and Hosterman, 1982). This definition cannot be reconciled with that used by sedimentologists and it has to be accepted that both definitions will continue to be used, albeit for different purposes.

Mesozoic bentonites usually consist of smectite. As temperature rises during burial diagenesis smectite layers are progressively converted into illite, via a mixed-layer illite-smectite. These beds are known as K-bentonites because of the introduction of potassium in the illitization reaction. Most Paleozoic clay-altered volcanic ashes are of this type. In coal-bearing strata of all ages the volcanic ash usually alters to kaolinite forming thin beds known as *tonsteins*. Only since the 1980s has the volcanic origin been generally accepted.

Fisher and Schmincke (1984) suggest that the nomenclature of bentonites should reflect the dominant clay mineral species with smectite (s)-bentonite, kaolinite (k)-bentonite and illite (i)-bentonite. K-bentonite is a well-established term and Huff (1983) has made a good case for its retention. Likewise the term tonstein is also well-established and will continue to be used by coal geologists. Possibly smectite-bentonite should be adopted as this would eliminate potential confusion between

bentonite as a general term for the whole group and a specific member within the group.

Recognition of bentonites

Field characteristics

Bentonites typically occur as thin beds with a wide lateral extent of up to hundreds of kilometers. The contacts with the enclosing sediment are nearly always sharp. If the material is unweathered internal lamination and graded bedding may be visible. The expansion of smectite during weathering causes preferential loss of bentonites in surface exposures. Tonsteins on the other hand may be more durable than the host sediments because kaolinite does not expand and there is an interlocking texture. Many tonsteins have the appearance of flint clays, but others are more granular. Bentonites are mainly associated with shales and coals because a low energy depositional environment is required for their preservation. Ashfalls may incorporate minor amounts of organic matter, but the content is significantly less than in the enclosing sediments and hence there is a usually a color contrast.

Mineralogy

The clay mineralogy of bentonites differs significantly from that of the associated sediments. The normal detrital clay assemblage of kaolinite, illite and chlorite is absent and in tonsteins the kaolinite is well-ordered in contrast to most detrital kaolinites. Bentonites are dominated by one clay mineral to the extent that many are monomineralic and in this they are exceptional.

The clay minerals form from unstable volcanic glass and to a lesser extent from some of the pyrogenic minerals. Many of the latter are relatively stable and survive the ash alteration. These minerals are diagnostic of the volcanic origin and also of the original ash composition. Quartz and biotite are common, sanidine and high temperature plagioclase feldspars less so and olivine, pyroxene and amphibole are rare. The relative abundances largely reflect the dominance of acid volcanics, but with weathering stability superimposed. In bentonites there is a restricted heavy mineral suite consisting mainly of zircon, apatite and ilmenite/magnetite. Weaver (1963) emphasized the interpretative value of this restricted suite, which is unlike that normally encountered in detrital sediments.

As the thickness of the volcanic ash decreases away from the eruptive source so the grain size of the particles decreases and their proportions change. Minerals are generally most abundant between 2mm and 1/16mm and are practically absent below 10 microns, whereas glass shards can be much smaller (Fisher and Schmincke, 1984). These features are inherited by bentonites. There is also mineral fractionation in air-fall ashes and in bentonites a noteworthy result of this eolian fractionation is the enrichment of biotite at the base of some units (Diessel, 1985; Huff and Morgan, 1990).

Textures

In the magma the pyrogenic minerals develop relatively freely resulting in euhedral crystals. These are found in bentonites

and also high temperature forms such as beta quartz crystals. During explosive volcanism crystals are shattered and quartz splinters are very common. As would be anticipated minerals with well-developed cleavages also fragment. There is therefore a contrast with the shape of grains in normal detrital sediments.

Vitric particles are the other main component of volcanic ashes. Cusped and platy shards result from the shattering of bubbles in silicic magmas and the characteristic shape may survive the alteration to clay. Clay-altered pumice shards may retain the shape but lose the internal structure and consequently are more difficult to identify positively.

Composition

The major element composition of bentonites essentially reflects the diagenetic conditions and the resulting clay mineral proportions rather than the magmatic origin. There are rare instances where vitric particles have been preserved, usually by an early diagenetic cement. Glass inclusions in pyrogenic minerals are more common and are sufficiently large to be analyzed by an electron microprobe, as in the work of Lyons *et al.* (1993).

Not all elements are mobile in the alteration process and the immobile elements are concentrated. The radioactivity of many bentonites in borehole logs drew attention many years ago to the high concentrations of Th and U. More recently it has been appreciated that classification schemes for altered volcanic ashes using immobile elements (Winchester and Floyd, 1977) also apply to bentonites (Lyons *et al.*, 1993). The use of these elements confirms the volcanic origin, but more importantly provides information on the original ash composition and the tectonic setting of the vulcanicity.

Classification of tuffs and bentonites

Tuffs are classified on the glass-mineral proportions and range from vitric tuffs to crystal tuffs (Pettijohn, 1975). As some minerals and textures survive the alteration process such a classification should be applicable to bentonites. The petrography of tonsteins has been studied in the greatest detail because of their essential role in coalfield correlations and also tonsteins represent the worst case scenario in terms of the extent of alteration. Most authors use Schullers classification (see Bohor and Triplehorn, 1993), which is kristal tonstein (crystals of kaolinite), graupen tonstein (grains of kaolinite), pseudomorphosen tonstein (kaolinite pseudomorphs after silicates) and dichte tonstein (fine-grained kaolinite). Bouroz *et al.* (1983) and Bohor and Triplehorn (1993) have made some progress in relating the Schuller classification to the tuff nomenclature. Dichte tonstein is interpreted as a clay-altered vitric tuff. A graupen tonstein could be equivalent to a vitric tuff containing pumice shards. There is also the possibility raised by Diessel (1985) that highly altered biotites which lose the original lath-shape of the grains and become barrel-shaped could be responsible for a texture characteristic of graupen tonsteins. The pseudomorphosen tonsteins are clearly altered crystal tuffs and so are some of the kristal tonsteins. The difficulty with other kristal tonsteins is that the crystals of kaolinite are vermicular and may have formed from the matrix

rather than being a pyrogenic mineral. If this was resolved then bentonites could be related to the equivalent tuff category with greater certainty.

Rate of ash alteration and clay stability

The alteration of volcanic glass is reviewed in detail by Fisher and Schmincke (1984). The rate of alteration and formation of intermediate products are further discussed in Bohor and Triplehorn (1993) with greater emphasis on the formation of the clay minerals. There is textural evidence from bentonites that clay minerals sometimes formed relatively rapidly. The rate does depend on a number of factors including ash composition and the pore solution chemistry, which is also influenced by the depositional environment and the permeability of the enclosing sediments.

In the earlier literature there is an emphasis on low pH for the formation of kaolinite. The work of Garrels and Christ (1965) and others shows low ionic activities of component elements are also important. In seawater, activities are higher and smectite is stable. For pore solutions to remain within the kaolinite stability field during diagenesis the system must remain open.

Use of bentonites

Those bentonites consisting of smectite are of economic value and have many commercial uses (Grim and Guven, 1978). Tonsteins are generally not of such value with the exception of some deposits in China.

Bentonites are comparable to tephra layers in that they are chronostratigraphic markers and are very important in many parts of the stratigraphical column. Tonsteins came to prominence over a hundred years ago because of their stratigraphic values, and correlation of coal seams in the paralic coalfields of mainland Europe would have been inconceivable without them. The survival of pyrogenic minerals in bentonites creates excellent opportunities for absolute age dating, often from parts of the column where other suitable materials are absent. The time consuming task of separating a sufficient mass of minerals for analysis is now redundant with current instrumentation (SHRIMP) capable of producing age profiles within grains.

Summary

Bentonites are clay-altered volcanic ash layers. They are formed during explosive volcanism and as a consequence have a wide distribution. Bentonites are characteristically preserved as thin beds in low energy depositional environments, such as shales and coals, and have considerable stratigraphic value. Many bentonites in Mesozoic sediments consist of smectite. Some authors would restrict the term bentonite to smectite rich deposits irrespective of origin. As the diagenetic level increases the smectite is converted to illite via a mixed-layer clay. These are the K-bentonites. Another group were subjected to greater alteration, which produced kaolinite and these are the tonsteins. The terms K-bentonite and tonstein are well established in the literature and should be retained. If

smectite-bentonite were generally adopted potential confusion could be avoided.

Bentonites are recognized as altered volcanic ashes on bed form, structures, textures, mineralogy and trace element geochemistry. The latter two also enable the original ash composition and the tectonic setting of the volcanism to be determined. Although tonsteins result from the greatest level of alteration their classification and that of tuffs have many features in common.

BERTHIERINE

Introduction

Berthierine is an iron-rich, aluminous, 1 : 1-type layer silicate belonging to the serpentine group (Bailey, 1980; Brindley, 1980, 1981). The name honors Berthier, who reported the first studies of this mineral in 1827. In the past, this clay mineral was also known as septechlorite, septechamosite, chamosite, 7Å-chamosite, and 7Å-chlorite, but berthierine is now the accepted name (Brindley *et al.*, 1968). Berthierine was considered rare until recently. The failure to recognize berthierine arose mostly from its chemical similarity to Fe-rich chlorite (chamosite); these phases share many significant X-ray powder diffraction (XRD) lines. The ease with which berthierine can be mistaken for kaolinite in XRD patterns of oriented crystal aggregates has also contributed to its misidentification (Moore and Reynolds, 1997, p. 139).

Berthierine is chemically and structurally similar to odinite. However, odinite is now formally recognized as a distinct 0.7 nm phase (Bailey, 1988a), and exhibits some key differences from berthierine, the most significant being the abundance of ferric iron. Odinite is a member of the verdine facies, a group of green clay minerals present on many shallow, marine shelves and reef lagoonal areas in tropical locations (Odin, 1988). It has been previously identified as berthierine or 7Å-chamosite in some localities (e.g., Porrenga, 1967; Rohrlach *et al.*, 1969).

Berthierine is best known from shallow marine environments, particularly ironstones (Van Houten and Purucker, 1984). However, it is increasingly recognized in brackish to nonmarine environments. These include laterites, flint clays and other pedogenic settings, and estuarine/deltaic sandstones, where it may have precipitated directly or formed by alteration of a precursor (kaolinite, aluminous goethite, odinite). Berthierine and odinite themselves may be precursors to diagenetic chamosite (Bailey, 1988a, b; Hornibrook and Longstaffe, 1996).

Structure and chemistry

Berthierine occurs in two structural forms, orthohexagonal and monoclinic, the former being most abundant. Both can be present in the same sample. The cell parameters of berthierine are $a \cong 0.540$ nm, $b \cong 0.936$ nm, $c \sin \beta \cong 0.170$ nm, and $\beta \cong 104.5^\circ$ and 90° (Bailey, 1980). Disorder within the structure is common, arising from variations in layer stacking and chemistry (Brindley, 1980).

Berthierine is characterized in XRD by a (001) diffraction at 0.7 nm, which defines its 1 : 1 layer structure, and a (060) diffraction at 0.1555 nm, which indicates its dominantly trioctahedral character. The XRD identification of berthierine is described in Bailey (1980, 1988b) and Brindley (1980). Identification by XRD alone is difficult, however, because of the presence of two berthierine polytypes and the similarity to chamosite. Chlorite ought to be distinguishable from berthierine in XRD by its characteristic 1.4 nm (001) diffraction. However, this diffraction is very poorly developed or absent in chamosite, while its (002) diffraction at 0.7 nm overlaps that of the berthierine (001). Berthierine also can occur with chamosite (as a physical mixture and/or an interstratification), which further complicates identification. Unambiguous recognition of berthierine commonly requires direct measurement of

layer thickness using TEM (transmission electron microscope) lattice-fringe images (e.g., Jiang *et al.*, 1992).

The generalized formula of berthierine is $(R^{2+}_a R^{3+}_b \square_c)(Si_{2-x} Al_x)O_5(OH)_4$, where R^{2+} (Fe, Mg, Mn) and R^{3+} (Fe, Al) are cations in octahedral positions, \square describes possible vacant octahedral sites, and $a + b + c = 3$ (Brindley, 1982). Berthierine is dominantly trioctahedral, with a typical composition of $(Fe^{2+}_{1.5} Mg_{0.375} Al_{1.0} \square_{0.125})(Si_{1.25} Al_{0.75})O_5(OH)_4$ (after Moore and Reynolds, 1997). However, a wide range in composition is known (Brindley, 1980, 1982). For example, end-member Fe-berthierine $[(Fe^{2+}_2 Al)(SiAl)O_5(OH)_4]$ occurs in Cretaceous laterite deposits of Minnesota (Toth and Fritz, 1997). By comparison, di-trioctahedral berthierine is present in oil-sands from Alberta, $(Fe^{2+}_{1.01} Al_{0.82} Mg_{0.46} Fe^{3+}_{0.28} Mn_{<0.01} \square_{0.43})(Si_{1.74} Al_{0.26})O_5(OH)_4$ (Hornibrook and Longstaffe, 1996). Its composition suggests the possibility of a series between berthierine and odinite. Odinite is similar to berthierine in that it is Al- and Fe-rich, has a 1 : 1 layer structure, and shares many of the same XRD lines. However, it is richer in Fe^{3+} , Mg and Si, and contains less Al than most berthierines. It has a representative formula of $(Fe^{3+}_{0.8} Mg_{0.8} Al_{0.53} Fe^{2+}_{0.3} \square_{0.57})(Si_{1.8} Al_{0.2})O_5(OH)_4$ (after Moore and Reynolds, 1997).

Occurrence and formation

Marine

Berthierine is most commonly associated with marine-oolitic ironstone formations, which are generally considered to have formed in low energy, marginal marine shelf environments in tropical to subtropical regions. There, berthierine is typically a component of pisoids and ooids, consisting of concentric sheathes around a nucleus of clay, ferric oxide, other ooids, fossil fragments or quartz grains (Bhattacharyya, 1983; Van Houten and Purucker, 1984; Maynard, 1986; Siehl and Thein, 1989).

Van Houten and Purucker (1984) summarized possible origins for such berthierine and other 'chamositic' minerals. Neof ormation of berthierine is possible where grain-coatings, pore-linings and void-fillings are observed. However, the general consensus favors early diagenetic, anoxic modification of a precursor, which had accumulated as granules on an oxygenated seafloor. Numerous identities for this early substrate have been proposed. Bhattacharyya (1983) showed that remobilization of iron from hydroxides could react with detrital kaolinite to form berthierine in seawater. Odin (1988) and his coauthors suggested that odinite could evolve to berthierine during early diagenesis, producing a better organized 0.7 nm structure with only moderate chemical modification. Morphological relationships are usually cited as the main difficulty in accepting odinite as a precursor to berthierine. Odinite in Recent sediments almost always occurs as peloids of presumed fecal origin, whereas there are no reports of grain-coating or pore-lining odinite. Reworked, transported and transformed lateritic minerals are another possible precursor for berthierine in shallow marine sediments.

Nonmarine

Nonmarine occurrences of berthierine are reported with increasing frequency, including laterites (Toth and Fritz,

1997), Arctic desert soils (Kodama and Foscolos, 1981), coal swamps (Iijima and Matsumoto, 1982), fresh to brackish floodplain and estuarine/deltaic sediments (Taylor, 1990; Hornibrook and Longstaffe, 1996), and flint clays (Moore and Hughes, 2000).

Berthierine from laterites and estuarine sandstones is likely of most significance. For example, the Lower Cretaceous Weald Clay of southeast England contains transported berthierine-bearing pisoids and ooids derived from Fe-rich soils. These grains were deposited in a scour within a fresh to brackish water mudplain (Taylor, 1990). *In situ* formation of berthierine has been reported in a laterite buried beneath a lignitic horizon in Minnesota (Toth and Fritz, 1997; Fritz and Toth, 1997). There, berthierine formed by alteration of kaolinite and by neof ormation. Berthierine formation is attributed to percolation of fresh water under reducing conditions through a pisolitic laterite (gibbsite, kaolinite, and goethite), which had developed on a low-relief peneplain. Reduction of Fe³⁺ was accomplished via oxidation of organic carbon. The absence of sulfate-inhibited pyrite formation, thus facilitating berthierine and siderite formation. Radial bladed and radial blocky coats of berthierine on pisoids formed first. As the soil became saturated by groundwater, precipitation of macroscopic crystals of Fe-berthierine followed in the voids between pisoids. The raised water table was associated with a regional transgression of the Western Interior Seaway during Late Cretaceous time. Such laterites represent possible sources of detritus for some varieties of marine ironstones. Likewise, the presence of such berthierine and siderite in nonmarine sediments may be correlatable with sequence or parasequence boundaries (Toth and Fritz, 1997).

Well-crystallized laths of berthierine, together with Fe-rich saponite and traces of chamosite, occur as early diagenetic pore-linings and grain-coatings on sand grains in the estuarine/deltaic Lower Cretaceous Clearwater Formation oil-sand deposits of Alberta (Hornibrook and Longstaffe, 1996). The stable isotope compositions of this berthierine indicate formation in the presence of meteoric water at 25–45°C. Berthierine formation was followed by calcite precipitation, and then emplacement of hydrocarbons.

Volcanic rock fragments in these sands provided a leachable source of Fe, which accreted about grains in the form of hydroxides or odinite in the freshwater estuary. High sedimentation rates helped to establish reducing conditions in the estuarine sediments, which favored transformation of Fe-minerals to berthierine. The presence of calcite rather than siderite suggests that most available iron had been consumed by Fe-clays. Calcite $\delta^{13}\text{C}$ values of up to +23‰ indicate that extreme reducing conditions (microbial CO₂-reduction) had been established by the time of carbonate precipitation. In the absence of sulfate and prior to CO₂ reduction, microbes may have acted first to reduce Fe³⁺, and triggered berthierine generation. Once Fe was reduced and more or less fixed into clays, calcite crystallization and microbial CO₂ reduction ensued. The possibility remains that odinite was the precursor to berthierine, and that ferric iron was reduced *in situ*. Sub-tropical conditions existed in this area during the Early Cretaceous, and the estuarine setting would have favored odinite formation. While the blades and laths of Clearwater berthierine are unlike the morphology known for Recent odinite, it almost certainly becomes unstable in most ancient sediments, transforming to better crystallized phases, including berthierine.

Reactions during burial diagenesis

Reactions involving berthierine during burial diagenesis are of growing interest. For example, reaction between siderite and kaolinite at 65–150°C under reducing conditions produced aluminous, low-Mg berthierine in shales associated with coal swamps (Iijima and Matsumoto, 1982). Replacement of kaolinite by chlorite during burial diagenesis of mudstones is also suspected to proceed through a berthierine intermediary (Burton *et al.*, 1987). Berthierine is increasingly considered to be a diagenetic precursor to chamosite, based on the numerous observations of berthierine-chamosite intercalation (e.g., Ahn and Peacor, 1985; Hillier and Velde, 1992). Temperatures as low as 70°C have been suggested for initiation of this reaction (Jahren and Aagaard, 1989; Hornibrook and Longstaffe, 1996).

Chamosite is a common grain-coating and early pore-lining in many sandstones. These rims, where they are not too thick, preserve porosity and permeability by inhibiting further diagenetic mineral growth. In contrast, development of thick rims reduces the potential for hydrocarbon saturation and increases the likelihood of formation damage during hydrocarbon recovery. Berthierine (and possibly odinite) may be low-temperature precursors of this chloritic rim. Hence, depositional and early diagenetic environments like those in which the Clearwater berthierine formed may illustrate one set of conditions under which formation of Fe-clay rims is most favorably initiated.

BIOCLASTS

Bioclasts, a.k.a. fossils, shells, skeletal particles, biotics, etc., are an important component of many limestones, shales, and sandstones and are volumetrically the dominant to exclusive particulate building block of many limestones. They are typically the major tool for age determination and paleoecological information. Most shells are constructed of calcium carbonate (aragonite, calcite, high-magnesium calcite), silica (opal), or phosphate (apatite or colophonite) with varying proportions of organic compounds. In the rock record, the original mineralogy is commonly altered to a more stable

calcite, dolomite, or microcrystalline quartz. The original mineralogy is rarely taxonomically diagnostic, but strongly influences the type of preservation. Aragonite shells can be neomorphosed to calcite with varying degrees of fidelity to the original structure, but are commonly dissolved wholesale and preserved only as filled molds or lithified casts of the body cavity (steinkerns). In contrast, calcite or Mg-calcite skeletons typically preserve fine structural details and rarely form molds. The proportions of minerals within some shells and of minor elements, trace elements, and stable isotopes within the minerals can vary with the taxa and with environmental parameters, notably temperature and salinity. Thus they are sources of paleoenvironmental information, if the signal is preserved and can be calibrated.

Identification of bioclasts is easiest, most detailed, and most reliable where well-preserved specimens can be observed on bedding planes or etched surfaces or can be isolated from the rock by disaggregation or dissolution of the matrix. This is possible in limestones only where the mineralogy of the bioclasts differs from that of the matrix, typically through selective silicification of the fossils, as in the famous Permian biotas from the Glass Mountains, Texas. In the more common case, where both bioclasts and matrix or cement are calcite, identification must proceed through polished sections, thin sections, or acetate peels. Recognition depends on distinctive cross-sections, diagnostic structures, or skeletal wall structure.

Outstanding, well-illustrated general references on bioclast description and identification include Majewske (1969), Horowitz and Potter (1971), Milliman (1974, pp. 52–137; identification key pp. 315–318), Bathurst (1975, pp. 1–76), Scholle (1978), Flügel (1982), Adams and Mackenzie (1998). In the highlights of bioclast identification that follow, geologic range and original mineralogy of taxa and typical dimensions of specific features are indicated parenthetically.

Algae

Skeletons of various algae are major rock formers in the Phanerozoic. In addition algae and other microbes bound sediment (stromatolites, now cyanobacteria or microbialites: see *Microbially Induced Sedimentary Structures*) and produced carbonate mud through much of geologic time. Coralline red algae (Ordovician–Silurian? E. Cretaceous–Recent; see *Algal and Bacterial Carbonate Sediments*; Mg calcite) are typified by a layer of rectangular chambers (<10–20 µm). Nodules formed by red algae (rhodoliths), in consortium with encrusting bryozoans, worms, corals, foraminifers, etc., are conspicuous markers of slow deposition, for example, ushering in transgressive sequences. Solenoporids (Cambrian–Paleocene; Mg calcite?) also form nodules or frameworks of larger, polygonal cells (10s–100s µm). Halimedecean green algae (Ordovician–Recent; aragonite) are prodigious producers of needle mud (1–10 µm) and, in the Cenozoic, producers of segments (1–5 mm) calcified around filaments to give the appearance of Swiss cheese in section. Phylloid algae is a form designation for skeletal fragments of both halimedecean-like and coralline-like algae that resemble cabbage leaves (cm-scale; <1mm thick) and accumulated in broad mounds in the Late Paleozoic. Dasyclad green algae (Cambrian?–Ordovician–Recent; aragonite) are perforated cylinders, kegs, or spheres (100s µm) with a hollow central axis. Calcispheres (Devonian?–Recent), in their most common and simplest form are a hollow spheres (50–225 µm) with a thin (3–30 µm)

calcareous wall. Some have multi-layered walls or protruding hollow spines. The central cavity is invariably filled with cement, suggesting exclusion of sediment, but the nearest living analogs, aragonitic reproductive cysts of *dasyclad* algae, have a covered hole. The modern forms are benthic as were the associations of Paleozoic forms, but Cretaceous associations were pelagic. Charophytes (Silurian–Recent; calcite) are fresh- or brackish-water green algae with calcified subspherical sex organs (100s μm) typified by spiral ridges on the exterior. *Coccoliths* (Late Jurassic–Recent) are calcareous discs (2–20 μm) produced by planktonic yellow-green algae. In very thin sections, typical forms appear as dual concentric rings with a swastika cross in cross-polarized light.

Foraminifers (Cambrian–Recent)

Foraminifers are important guide fossils from the Late Paleozoic to Recent and are locally rock formers. They are ‘microfossils’ that exceptionally reach 10 cm in size with chambers in a multitude of shapes, arrangements, and wall structures. Planktonic forms, numerous since the Jurassic, typically have globular chambers (100s μm) with perforate walls of calcite. Benthic and encrusting forms have walls of Mg calcite (microgranular, hyaline, porcellaneous textures; Fig. B14), calcite, agglutinated sediment, chitin, or, rarely, aragonite.

Radiolarians (Proterozoic–Recent)

Radiolarians are marine plankton whose porous skeletons (siliceous, 10s μm) have superficially radial symmetry commonly adorned with spines. They are useful guide fossils and local rock formers.

Sponges (Proterozoic–Recent)

Porous walls that may be convoluted or chambered surround a central cavity (mm–m) with a single large opening in a typical sponge. Hard parts, where present, are calcareous skeletons, isolated calcareous or siliceous spicules (10s–100s μm), or frameworks of fused spicules. *Stromatoporoids* (Cambrian to Recent), now recognized as sponges, are important rock formers Silurian through Devonian and locally in the Mesozoic. Typical skeletons (aragonite in Recent) consist of planar, wavy, or even spherical laminae separated by pillars. Megascopic clusters of radial furrows on the surface (*astrorhizae*) are characteristic, but scarcely discernible in thin section. *Archeocyathids* are possible sponges that formed ‘reefs’ in the Early and Middle Cambrian. Typical skeletons are shaped like saucers, bowls, or inverted cones with porous calcareous walls, in most cases double walls, joined by radial partitions.

Cnidarians (Ordovician–Recent)

Corals, octocorals or alcyonarians, and milleporids comprise the calcified cnidarians. Only the corals are important rock formers, although the smooth to roughly warty Mg-calcite spicules (0.1–1 mm) of octocorals can form appreciable carbonate sand. The basic structure of the outer walls and septa of corals is bundles of acicular crystals that radiate from a few up to 90° from a dark central axis (Fig. B14). The needles are aragonite in the scleractinians (Triassic–Recent), but were calcite in the *rugosans* and *tabulates* (both Ordovician–

Permian). In the other elements that partitioned the living quarters of the Paleozoic corals, the *tabulae* and *dissepiments*, the fibrous crystals are perpendicular to the surface. Paleozoic corals include solitary forms, typically conical or cylindrical with radiating septa, and massive colonies of nearly parallel-growing corallites that expand by budding new individuals. *Scleractinians* are colonial with hemispherical, spherical, branching, or encrusting forms.

Bryozoans (Ordovician–recent)

Bryozoans colonies are typically dense branching cylinders (ramose) or lacy reticulate sheathes (*fenestrate*), although massive, box-like, and encrusting habits are not uncommon. Wall structure is generally a thin inner layer of granular carbonate overlain by laminated layers that locally pucker toward the exterior into dense rods. The mineralogy in modern forms is calcite, Mg calcite, aragonite, or mixed. The living chambers are sub-spherical in *fenestrates* and partitioned tubes that bend to an opening in the outer wall in branching forms. Bimodal size of living chambers and hooded openings are characteristic of some bryozoans. *Fenestrate* colonies in longitudinal cuts appear as a line of isolated beads (30–50 μm) spaced about 1 mm apart. Modern marine bryozoans are most abundant on temperate shelf settings; Paleozoic bryozoans appear to have more tropical associations.

Brachiopods (Early Cambrian–Recent)

Taxonomically useful variety is not wanting in brachiopods, but of all the phyla, they have perhaps the most consistent form, two shells, each bilaterally symmetrical, and wall structure, a very thin outer layer and a thicker inner layer, both commonly of calcite. The inner layer typically consists of fibers oriented about 10° to the shell surface that produce a sweeping extinction band nearly perpendicular to the surface under crossed polars (Fig. B14). The internal structures of the shell, such as teeth and the distinctive loops or spirals that support the aeration apparatus have the same structure. The large order of *strophomenids* (Ordovician–Triassic) has a laminar inner layer that gives a similar extinction pattern. The calcite composition makes the shells very stable; they are rarely dissolved and have been widely used to provide pristine material for stable isotopic analyzes. The valves typically remain articulated after death, in contrast to the bivalves. Other distinctive features are series of hollow tubes called *punctae* (10s μm diameter) that extend across the shells in certain suborders. Other suborders have superficially similar rods of calcite, *pseudopunctae*, that warp the shell laminae toward the interior surface. The occurrence of long, slender spines along the hinge line or in rows along the shell or simply as fragments associated with the shells helps distinguish brachiopods from bivalves. In section, the hollow calcite spines show concentric lamination and a pseudouniaxial cross under crossed polars. Brachiopods were major bioclast contributors throughout the Paleozoic; a few survived the end-Permian extinction and staged a moderate resurgence in the Jurassic, but they have since declined to minor importance.

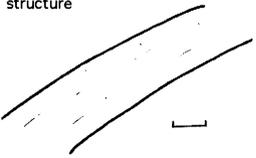

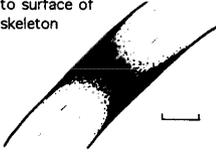

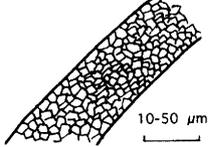

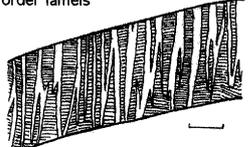

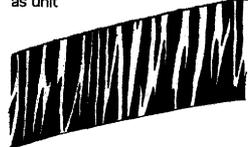

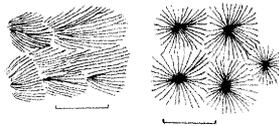

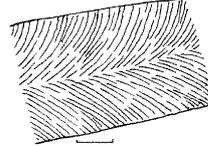

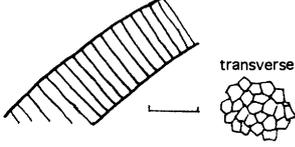

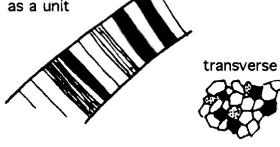

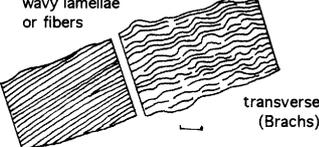

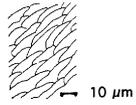

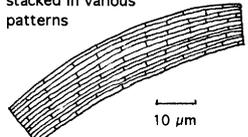

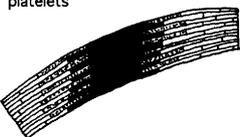

Microstructure Common minerals (rare minerals in parenthesis)	Appearance of bioclast in plane transmitted light	Appearance under crossed polars	Examples
Homogeneous Calcite (Aragonite)	No visible structure 	Extinction band perpendicular to surface of skeleton 	Trilobites Ostracodes Mollusks
Microgranular Calcite (Aragonite)	Irregular grains  10-50 μm	Optically random orientation 	Foraminifers Mollusks
Single crystal Calcite	Porous skeletal elements as single crystal. Pores commonly filled by syntaxial spar. 	Unit extinction of element 	Echinoderms Sponge spicules
Crossed lamellar Aragonite (Calcite)	Chevrons of pseudopleochroic, first- order lamels 	First-order lamels extinguish as unit 	Mollusks
Spherulitic crystals Aragonite Calcite (Rugose & Tabulate corals)	Fibrous crystals radiating from point or dense line. longitudinal transverse 	Each crystal extinguishes parallel to long axis. Rugose 	Corals
Simple prismatic Calcite (Aragonite)	Polygonal prisms perpendicular to shell surface  transverse	Each prism extinguishes as a unit  transverse	Mollusks Brachiopods (rare)
Foliated Calcite	Thin, parallel (left) to wavy lamellae or fibers  transverse (Brachs)	Extinction band perpendicular to surface of skeleton (cf. homogeneous, nacreous)  10 μm	Brachiopods Bryozoans Worm tubes Bivalves
Nacreous Aragonite	Platelets $\sim 1\mu\text{m}$ thick, stacked in various patterns  10 μm	Extinction parallel to platelets 	Molluscs

Figure B14 Common types of skeletal microstructure as seen in thin section. Scale bars are 200 μm , except as noted. Modified from Scoffin (1987) and Majewske (1969).

Mollusks (Cambrian–Recent)

Three classes of mollusks are geologically important; gastropods and bivalves as bioclasts of steadily increasing volume and diversity from the Cambrian to the present and the cephalopods as excellent guide fossils, primarily in the Mesozoic. The wall structures of mollusks are diverse; six types (nacreous, prismatic, homogeneous, foliated, cross-lamellar, complex cross-lamellar; (Fig. B14)) were identified in the pioneering work of Bøggild (1930) and some subsequent work has subdivided them extensively. Foliated and some simple prismatic layers are calcite; the others are aragonite. The combinations of layers have some taxonomic value, but preservation of the aragonite layers is commonly poor to nil.

Gastropods are most readily recognized by their spiral shells with large, generally smooth and unsegmented, internal cavities. They have two to six wall layers, commonly three, with most or all composed of aragonite.

Bivalves can be confused with other mollusks in small fragments or with brachiopods if a foliated layer is prominent. However, they generally have two or three shell layers, of which at least one is originally aragonite, so it has a structure not found in brachiopods or is extensively dissolved. Bivalve shells are not bilaterally symmetrical and lack spines or internal structures, except teeth. Exceptional bivalves are the oysters and some pectens, which have shells entirely of calcite, and the rudists, which resembled giant solitary corals and formed reefs in the Tethyan Cretaceous.

Cephalopods were represented primarily by nautiloids (Cambrian–Recent) in the Paleozoic and ammonoids (Devonian–Cretaceous) in the Mesozoic. Both had coiled and straight conical forms, partitioned internally by regularly spaced septa that were perforated by a tube, the siphuncle, running the length of the shell. The septa of nautiloids are simple, slightly curved, and turned back along the siphuncle. In ammonoids the septa are fluted; intensely fluted and turned forward along the siphuncle in advanced forms. The pattern of fluting where it intersects the shell wall and the external ornamentation are primary taxonomic features of ammonoids. The shells are entirely aragonite, except for the small, unarticulated cover of the aperture, the apertical, which is preferentially preserved in some strata because it is calcite. Belemnite cephalopods (Mississippian–Eocene) are represented by dense, black, torpedo-shaped fragments of an internal ‘counterweight’ composed of radial calcite crystals.

Annelids

Among the annelid worms, calcified, encrusting serpulids have a fossil record extending back perhaps into the Precambrian. They secrete tight planispiral coils (mm) and long, straight to irregular tubes (mm–cm). Wall structure, which helps distinguish them from vermetid gastropods and scaphopods, is subparallel laminae of microcrystalline carbonate that appear as concentric circles in cross-section, typically giving a pseudouniaxial cross under crossed polars. Mineralogy is aragonite, Mg calcite, or a mixture. Both aragonite and Mg contents increase dramatically with temperature. Serpulids occur in abundance only locally, but as encrusters on soft as well as hard substrates, they can indicate the existence of forms, for example, aquatic grasses, that have scant fossil records.

Arthropods (Cambrian–Recent)

Arthropods, the most abundant and diverse of animals, are represented in the fossil record mainly by trilobites and ostracodes. Trilobites (Early Cambrian–Permian) are the most useful guide fossils in the Early Paleozoic but were rarely major sediment producers. The segmented exoskeleton bends under around the margins to produce the characteristic ‘‘shepherds crook’’ in cross-section. Microcrystalline calcite of the skeleton resembles the homogeneous structure of mollusks; the optic axis is oriented perpendicular to the surface, producing a broad extinction band under crossed polars (Fig. B14). Ostracodes (Cambrian?–Recent) have two valves (0.5–20 mm), typically ovoid in outline, with smooth to highly ornamented surfaces. The valves are essentially mirror images, but one is slightly larger and overlaps the other. The adult valve has a narrow, acute inward projection from the margin. The shell is calcite with 1–10 mole percent MgCO₃; the structure appears similar to that of trilobites. Ostracodes can be useful paleoenvironmental indicators as they inhabit marine, brackish, and fresh waters.

Echinoderms (Cambrian–Recent)

Echinoderms are readily recognized by their apparent pentagonal symmetry and by uniform extinction under crossed polars (Fig. B14). Syntaxial overgrowths of cement commonly fill the orderly network of pores (10 μm) in the original Mg calcite skeleton; occasionally staining by organic or iron compounds preserves the outline of the network within the resulting single crystal. Recognition of subgroups within the echinoderms depends on characteristic shapes of segments, such as the short cylinders (mm) with axial tubes of crinoid stems (Ordovician–Recent), prodigious sediment producers in the mid-Paleozoic.

Conclusions

Identification of bioclasts relies on a number of features such as distinctive cross sections, diagnostic structures, or skeletal wall structure. The taxonomic level of identifications varies greatly with the taxa and the preservation, as well as the exigencies of the study. Foraminifer and bryozoan species are routinely determined in thin section, but the most common purpose of study is to draw paleoenvironmental conclusions from the overall biotic assemblage.

BIOEROSION

The term bioerosion was coined by Neumann (1966) for hard substrate destruction by organisms (Greek, “bios” life; Latin “erodere” erode). It was originally restricted to calcareous rocks but is now being used for biogenic removal of all types of rocks, engineering works, and mineral and organic skeletons. The term should only apply to activities removing grains or fibers, for example, an organism which just pushes its substrate aside does not qualify as a bioeroder.

Classification

Bioeroders leave characteristic traces of their action which may remain visible in the sedimentary record. These traces are named like other trace fossils; their taxonomic treatment is independent of their producers (e.g., a sponge boring is not named “*Cliona*” after its presumed producer but is cited as the trace fossil taxon “*Entobia*”). Bioerosion may be classified according to several overlapping schemes.

- origin of substrate attack: surface (rasping or etching) or interior (boring);
- type of substrate: rock (calcareous or non-calcareous) and carbonate hardparts (lithic); wood (xylic) or bone (osteic);
- size of traces: micro- or macroscale.

The ecology of bioeroders is highly variable: they use their substrate as food (e.g., boring fungi, shipworms, termites or hyenas), as their domicile (e.g., boring sponges or bivalves, some ants), as a brooding place (e.g., woodpeckers, printer beetles), or they remove it in search of food (e.g., sea urchins, parrotfish, moon snails).

Importance

Rasping or boring organisms rapidly recycle substrates and produce fine-grained detritus. Their impact on the global carbon cycle and sediment production largely depends on the nature of the substrate: just a small percentage of bones is scraped off by carnivores, and only a limited array of coastal borers (e.g., some bivalves and sea urchins) can tackle all type of material. Insect wood boring is a prominent factor in forest ecology, and this book probably would appear in Spanish if shipworms had not devastated the Armada sailing against England in 1588. Most significant (in ecological and sedimentological terms) is the action of marine calcareous bioeroders. They provide cavities for secondary dwellers as well as bare space for settlement of larvae, thus enhancing diversity; they produce enormous amounts of lime mud, and they shape the morphology of limestone coasts.

Substrate types

Wood

Wood bioerosion basically is a terrestrial phenomenon. Apart from minute tunnels produced by oribatid mites, the resulting traces are macroborings. The substrate is almost exclusively removed from the inside, independent of the animal group involved (structures in wood made by fungi or microorganisms are not bioerosive—see first paragraph). Several groups of wood borers are able to digest lignin thanks to their intestinal symbionts, others cultivate fungi in their tunnels, yet others excavate holes as nests or as permanent domiciles. Insects are the most prominent and most diverse wood borers (ecologically and taxonomically) but given the paucity of terrestrial sediments their traces rarely enter the fossil record. Driftwood in fluvial and brackish realms is bored by only a few highly specialized groups, in contrast to the importance of marine borers. Here, rather few genera of the bivalve families, Pholadidae and Teredinidae, account for most of the fossil wood bioerosion. Borings in driftwood or coal seams do not necessarily indicate marine conditions, however, instead they may signal sea-level lowstand (e.g., Bertling and Hermanns, 1996).

Non-calcareous rocks

Bioerosion of crystalline rocks and siliciclastic sediments mainly occurs in the coastal zone. Fungi, snails, sea urchins, shrimps and pholadid bivalves may attack even the hardest substrates. In their search for shelter and/or food, they bore exclusively by mechanical means. Fungi are primary colonizers, mainly found above the low-tide level. Together with snails which rasp off green algae, they have limited bioerosive effect. The other groups require permanent water cover. Sea urchins are most effective, annually removing 1–10 mm of substrate, or up to 2 kg/m²a (per square meter per year) (Alloué *et al.*, 1996).

Carbonates

Carbonate bioerosion is characterized by an intricate interaction of rasping and micro- and macroboring, each with different organisms involved (Kiene, 1989). The process is further complicated by penecontemporaneous biogenic encrustation and physical erosion: biogenic loss of substrate may be compensated or aggravated within a few months time. Bioerosion is crucial in carbonate sedimentology, especially in reef environments, reducing the grain size of components (skeletons) to mud and exporting large masses of carbonate from reefs: 30 percent to 40 percent of reef fine sediment is made up of chips produced by boring sponges (see Hutchings, 1986).

Experimentally measured bioerosion rates vary with substrate, type and agents of bioerosion (Trudgill, 1983; Hutchings, 1986). From 0.5 mm to 10 mm of substrate may be eroded annually, corresponding to values of 1 to 20 kg/m²a. Most efficient are clionid sponges and parrotfish which remove 2–3 t/ha of reef coral each year. This silt-sized material is deposited either in cavities of the reef itself or is exported to the fore-reef and lagoon, respectively.

Carbonate macroborers largely use chemicals such as calcium-complexing proteins (acids have not been identified) in addition to mechanical abrasion. The mostly suspension-feeding animals (bivalves of families Mytilidae and

Gastrochaenidae, various polychaetes and sipunculans, clionid and other sponges, thoracic barnacles, among others) use the substrate for their dwellings. They tend to resemble the producers body outline closely (e.g., Bromley, 1994). The fossil borings hence are highly characteristic, sometimes down to the species level, allowing substantial inferences about the paleoenvironment. Modern macroborers exhibit a depth zonation: bivalves, sipunculan and polychaete worms are frequent and abundant down to the normal-wave base whereas sponges may still occur in bathyal depths (Bromley and Allouc, 1992). This distribution reflects the ecological demands of the borers: they require low sedimentation rates and at least fair water movement and nutrient conditions; in addition, a denser substrate and longer exposure will result in more intense macroboring. Rasping bioeroders as well as encrusters are antagonistic to borers of all types.

Microborings in carbonates are produced by fungi, cyanobacteria, chlorophytes, and rhodophytes. Diameters between 5 and 2000 μ necessitate (electron) microscopic examination. A strong apparatus effort is rewarded by excellent depth indicator values of microborings: maximum diversity is above the storm-wave base with chlorophytes and cyanobacteria being the dominant producers. Between 30 m and 100 m depth, chlorophyte borings govern the spectrum, followed by fungi in depths below 150 m (Vogel *et al.*, 2000). The bioerosive action of microborers is strongest in the supratidal zone; honey-combed limestone coasts (“biokarst”) and notches are morphological features exclusively due to microborers. Without continuous physical removal of substrate, microborers are most efficient in the first year after substrate availability; later they cannot compete with macroborers.

Rasping bioeroders are less coherent ethologically. Sea urchins, amphineurans and snails graze on filamentous chlorophytes on limestone just as much as on other substrates (see above), removing their substrate accidentally. Various families of reef fish have the same effect on coral skeletons while feeding either on boring green algae (e.g., parrotfish and surgeonfish) or the coral polyps (butterflyfish and puffers). A third group, octopuses and the gastropod families Muricidae and Naticidae, only affects the calcareous shells of molluscs as these predators drill through their victims tests in order to access the soft parts.

Taphonomy

The preservation of bioerosion traces is at least to some extent hindered by their self-destructive nature. As long as no significant sedimentation occurs, successive generations of bioeroders obliterate the structures of their predecessors. This process may be modified by rapid infill and cementation of vacated borings, followed by renewed bioerosion. The original substrate may thus be replaced by micrite filling bored boreholes with the outer shape still intact. Surface raspings and very shallow microborings have the least preservation potential, whereas the deeply penetrating borings of larger animals may still be recognized even after several centimeters of substrate have been eroded. For this reason, the fossil record of bioerosion is strongly skewed toward the borings of bivalves, worms and sponges. Preservation is optimal when the producers are killed by overgrowth or sedimentological events such as sudden burial (obrution) or emersion.

Taphonomy: Sedimentological Implications of Fossil Preservation

BIOGENIC SEDIMENTARY STRUCTURES

Biogenic sedimentary structures (trace fossils or ichnofossils) are biologically produced structures that include tracks, trails, burrows, borings, fecal pellets and other traces made by organisms. Excluded are markings that do not reflect a behavioral function. Owing to their nature, trace fossils can be considered as both paleontological and sedimentological entities, thereby bridging the gap between two of the main subdivisions in sedimentary geology. Four major categories are recognized: (1) *bioturbation structures*—they reflect the disruption of biogenic and physical stratification features or sediment fabrics by the activity of an organism: includes tracks, trails, burrows, and similar structures; (2) *biostratification structures*—they consist of stratification imparted by the activity of an organism: biogenic graded bedding, byssal mats, certain stromatolites, and similar structures; (3) *biodepositional structures*—they reflect the production or concentration of sediments by the activity of an organism: includes fecal pellets, pseudofeces, products of bioerosion, and similar structures; and (4) *bioerosion structures*—a biogenic structure excavated mechanically or biochemically by an organism into a ridged substrate: includes borings, gnawings, scrapings, bitings, and related traces.

The contributions of ichnology to sedimentary geology are considerable, including: (1) the production of sediment by boring organisms; (2) the consolidation of sediment by suspension feeders; (3) the alteration of grains by sediment-ingesting organisms; (4) the destruction of sedimentary fabrics and sedimentary structures; (5) the construction of new fabrics and sedimentary structures; (6) the initial history of lithification; (7) the interpretation of depositional environments; (8) the delineation of facies and facies successions; (9) rates of deposition; (10) substrate coherence and stability; (11) aeration of water and sediments; and (12) the amounts of sediment deposited or eroded. Recent summaries dealing with general ichnological principles can be found in Pemberton *et al.* (1992), Bromley (1996) and Pemberton *et al.* (2002).

The conceptual framework of ichnology

The importance of ichnology to the fields of stratigraphy, paleontology, and sedimentology stems from the fact that trace fossils display the following characteristics: (1) long temporal range—although a disadvantage in refined biostratigraphy, it greatly facilitates paleoecological comparisons of rocks differing in age; (2) narrow facies range—reflects similar responses by tracemaking organisms to given sets of paleoecological parameters; (3) no secondary displacement—biogenic sedimentary structures, where preserved intact, are closely related to the environment in which they were produced; (4) occurrence in otherwise unfossiliferous rocks—trace fossils are commonly enhanced by the very diagenetic processes that can obliterate body fossils, especially in siliciclastic regimes; (5) creation by soft-bodied biota—many trace fossils are formed by the activities of organisms that generally are not preserved because they lack hard parts; such organisms, in many environments, represent the greatest biomass; (6) a particular structure may be produced by the work of two or more different organisms living together, or in succession, within the structure; (7) the same individual or species of organism may produce different structures corresponding to different behavior patterns; (8) the same individual may produce different structures corresponding to identical behavior but in different substrates (e.g., in sand, in clay, or at sand–clay interfaces); and (9) identical structures may be produced by the activity of systematically different trace-making organisms, where behavior is similar (Ekdale *et al.*, 1984).

Such characteristics make trace fossils very useful in facies analyzes, including reconstruction of individual paleoecological factors, sedimentary dynamics, and the documentation of local and regional facies changes.

Classification of trace fossils

Unique classification schemes have been developed in order to interpret and decipher trace fossils. Historically, the more important classifications have included the preservational, behavioral, and phylogenetic aspects of the tracemaker.

Preservational classifications

Classifications of the stratigraphic arrangements and modes of preservation of trace fossils are both descriptive and interpretive. These preservational concepts may be reduced to two basic facets: (1) topology, including modes of occurrence and

the mechanical-sedimentological processes of alteration and preservation, and (2) physiochemical (pre- through post-diagenetic) processes of preservation and alteration. Toponomic (or stratinomic) classification schemes have been devised (see Pemberton *et al.*, 1992 for details). Most of these schemes attempt to relate the position of the trace fossil with respect to the main casting medium, which is commonly sandstone or siltstone. Diagenetic preservational schemes have been stressed by numerous authors (e.g., Ekdale *et al.*, 1984). The burrowing activities of benthic organisms can result in significant changes in porosity-permeability patterns that will have a significant effect on later diagenesis (Gingras *et al.*, 1999). Likewise, burrow linings that may be simple secretions of mucus or particulate walls, agglutinated by organic compounds are preferred sites for subsequent mineralization. Therefore, diagenetic processes that obliterate other fossils may even enhance the preservability of trace fossils.

Behavioral classification

Perhaps the single most important facet of ichnology is the behavioral interpretation of trace fossils. Fundamental behavioral (or ethological) patterns are dictated and modified not only by genetic preadaptations, but also by prevailing environmental parameters. Ekdale *et al.* (1984) recognized seven basic categories of behavior (Figure B15); resting traces (*cubichnia*), locomotion traces (*repichnia*), dwelling traces (*domichnia*), grazing traces (*pascichnia*), feeding burrows (*fodinichnia*), farming systems (*agrichnia*), and escape traces (*fugichnia*). Ekdale (1985) added predation traces (*praedichnia*), and Frey *et al.* (1987) emphasized the importance of equilibria (*fugichnia*) to all other behavioral patterns. The basic ethological categories evolved early and have generally persisted throughout the Phanerozoic. Although individual tracemakers have evolved, basic benthic behavior has not.

Phylogenetic classification

One of the most frustrating—albeit most fascinating—aspects of ichnology is the attempt to establish the zoological affinities of specific ichnofossils (Figure B16). This results because ichnofossils reflect the behavior of animals, and only to a small extent reflect their anatomy or morphology. The result is that more than one genus or species of ichnofossil may have been constructed by a single species of animal, or conversely different species of animals may have made identical species or genera of trace fossils (Frey and Seilacher, 1980). For example, specimens of *Skolithos linearis* at one locality may show affinities to the phoronids whereas at another locality they may show affinities to onuphid polychaetes. Finally, a nestler or commensal organism in some instances may be better suited for preservation within a burrow than the animal that constructed the burrow. Therefore, each occurrence of a given ichnofossil must be treated on an individual basis; sweeping generalizations on their zoological affinities should be avoided. Notable exceptions include certain types of distinctive, hard substrate borings and those rare instances where the tracemaking organism is preserved within the burrow. In most cases, however, attributing a particular trace to a particular soft-bodied organism depends on a uniformitarian approach and other indirect lines of evidence.

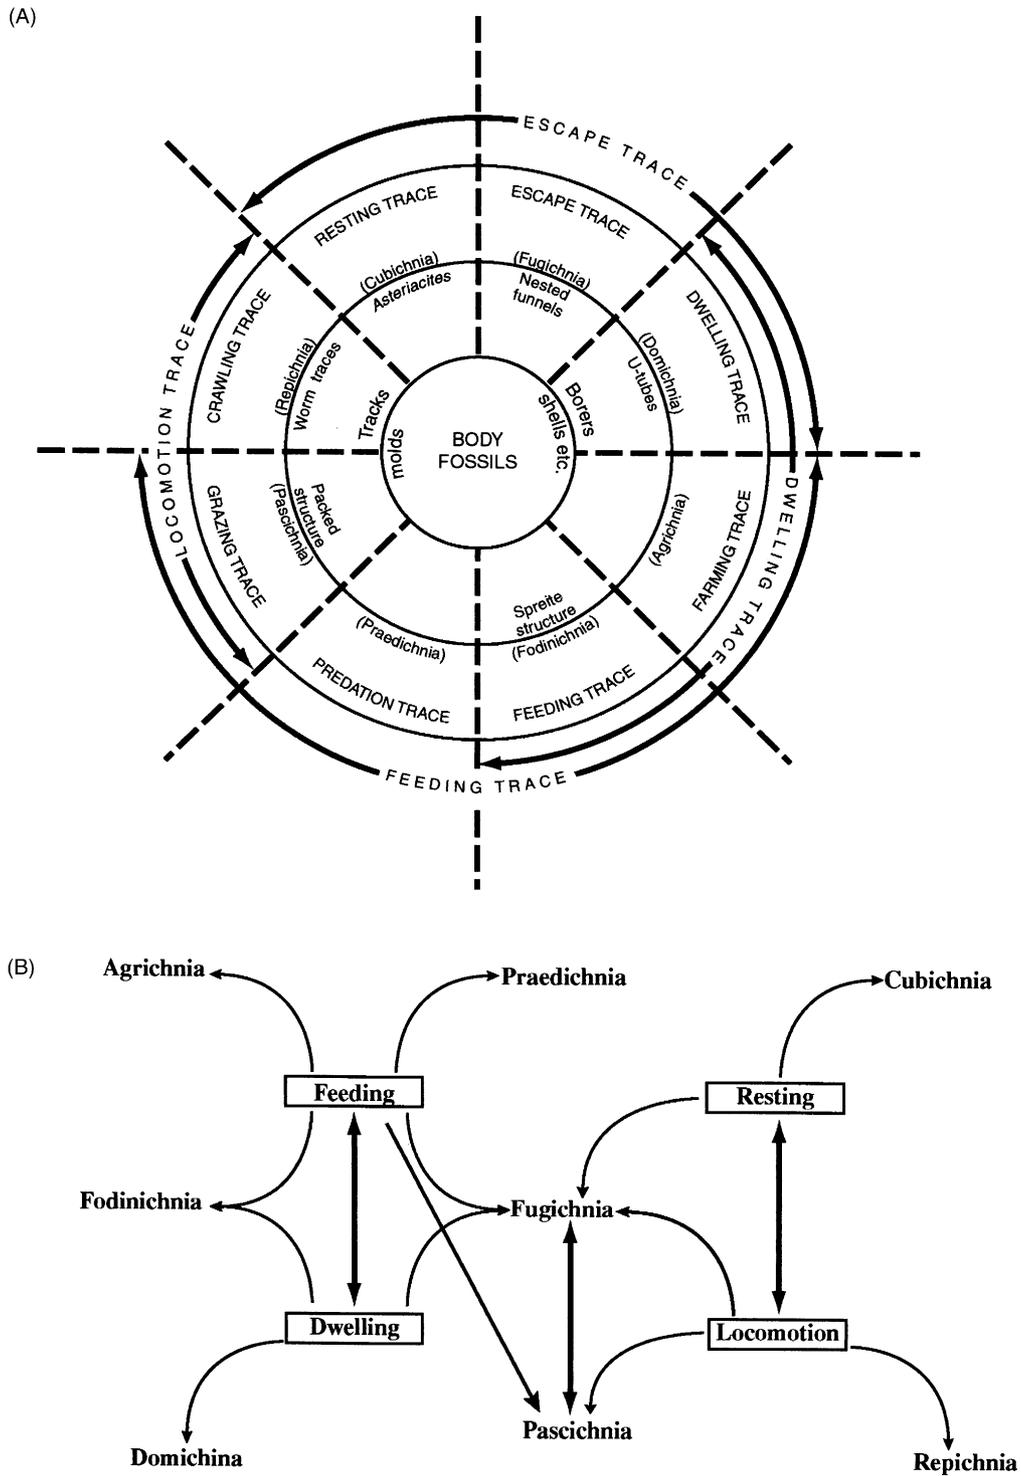

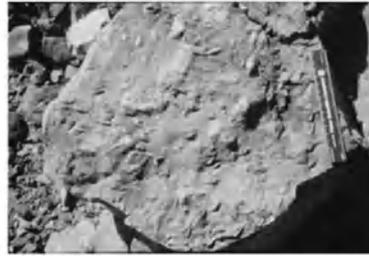

Figure B15 Classification of trace fossils. (A) Ethological classification of trace fossils; (B) Interactions between behavioral categories. (Modified after Pemberton *et al.*, 1992).

Phylogenetic Classification

Although very difficult sometimes it is possible to match the trace making organism to the individual trace fossil. One must approach this with caution but it can assist in paleoecological

Lockeia is thought to represent marks left by the foot of a bivalve

Schaubcylindrichnus is thought to represent the dwelling burrow of a Sabellarid polychaete

Figure B16 Phylogenetic classification of trace fossils is based on the investigation of modern trace-making organisms. (Modified from Pemberton *et al.*, 2002).

The ichnofacies concept

Perhaps the essence of trace fossil research involves the grouping of characteristic ichnofossils into recurring ichnofacies. This concept developed by Adolf Seilacher in the 1950s and 1960s, was based originally on the fact that many of the parameters that control the distribution of tracemakers tend to change progressively with increased water depth (Figure B17). Because of the potential geological value of this bathymetric relationship, the Seilacherian ichnofacies sequence soon came to be regarded almost exclusively (albeit erroneously) as a relative paleobathometer. Today the ichnofacies concept remains valuable in paleoenvironmental reconstruction, but paleobathymetry is only one aspect of the modern ichnofacies concept (Frey *et al.*, 1990).

Ichnofacies are part of the total aspect of the rock and therefore, like lithofacies, are subject to Walther's Law (see *Sedimentologists: Johannes Walther*). For example, isolated bored shells or clasts do not in themselves constitute the *Trypanites* ichnofacies and a bored log is not an example of the *Teredolites* ichnofacies. Rather, there should be some semblance of stratification, lateral continuity, and vertical succession.

Archetypal ichnofacies

Nine recurring ichnofacies have been recognized, each named for a representative ichnogenus: *Scoyenia*, *Trypanites*,

Teredolites, *Glossifungites*, *Psilonichnus*, *Skolithos*, *Cruziana*, *Zoophycos*, and *Nereites*. These trace fossil associations (Figure B17) reflect adaptations of tracemaking organisms to numerous environmental factors such as substrate consistency, food supply, hydrodynamic energy, and salinity and oxygen levels (Pemberton *et al.*, 1992). Traces in nonmarine and brackish marine settings are in need of further study; the marine softground ichnofacies (*Psilonichnus*, *Skolithos*, *Cruziana*, *Zoophycos*, and *Nereites*) are distributed according to numerous environmental parameters; traces in the firmground (*Glossifungites*), woodground (*Teredolites*), and hardground (*Trypanites*) ichnofacies are distributed on the basis of substrate type and consistency. Representative occurrences of the various ichnofacies are summarized below. Each may appear in other settings, however, as dictated by characteristic sets of recurrent environmental parameters.

Nonmarine ichnofacies

The use of trace fossils in the interpretation of freshwater deposits is becoming increasingly important. Recent work by Buatois and Mángano (1995), among others, have stressed the abundance and diversity of tracemaking organisms in freshwater environments and emphasized their potential importance in paleoenvironmental reconstruction. Distinct differences in trace fossil types and abundance have been

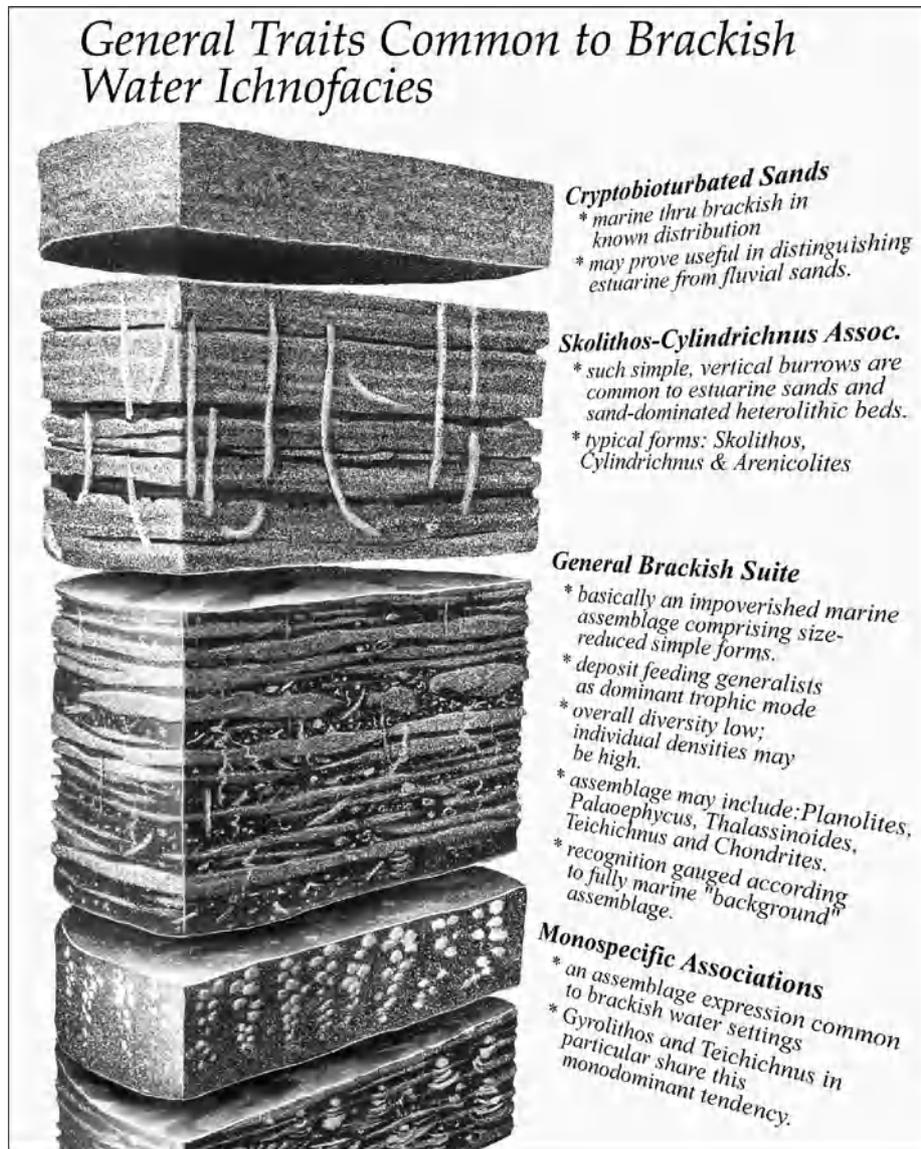

Figure B17 General brackish water trace fossil assemblage. (Modified from Pemberton *et al.*, 2002).

reported from a wide range of freshwater-terrestrial environments, in both ancient and recent settings (Ekdale *et al.*, 1984). At present, nonmarine environments have been characterized by three main ichnofacies: the *Scoyenia*, the *Mermia*, and the *Termitichnus* ichnofacies. Frey *et al.* (1984) concluded that the *Scoyenia* ichnofacies remains a valid concept within appropriate limits and suggests deposition on the shore of ephemeral lakes and the overbank of sluggish rivers. The *Scoyenia* assemblage is characterized by: (1) small horizontal, lined, backfilled feeding burrows; (2) curved to tortuous feeding burrows; (3) sinuous crawling traces; (4) vertical, unlined, cylindrical to irregular shafts; and (5) vertebrate and arthropod tracks and trails. Buatois and Mángano (1995) concluded that the *Mermia* ichnofacies typifies unconsolidated, fine-grained, permanent subaqueous substrates, and well-oxygenated, low-energy lake bottoms. The *Mermia* assemblage is

characterized by: (1) dominance of horizontal to sub-horizontal grazing and feeding traces produced by mobile deposit feeders; (2) subordinate occurrence of locomotion traces; (3) generally high to moderate diversity and abundance; and (4) low abundance of specialized grazing structures. Smith *et al.* (1993) named the *Termitichnus* ichnofacies as a distinct terrestrial assemblage characterizing paleosols. The *Termitichnus* ichnofacies is characterized by: (1) vertebrate tracks and trails; (2) low diversity and abundance; (3) dominated by bee, beetle, and termite nests; (4) few feeding structure; and (5) rhizoliths, coprolites, and leaf miners. Prospects for the recognition of additional archetypal nonmarine ichnofacies remain encouraging. For example, Ekdale *et al.* (1984) and Frey and Pemberton (1987) noted that distinct suites of trace fossils characterize eolian dunes, fluvial, paleosol, and lake environments, among others.

Brackish water ichnofacies

Brackish marginal marine environments are widespread in the modern, and are being documented with more frequency from the rock record. The general brackish water trace fossil assemblage (Figure B18) reflects inherently fluctuating environmental parameters (salinity, exposure, sedimentation rates, temperature, and shifting substrates). These factors suggest that the benthic biota of brackish water environments is indeed unique and in contrast to Bromley and Asgaard (1991) the influence of salinity gradients can hardly be divorced from the ichnocoenose concept. For the same reasons that distinct non-marine associations are now being recognized, unique brackish water assemblages are also widespread. In summary, brackish water environments tend to be characterized by: (1) an impoverished marine suite of benthic organisms; (2) trace-making infaunal animals are more abundant than epifaunal animals; (3) soft bodied organisms are more prevalent than shelled organisms; (4) some animals show a distinct size reduction; (5) some animals are bathymetrically displaced; (6) a higher percentage of the assemblage of benthic organisms are trophic generalists whose activities result in morphologically simple burrows; and (7) although diversity is reduced, high individual densities may be attained (Pemberton *et al.*, 1992).

Marine soft ground ichnofacies

The *Psilonichnus* ichnofacies is associated with supralittoral/upper littoral, moderate to low-energy marine and/or eolian conditions typically found in beach to backshore to dune environments. The comments by Bromley and Asgaard (1991) notwithstanding, the *Psilonichnus* ichnofacies was founded on fossil examples (Frey and Pemberton, 1987) and is no more theoretical than any other recurrent ichnofacies; rather, the modern ichnocoenoses were emphasized to show the richness that one might reasonably expect to have existed for various ancient ichnofaunas. Furthermore, one of the major tenets of ichnofacies reconstruction is that the namebearer need not be present in every occurrence of the ichnofacies; thus, just as *Cruziana* is rare in post-Paleozoic occurrences of the *Cruziana* ichnofacies, *Psilonichnus* may well be absent in pre-Mesozoic occurrences of the *Psilonichnus* ichnofacies.

The *Skolithos* ichnofacies (Figure B19) is generally associated with high-energy, sandy, shallow-marine environments. The trace fossils are characterized by: (1) predominantly vertical, cylindrical or U-shaped burrows; (2) few horizontal structures; (3) few structures produced by mobile organisms; (4) low diversity, although individual forms may be abundant; and (5) mostly dwelling burrows constructed by suspension feeders or passive carnivores.

The *Cruziana* ichnofacies (Figure B20) usually is associated with infralittoral/shallow circalittoral marine substrates below minimum wave base and above maximum wave base. The trace fossils are characterized by: (1) high diversity; (2) low individual densities; (3) a mixed association of vertical, inclined, and horizontal structures; (4) presence of structures produced by mobile organisms; (5) they are dominated by feeding and grazing structures constructed by deposit feeders some of which show quite complex behavior patterns resulting in complex trace fossils (Pemberton *et al.*, 1992).

The *Zoophycos* ichnofacies ideally is found in circalittoral to bathyal, quiet-water marine muds or muddy sands, below

maximum wave base to fairly deep water in areas free of turbidity flows and subject to oxygen deficiencies. The trace fossils are characterized by: (1) low diversity, though individual traces may be abundant; (2) grazing and feeding structures produced by deposit feeders; and (3) horizontal to gently inclined spreiten structures (i.e., repetitive parallel or concentric burrows or traces). However, the ichnofacies also may occur in restricted intracoastal settings, particularly in Paleozoic sequences; the ichnogenus *Zoophycos* possibly represents greater depths of burrowing in Mesozoic and Cenozoic deposits than in Paleozoic deposits (Pemberton *et al.*, 1992), hence the character of the *Zoophycos* ichnofacies may vary from one part of the stratigraphic column to the next.

The *Nereites* ichnofacies typically is associated with bathyal/abyssal, low-energy, oxygenated marine environments subject to periodic turbidity flows. The trace fossils are characterized by: (1) high diversity but low abundance; (2) complex horizontal grazing traces and patterned feeding/dwelling structures; (3) numerous crawling/grazing traces and sinuous fecal castings; and (4) structures produced by deposit feeders, scavengers, or possibly harvesters (Ekdale *et al.*, 1984). As presently understood, the *Nereites* ichnofacies is restricted primarily to flysch or turbidite sequences; sediments in the great expanses of seafloor beyond influence of turbidity flows consist chiefly of bioturbate textures rather than discrete traces hence there is no well-preserved record of specific ichnocoenoses.

Substrate controlled ichnofacies

The remaining three ichnofacies represent specialized, substrate-controlled tracemakers and, environmentally, are very general in scope. The *Glossifungites* ichnofacies develops in firm but un lithified substrates (i.e., dewatered muds) the *Trypanites* develops in fully cemented substrates, and the *Teredolites* ichnofacies forms in woody substrates. Such horizons may be critical markers in the evolving concept of sequence stratigraphy (see *Substrate-Controlled Ichnofacies*).

Evaluation of the models

These archetypical models, particularly the marine ones, have proven to be valuable indicators of general environmental conditions. For instance, except for a capping layer of planar bedforms, climbing ripples, or antidunes, primary physical sedimentary structures of fluvial point bars may be strikingly like those of estuarine point bars. However, biogenic sedimentary structures are very different in the two settings.

Perhaps the most misunderstood aspect of these recurrent ichnofacies is their use in paleobathymetry. Although some workers have been complacent in this aspect of environmental reconstruction (cf. Frey *et al.*, 1990), various ichnologists have long and persistently emphasized that local sets of environmental factors are most important in controlling the distribution of tracemakers, whether or not these parameters occur at specific water depths.

Nevertheless, many kinds of environmental parameters do tend to change progressively with water depth and distance from shore (grain size, energy levels, food resources, etc.), and these gradients affect corresponding changes in the distribution of physical and biogenic sedimentary structures. To

Seilacher's Concept of Recurring Ichnofacies

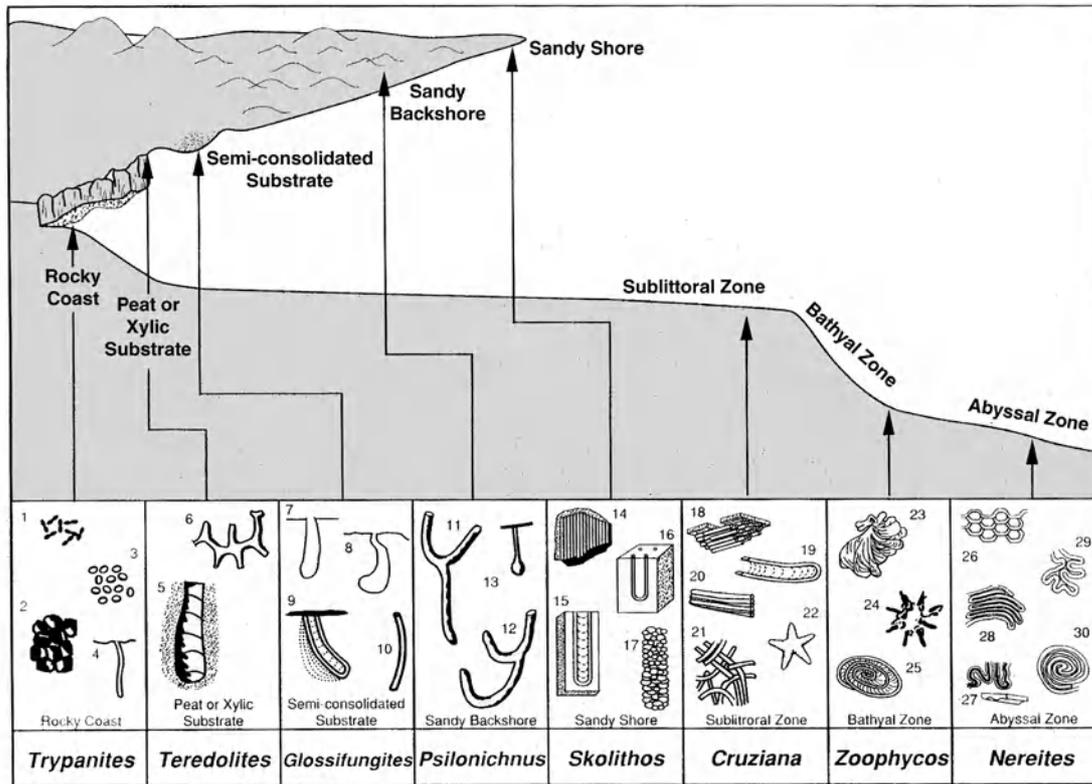

TRACE FOSSILS ➡ BEHAVIOR ➡ ENVIRONMENT

Trace fossils are a manifestation of behavior which can be modified by the environment.

ECOLOGICAL CONTROLS

The distribution and behavior of benthic organisms is limited by a number of interrelated ecological controls, including:

that extent, trace fossil associations are indeed useful in paleobathymetry.

Equally important is the long temporal duration of most kinds of trace fossils. These basic benthic behavioral patterns are more nearly like stable ecologic niches than individualistic records of particular animal species (Frey and Seilacher, 1980). As long as the functional niche remains advantageous under given environmental conditions, many different animal species, over long intervals of geologic time, may be expected to exploit it: their preserved traces are strikingly similar and have equivalent significance. Hence, although we conveniently speak of the “*Skolithos* animal” as the architect for a particular kind of dwelling structure, numerous different animal species actually were involved. The longevity of recurrent ichnofacies thereby exceeds the longevity of recurrent biofacies by a considerable margin, and are correspondingly more useful as archetypal models not only for environmental interpretation but also for comparisons of depositional environments of widely differing ages.

The purpose for recognizing these recurrent ichnofacies must not be overlooked. Interpreted in terms of the original trace fossil assemblage, these ichnofacies are merely archetypal facies models with which the local ichnofacies may be compared. The archetypes are intended to supplement, not supplant, local ichnofacies designations, some of which are quite distinctive.

The idealized ichnofacies succession works well in most “normal” situations (Frey and Pemberton, 1987), including distributions according to salinity gradients (cf. Bromley and Asgaard, 1991); yet one should not be surprised to find nearshore assemblages in offshore sediments, and vice versa, for example, if these accumulated under conditions otherwise like those preferred by the tracemaking organisms. The basic consideration rests not with such inanimate backdrops as water depth or distance from shore, or some particular tectonic or physiographic setting, but rather with such innate, dynamic controlling factors as substrate consistency, hydraulic energy, rates of deposition, turbidity, oxygen and salinity levels, toxic

CRUZIANA ICHNOFACIES

substances, the quality and quantity of available food, and the ecologic or ichnologic prowess of tracemakers themselves.

Finally, the models should not be divorced from associated patterns of bioturbation. Numerous local ichnofacies, particularly those representing low-energy conditions and slow rates of deposition, are set in a complex biogenic fabric. Several generations of burrows may be discernible via their crosscutting relationships, showing that the same volume of sediment passed repeatedly through various styles of reworking. In environmental reconstruction, such ichnologic fabrics may be equally as important as the individual, named trace fossils (Frey and Pemberton, 1984).

Paleoenvironmental significance of trace fossils

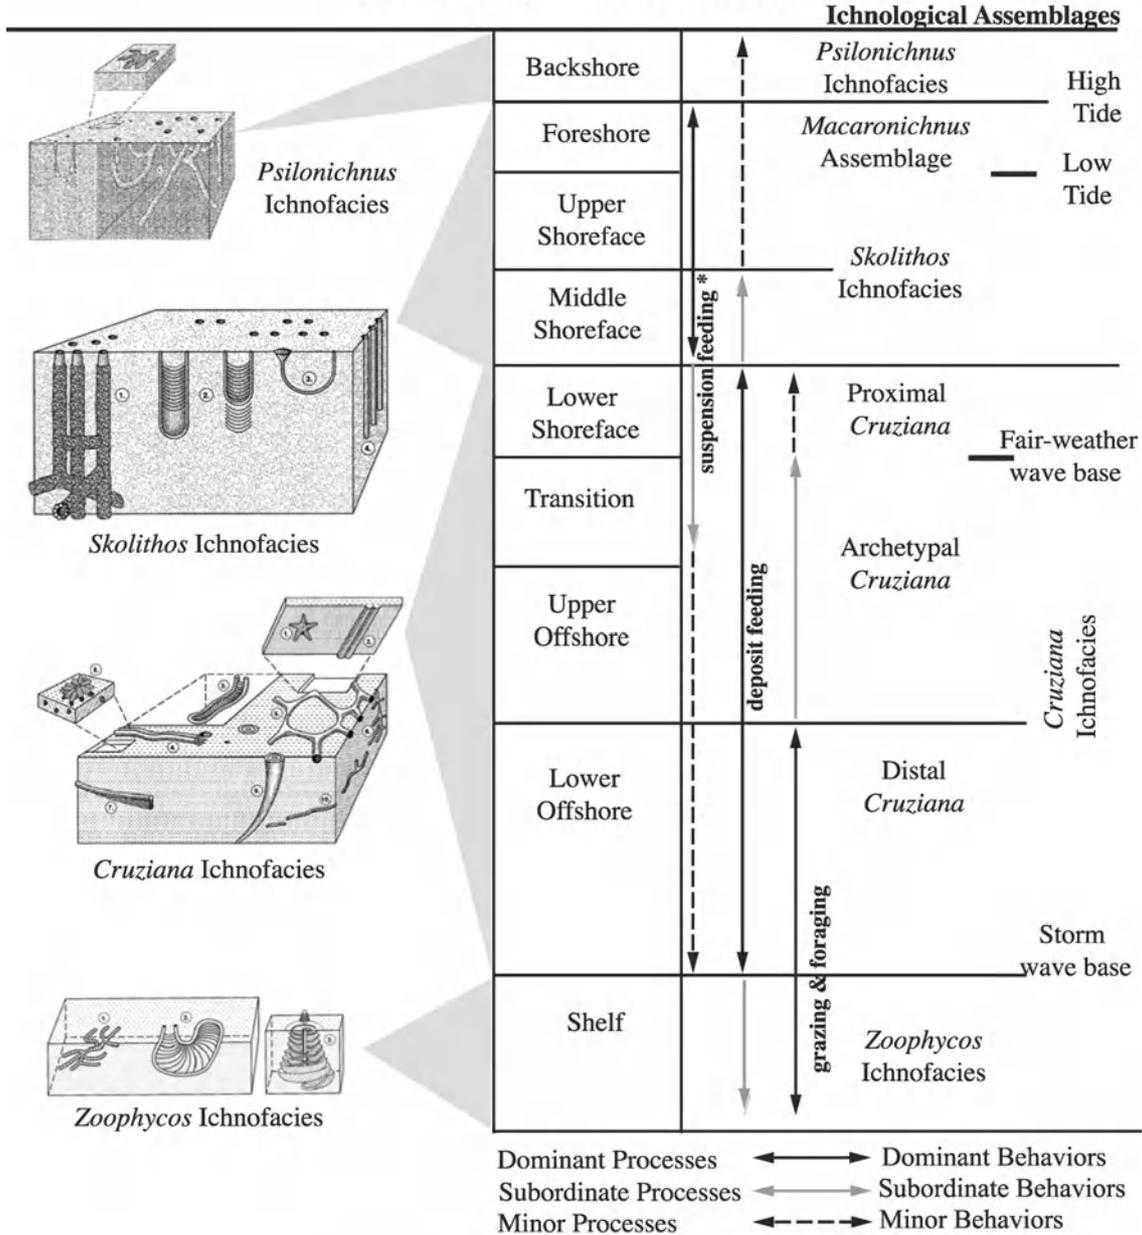

The concept of functional morphology, a basic premise employed by ecologists and paleoecologists in environmental reconstruction, is equally applicable to ichnology. In fact, trace fossils are unique in that they represent not only the morphology and ethology of the tracemaking organism but also the physical characteristics of the substrate; they are closely linked to the environmental conditions prevailing at the time of their construction. Frey and Seilacher (1980) re-emphasized that such variables as bathymetry, temperature, volumes of sediment deposited or eroded, aeration of water and sediment, and substrate coherence and stability, have a profound effect on resultant trace fossil distributions and morphology, and hence

can be used in the determination of original biological, ethnological, and sedimentological conditions.

The application of ichnology to paleoenvironmental analysis goes far beyond the mere establishment of gross or archetypal ichnofacies. For instance, shallow-water, coastal marine environments comprise a multitude of sedimentological regimes, which are subject to fluctuations in many physical and ecological parameters (see *Coastal Sedimentary Facies*). In order fully to comprehend the depositional history of such zones in the rock record, it is imperative to have some reliable means of differentiating subtle changes in these parameters. Detailed investigations of many of these coastal marine zones in Georgia have shown the value of utilizing biogenic sedimentary structures (in concert with physical sedimentary structures) in delineating them (Frey and Pemberton, 1987). The application of these studies in deciphering paleoenvironments has also proven invaluable. For example, the shoreface consists of a seaward-sloping sediment wedge extending from the low tide mark, generally to the fairweather (minimum) wave base, corresponding to approximately 10–20 m of water depth. The shoreface setting is dominated by wave energy and, as a result of decreasing wave interaction with the substrate in a seaward direction, shows a pronounced basinward fining. The shoreface is classically divided into three subenvironments (from seaward to landward): the lower, the middle and the upper shoreface. The boundaries between these are not always clearly defined (Reinson, 1984). Although the large-scale

regional context may vary, the specific subenvironments of the shoreface are not significantly different whether they occur as part of a strandplain, barrier island or wave/storm-dominated delta (free from interference from active distributary channels). The shoreface grades distally into offshore units and landward into foreshore deposits. A complete

shoreface progradational succession reflects offshore to foreshore environments; consequently, these adjacent environments bear inclusion in any discussion of shoreface deposits *per se*. There are several excellent outcrop examples of Cretaceous shoreface deposits in the Western Interior Seaway. The integration of the sedimentology and ichnology within

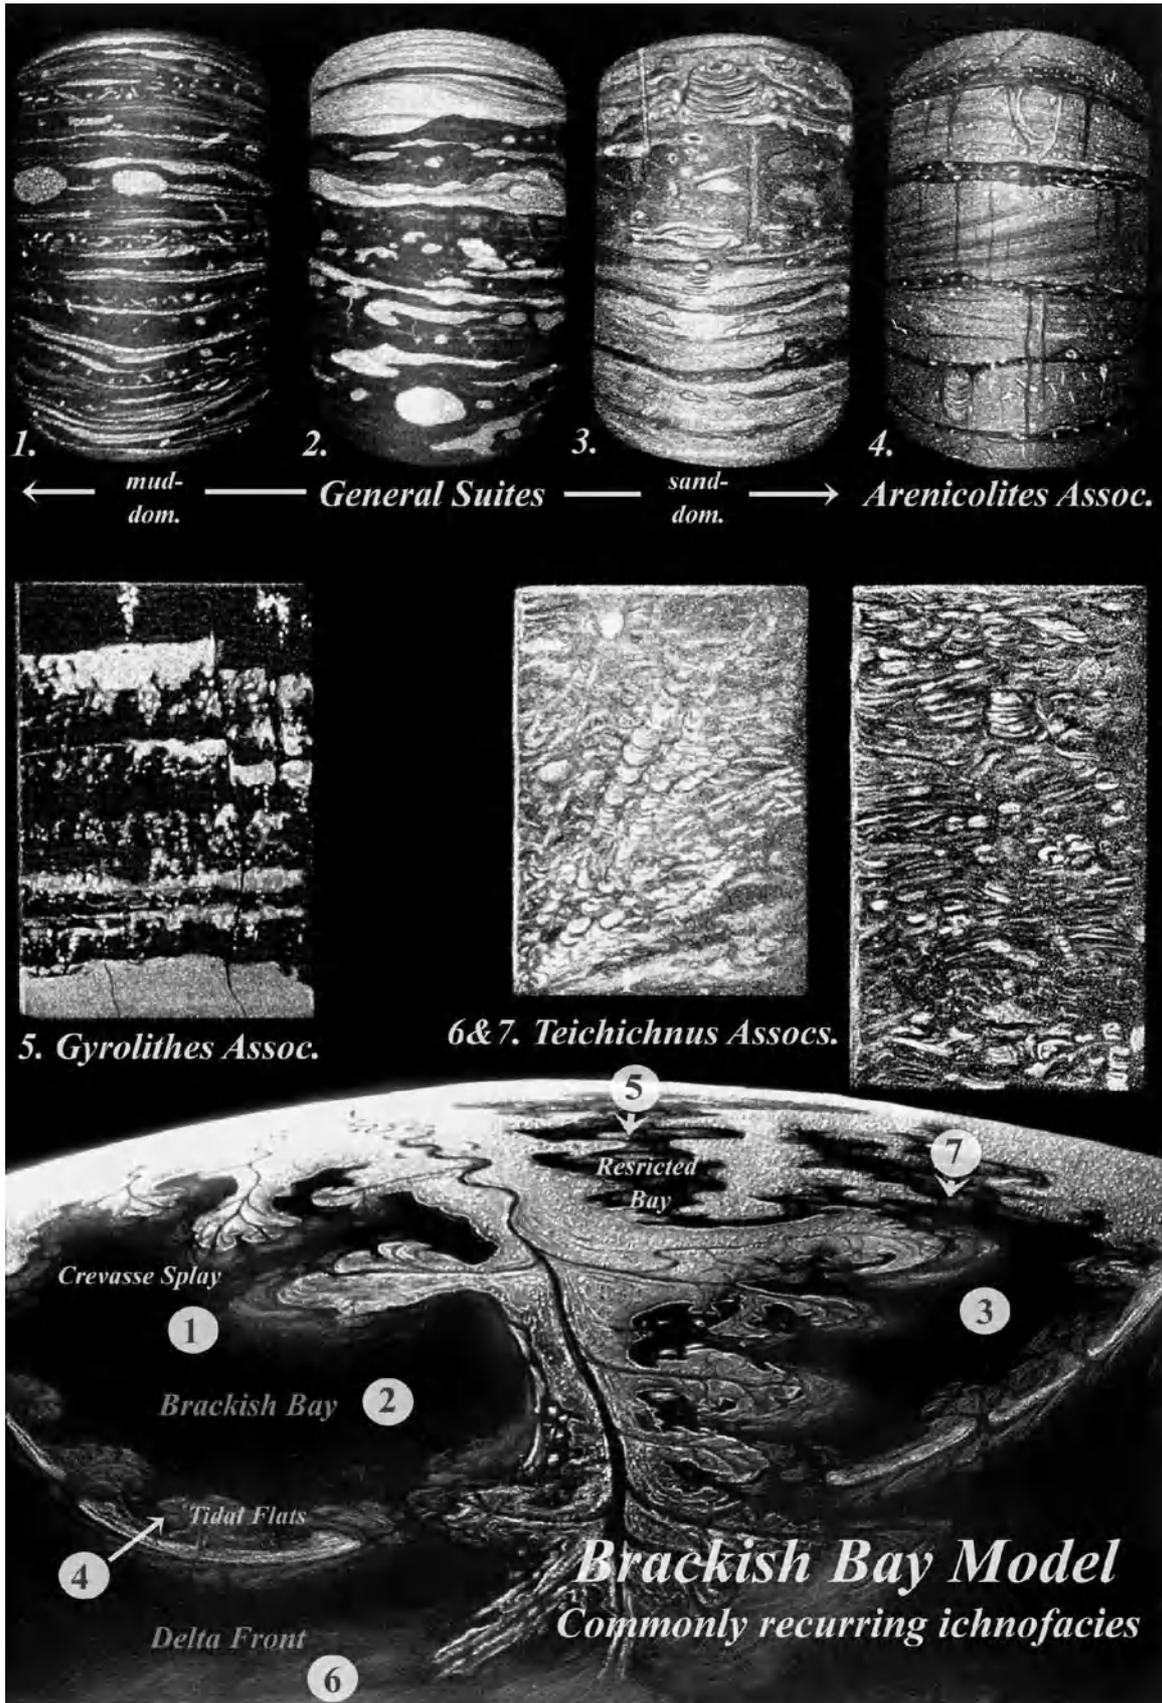

Figure B22 Schematic diagram of typical recurring trace fossil assemblages in brackish water bay-like environments (Modified from Pemberton et al., 2002).

these deposits affords the opportunity to characterize the facies and facies successions (Figure B21), and to explain the observed facies variability.

Hudson *et al.* (1995) recently stressed that Jurassic benthic molluscan assemblages in the Great Estuarine Group of Great Britain are controlled largely by salinity with different genera or groups of organisms characterizing a spectrum of mainly brackish water environments. As pointed out by Pemberton and Wightman (1992) salinity gradients also influence the nature of the ichnofauna. Although some behavioral patterns may occur on each side of the salinity transition, distinct ichnocoenoses are present in freshwater, brackish water and fully marine environments. Recently, marginal marine environments (including tidal channels, estuaries, bays, shallow lagoons, delta plains, etc.) have been recognized with more frequency in the rock record. Such environments characteristically display steep salinity gradients, which, when combined with corresponding changes in temperature, turbulence, exposure, and oxygen levels, result in a physiologically stressful environment for numerous groups of organisms. Brackish water bay-like environments include bays, sounds, lagoons, inter-distributary bays, and the central basins of wave-dominated estuaries to name just a few (Figure B22).

One of ichnology's greatest strengths, the bridging of sedimentology and paleontology, in some respects can be its greatest liability. Sedimentologists tend to use a strict uniformitarian approach to paleoenvironmental interpretation and rely heavily on modern analogues. Paleontologists, on the other hand, must temper their observations in the light of organic evolution. Although trace fossils can be considered as biogenic sedimentary structures and are difficult to classify phylogenetically, they are constructed by biological entities and are thus subjected at least to some degree to evolutionary trends. For example, occurrences of well-developed terrestrial trace fossil assemblages are much more prevalent in post-Cretaceous rocks. This development corresponds to the evolutionary explosion of the insects, brought on by the diversification of the angiosperms in the Late Cretaceous. Prior to this time terrestrial substrates may not have been as extensively bioturbated due to a paucity of tracemakers. Likewise, patterned grazing traces, which characterize deep-sea environments, show a trend toward more complex organization through most of the Phanerozoic. This trend may be related to the evolution of more efficient foraging strategies (Seilacher, 1986). For these reasons, paleoenvironmental interpretations based on trace fossils must be considered not in strict uniformitarian terms, but rather, in actualistic ones.

Equally important, unique quantitative environmental indicators are indeed rare in the geological record, and ichnology is no exception (Frey and Seilacher, 1980). However, trace fossils can supply a wealth of environmental information that cannot be obtained in any other way and which should not be ignored. Their potential usefulness is accentuated when fully integrated with other (chemical, physical, and biological) lines of evidence. Combined studies of physical and biogenic sedimentary structures constitute a powerful approach to facies analysis.

Summary

Ichnology and its significance to sedimentary geology is based on the following concepts:

(a) Biogenic structures represent the activity of soft-bodied organisms that are not generally preserved. Such

organisms (including many entire phyla) are commonly the dominant component of the biomass of many environments.

- (b) Biogenic structures are commonly enhanced by diagenesis and can be used in horizons where physical sedimentary structures have been masked. For example, in oil sands deposits bitumen staining obliterates most physical structures, but due to the concentration of clay minerals, it enhances the visibility of biogenic structures.
- (c) Biogenic structures can be associated with facies that do not contain any other fossils. In many siliciclastic regimes, diagenesis dissolves most of the shelly fauna and trace fossils represent the only clue as to the original biogenic component of the unit.
- (d) Biogenic structures can be used for the paleoecological reconstruction of depositional environments.
- (e) Biogenic structures are sensitive to fluctuations in sedimentary dynamics and are important in recognizing event beds and distinct sedimentation patterns.
- (f) Biogenic structures are sensitive indicators of substrate coherence and substrate-controlled ichnofacies are emerging as important elements in genetic stratigraphic paradigms.
- (g) Biogenic structures ordinarily cannot be transported and therefore represent the original environmental position of the trace making animal.
- (h) Biogenic structures are sensitive to changes in certain ecological parameters that are otherwise difficult to ascertain such as salinity and oxygen levels.
- (i) An integrated approach utilizing physical, chemical, biological, and ichnological lines of evidence constitutes a powerful tool for facies interpretation.

BLACK SHALES

Black Shales are fine grained, generally organic carbon-rich sedimentary rocks that primarily consist of a mixture of clay minerals, quartz silt, organic particles (mostly planktonic algae and plant debris), and kerogen. They may also contain variable amounts of disseminated finely crystalline calcite and dolomite, as well as phosphate (commonly as concretions). Most black shales are found in marine sediments (Potter *et al.*, 1980), but they can also form prominent deposits in lacustrine successions (Bohacs *et al.*, 2000). Their black color is due to two constituents: (1) the contained organic matter, and (2) finely disseminated pyrite. The reducing conditions indicated by the latter have long led geologists to believe that ancient black shales required anoxic bottom waters for their formation, and were a typical deposit of the distal, deepest portions of sedimentary basins (via comparisons with the abyssal Black Sea where carbonaceous muds currently accumulate).

The Black Sea is a stratified, silled basin, in which a lower marine water body is overlain by a layer of brackish water due large input of freshwater from rivers. Because of density contrasts a halocline is developed at a depth of approximately 200 m, severely restricting vertical advection of oxygen-rich surface waters. Oxygen demand by decaying and descending

organic matter exceeds oxygen replenishment by vertical advection, rendering the water column beneath the halocline anoxic and facilitating the accumulation of organic-rich muds. These observations have suggested to many geologists that organic carbon enrichment in the bottom sediments was basically a result of enhanced preservation (Wignall, 1994).

Although the Black Sea model dominated the study of black shales for many years, it is of limited use when studying ancient black shales. A major difference between the Black Sea and practically all black shales in the rock record is that the substantial depth (~2000 m) of the former, in conjunction with a stable halocline, greatly restricts circulation, whereas ancient black shales accumulated in much shallower epicontinental seas with a much larger width/depth ratio. Thus, on a geologic timescale at least, storms should have caused frequent mixing of the water column. With continued research into the origin of black shales, many occurrences that were initially interpreted according to the Black Sea model, are now in the process of re-evaluation.

Evolving views of the origin of the Late Devonian Chattanooga Shale of the eastern US may serve as an example for these changing perspectives in black shale deposition. On the basis of well developed fine lamination and apparently little evidence of benthic life, it was initially thought of as a very good representative of a basin with a stratified water column, and enhanced preservation as the primary cause for black shale accumulation. Recent research, however, has uncovered abundant evidence for wave reworking and intermittent erosion (Figure B23) of black shale (Schieber *et al.*, 1998). The observation that erosion surfaces of the type illustrated in Figure B23 can be traced for hundreds of kilometers actually forms the basis for a sequence stratigraphic interpretation of this succession (Schieber, 1998). Careful examination of shale fabrics has also revealed subtle but nonetheless widespread evidence (bioturbation features mostly) for benthic colonization of the seafloor. The high organic carbon contents in the Chattanooga Shale (up to 20 per cent) initially suggest that preservation due to oxygen restriction may have been mainly what controlled its accumulation. Yet, sedimentary and bioturbation features suggest that anoxia, if they indeed occurred, were intermittent, due to frequent water column mixing by storms or seasonal temperature variations. In the case of the Chattanooga Shale, therefore, surface productivity probably was also an important factor for organic carbon enrichment (Schieber *et al.*, 1998).

Although the “deep anoxic basin” model has enjoyed prominence for many years, when we look at black shales more closely we find increasingly that they can actually form in a wide range of depositional settings. Black shales do not constitute a large proportion of the sedimentary rock column, but they are of great economic interest as the main source rock for hydrocarbon production, as well as containing unusually high metal concentrations (Potter *et al.*, 1980). Estimates suggest that more than 90 percent of the world’s recoverable oil, and gas reserves were generated from black shales (Klemme and Ulmishek, 1991). Equally significant is the fact that the latter are restricted to six stratigraphic intervals that represent a mere one third of Phanerozoic time (Silurian, Upper Devonian-Tournaisian, Pennsylvanian-Lower Permian, Upper Jurassic, Middle Cretaceous, Oligocene-Miocene).

Because organic carbon results from photosynthesis by plants and algae, each atom of carbon buried implies a molecule of oxygen added to the atmosphere. Carbon burial is

Figure B23 Erosion surfaces in the Chattanooga Shale (entire exposure consists of black shale). Picture shows truncation of black shale packages by erosion surfaces (dashed white lines marked with large white arrows), and illustrates how succeeding black shale packages are draped conformably over these erosion surfaces. Small white arrows point out truncation of shale beds by erosion surface. In places erosion has removed in excess of 1 m of black shale between successive black shale packages (at a total Chattanooga thickness of less than 10 m).

linked to other global biogeochemical cycles and is a critical variable in our attempts to understand the history and evolution of the oceans and atmosphere, as well as global climate change. Over geologic time, carbon burial probably was responsible for a gradual rise in atmospheric oxygen levels. Also, by reducing the greenhouse effect it can lead to lower global temperatures and even ice ages (Bernier, 1997). In that context, considering that the geological record is punctuated by global episodes of widespread black shale formation (Klemme and Ulmishek, 1991), understanding what combinations of variables are required to produce a “black shale world” is of considerable significance.

Three factors control organic matter accumulation in sediments: (1) organic matter input; (2) organic matter decay; and (3) dilution of organic matter by other ingredients. Factor 1, organic matter input, has two components, detrital organic matter washed in by rivers and organic matter from primary production in the water column. The latter is strongly dependent on nutrient availability. Factor 2 relates to breakdown of organic matter, mostly by microbes. Its efficiency and the types of bacteria involved depend on oxygen availability in the water column and the sediment. Factor 3, dilution, has a terrigenous component (fluvial and eolian contributions), and an intrabasinal component of skeletal remains (e.g., coccoliths, radiolaria, foraminifera, diatoms, etc.). The fluvial component is linked to climate and relief in the source region, and to sea level fluctuations. Because the magnitude of this component rises and falls with continental runoff, it is directly linked to the nutrient input that impacts primary production. Relief and sediment supply are linked to tectonism, which in addition can affect subsidence rates, basin geometry, and water depth (Schieber *et al.*, 1998). Because each factor is a function of several other variables that are in part cross-linked to other factors, determining the magnitude of each of these factors in the rock record is far from trivial. Obviously, black shale formation is a multifaceted problem and depending on the interaction of the variables, there are multiple scenarios that

are conducive to black shale formation (Tyson and Pearson, 1991). Microbial mats can also promote accumulation, and preservation of organic-rich sediments in a wide range of environments (Schieber, 1999), a currently under appreciated fact (see *Microbially Induced Sedimentary Structures*).

Black shales are not only common in thick, basinal, successions, but also occur as thin tongues within basin-margin successions. The latter are thought to owe their existence to high stands of sea level when terrigenous input was at a minimum, and as such may mark maximum flooding surfaces (Creaney and Passey, 1993). Whether these shallow water black shale tongues reflect deposition beneath a nearshore zone of oxygen restriction, or simply are the outer edge of an expanding anoxic water body that usually occupies the basin center (Wignall, 1994), is still being debated. Nearshore oxygen restriction could, for example, be produced by salinity stratification due to freshwater plumes, or by high nearshore productivity fueled by nutrients in continental runoff. Alternatively, rapid sea-level rise could have caused expansion of central anoxic water bodies into shallow nearshore waters. Recent efforts to integrate black shales into a sequence stratigraphic context suggest that at the onset of transgression, black shale deposition may commence in the basin interior, that nearshore black shale deposition is possible early in transgressions, and that black shales related to maximum flooding can form during high stands of sea level (Wignall, 1994; Schieber *et al.*, 1998). Sea level variations may also have led to conditions with recurring water column mixing events and recycling of key nutrients (N, P) to surface waters, making possible a “productivity-anoxia feedback” mechanism to maintain high rates of carbon burial (Ingall *et al.*, 1993).

Black shales are the end product of the complex interplay among a range of geologic variables and processes, and there are no easy answers and no “one size fits all” models. The seemingly drab and uniform nature of many of these rocks poses a considerable challenge and requires us to extract

information by all means possible. Sedimentological study includes recognition and tracing of facies changes, sedimentary features, shale fabrics, erosion surfaces and internal stratigraphy, as well as information that can be derived from interbedded non-shale lithologies. Paleontological studies may provide data on paleo-oxygenation, primary production, substrate conditions, paleocurrents, bathymetry, and paleosalinity (Schieber *et al.*, 1998). Petrographic investigations provide the basic inventory of shale constituents, and may yield clues about provenance, compaction history, sedimentary processes (via small scale sedimentary structures), the origin and maturation of organic matter (Taylor *et al.*, 1998), and even paleo-oxygenation (via analysis of pyrite framboid size distribution; Wilkin *et al.*, 1997). Chemical analysis of major and trace elements can provide information on provenance (Roser and Korsch, 1986), and a range of proxies for paleo-oxygenation (Jones and Manning, 1994). Organic geochemistry can furnish information on the source of organic matter, its dispersal, and maturation (Engel and Macko, 1993). Certain organic molecules, such as photosynthetic pigments, may survive as "carbon skeletons" (biomarkers), and may identify the original source of diagenetically altered organic matter and potential indicators of water column anoxia (Brassell, 1992).

Summary

Black shales do not give up their secrets easily. The tools are at hand, however, to extract a wide range of data from them and allow for multiple avenues of inquiry. Past experience shows that interpretation from just one perspective (e.g., petrography, fabric study, trace element geochemistry, or organic geochemistry) leads to conclusions that often are in conflict with those coming from a different line of inquiry. Black shales need to be investigated in a multidisciplinary way and at multiple scales because of the complex interplay of variables that produces them. Conclusions derived from microscopic features must be in agreement with insights coming out of basin scale studies, as well as with findings from all scales in between. Once this is accomplished, patterns are likely to emerge that will not only tell us the critical factors for the formation of a specific example of a black shale, but also reveal the fundamental conditions that make a "black shale world" tick.

BRAIDED CHANNELS

Characteristics and definitions

Braided channels are a distinctive alluvial river morphology characterized by multiple, inter-woven branches separated by ephemeral braid bars (Bridge, 1993, Figure B24). Braided channels are also distinguished by the bewildering rapidity and complexity of the plan-form changes, channel migration and bar development processes during periods of high flow and intense bed load transport. There are several different descriptive criteria for defining braided channels (Bridge, 1993) but no strict quantitative criteria. Braided and anastomosed were originally synonymous but they are now regarded as distinctly different types of river morphology. Braided channels form in non-cohesive sand and gravel and are often associated with glaciated mountain regions but also occur on alluvial fans, interior and coastal plains, and in a variety of climatic regions.

The braided appearance varies with flow stage but even at high flow, when many bars are partially submerged, flow and bed-load transport in a braided channels remains divided

Figure B24 A reach of the braided gravel-bed Sunwapta River, Canada. Flow is left to right and length of channel shown is about 500 m. National Air Photo Library (Canada) A31610-32.

among several branches. Thus, the appearance of braiding caused only by local erosion of minor channels on bar surfaces during falling flow stage is excluded from the definition. The degree of braiding (braiding intensity or braid index) is measured either by the average number of branches across the river, or the total length of all branches relative to the length of the river segment (Bridge, 1993).

Causes and development of braiding

Braiding occurs spontaneously in unconfined flow over mobile, non-cohesive sediment (Paola, 2001). It occurs in rivers in which stream power is high relative to the size of sediment in the river (van den Berg, 1995). The transition to braiding occurs at much lower stream power in fine-grained sediment (sand) than in gravel or cobbles. High stream power (steep gradients and/or high discharge) contributes to development of a large width/depth ratio which is identified, theoretically, as a fundamental control on the occurrence of braiding and this, in turn, may be a response to a large sediment supply rate relative to the discharge (causing steeper gradient) and/or low bank resistance. Bank resistance due to cohesive bank material or vegetation cover inhibits braiding (Ferguson, 1987). Braiding can occur at a constant discharge so that variability of flow is not a primary factor, except that occasional large floods may cause a transient braided morphology, especially if the river is already close to a braided state. Aggradation is not necessary for braiding but short-term increases in sediment input may cause braiding or an increase in degree of braiding.

Beginning from a straight channel, braiding develops from the formation of single (alternating) bars, single mid-channel bars or multiple (laterally), mid-channel bars. These are low-amplitude bedforms, with a linguoid or diagonal crest, sometimes having downstream avalanche faces. Bars occupy most of the channel width, have a length several times the channel width and are connected to upstream scour pools. The bars cause development of channel sinuosity and braiding follows by either cut-offs of single-row bars or by bifurcation around mid-channel bars (Bridge, 1993, Figure B24). The braided pattern is maintained by repetition of these processes in the individual channels of the braided network because of the inherent instability of individual channels, the large stream-wise and temporal variations in transport rate and the frequent re-distribution of the river discharge among the individual channels. New channels may also form by avulsion of flow between branches and re-occupation of abandoned branches.

Morphology and bed material transport processes

Braided channel morphology follows similar functional relations to that of single channel streams. The braided channel is a network of branches, with links of varying length and nodes formed by channel confluences and bifurcations. The average distance between nodes (and, therefore, the length of braid bars), scales with the discharge of the whole channel, in much the same way as the wavelength of meanders in single channels (Ashmore, 2001). This length scale is related to the bars and bends formed within the individual branches, which often

closely resemble low-sinuosity meanders. The cross-section dimensions of branches follow hydraulic geometry relations very similar to those of single channel streams. In addition, the total width of braided channels (the sum of individual branch widths) varies in proportion to the square root of the discharge of the whole channel, as it does for single channel streams. Finally, the braiding intensity tends to increase with increasing total stream power and with finer bed-material grain size.

After initiation of braiding, braid bars grow and develop by episodic deposition associated with migration of the adjacent channels and the downstream migration or progradation of submerged bars or gravel sheets. In simple cases the process resembles the development of back-to-back point bars in a single channel, although the two sides of the bar need not develop simultaneously. However, in most cases, bars are built in complex sequences involving both progressive deposition and erosional modification. Systematic gradual accretion related to steady migration in one direction is largely absent because of the rapid and erratic shifts in channel configuration that characterize braided channels. Bed scour occurs in bends of individual branches but is greatest at confluence zones, which often have bars deposited immediately downstream. The orientation of confluence zones may change rapidly in response to migration of the upstream channels and changes in their relative discharge and sediment load, with the result that the confluences act as control points for the downstream distribution of sediment, sending it in different directions as they change orientation.

The rapid, unstable changes in channel morphology cause large spatial and temporal variations (at least 10 fold) in the total bed-load transport rate in braided rivers at a given (constant) total discharge (Shvidchenko and Kopaliani, 1998). Average total bed-load transport rate for braided rivers correlates well with variation in total stream power or discharge, but the local and short-term rates are extremely variable so that transport rate appears to be controlled more by local triggering of abrupt channel changes than by hydraulic conditions. Although braided channels have multiple branches, it is likely that bed-load transport at any particular time is restricted to only two or three branches, even at high flow stages.

Prospect

While the main elements of the morphology and dynamics of braided channels have been described, quantitative

understanding of the morpho-dynamics is still rudimentary (Ashmore, 2001), in part because of the difficulties of obtaining field data from these vigorous rivers. However, the combination of improved field technology, continued use of physical models, recent theoretical advances and the development of numerical models that can reproduce basic elements of the known characteristics of these rivers (Paola, 2001), promises to stimulate rapid advances in understanding braided river morpho-dynamics and therefore of the formation and characteristics of braided river sediments.

CALCITE COMPENSATION DEPTH

The calcite compensation depth (calcite compensation depth), a term coined by Bramlette (1961), is the depth in the oceans at which the rate of calcium carbonate accumulation equals its rate of dissolution. Dissolution of carbonate being supplied from the surface waters increases progressively with depth, thus the calcite compensation depth is the level at which the net accumulation of calcite is zero. The calcite compensation depth is often compared to the snow line along a mountain front where the supply of snow is exactly balanced by melting, leaving the elevations above draped with snow. By analogy, the seafloor and bathymetric highs in the oceans above the calcite compensation depth are draped in carbonate sediment.

The discovery that carbonate is largely absent in the oceans below about 4,500 m as a result of selective dissolution of carbonate goes back to the *HMS Challenger* expedition of the 1870s. Today, it is well established that the depth of the calcite compensation depth varies throughout the modern oceans, being in general deeper in the Atlantic than the Pacific. Similarly, the North Atlantic is more carbonate-rich than the South Atlantic, and there is variation among the sub-basins of the latter, this being a function of the circulation patterns within the oceans (Berger, 1970).

The ultimate sources of calcium carbonate to the oceans are riverine input from the weathering of terrestrial rocks and contributions from hydrothermal vents along the mid-ocean ridges. Carbonate is extracted from seawater biochemically by calcite- or aragonite-secreting benthic, nektonic, and planktonic organisms that form tests or skeletons, mainly within the photic zone. Beyond the shallow-water carbonate banks and atolls, which are dominated by megafaunal organisms, the tests of micro- and nanoplankton account for most of the carbonate "snow" supplied to the seafloor. Much of this material is packaged and transported to the bottom as fecal pellets produced by grazing organisms such as copepods (Honjo, 1976), where it accumulates above the calcite compensation depth as nannofossil, foraminiferal, and more

rarely, aragonitic pteropod ooze. Geographically, the rate of supply of pelagic carbonate may vary across the oceans by a factor of 10, depending on the biological productivity. Productivity is generally highest along the margins of oceanic gyres where upwelling is induced, as along the equatorial divergence. Conversely it is lowest in the gyre centers. Hence the calcite compensation depth is deepest along the equatorial Pacific and along some coastal upwelling zones.

Dissolution of carbonate at depth is a function of the corrosiveness of the water, which increases with depth along with decreasing carbonate-ion content, decreasing temperature, increasing hydrostatic pressure and increasing partial pressure of CO₂. Carbon dioxide is produced by the respiration of organisms and the combustion of organic matter, and tends to increase toward the ocean floor. Field experiments have verified laboratory and theoretical predictions that the oceans should be undersaturated with respect to calcium carbonate beneath the upper few hundred meters (Figure C1). This relationship was quantified during experiments where calcite spheres and later foraminiferal and nannofossil assemblages were suspended at intervals along deep-moored buoys in the oceans. Calcite loss indicated that a marked increase in dissolution occurred at around 3,700–4,000 m, a level named the "lysocline" (Berger, 1967), below which rapid dissolution ensues until the calcite compensation depth is reached. The lysocline may coincide with water mass boundaries, such as the top of the Antarctic Bottom Water in the South Atlantic.

Further experiments and observations, particularly those from the first four cruises of the Deep Sea Drilling Project, showed that planktonic foraminifers are more susceptible to dissolution than calcareous nannofossils, probably because of a lower magnesium content in the calcite lattice of the latter. More dissolution susceptible still are the aragonitic pteropod shells. Hence progressively deeper compensation depths and lysoclines could be measured for these various groups. Furthermore, it was conclusively demonstrated that the levels of these calcite compensation depths have varied throughout Mesozoic and Cenozoic time. Studies of these variations (e.g., Ramsay, 1974) have laid the groundwork for calculations of global carbonate sediment budgets over geologic time. Such

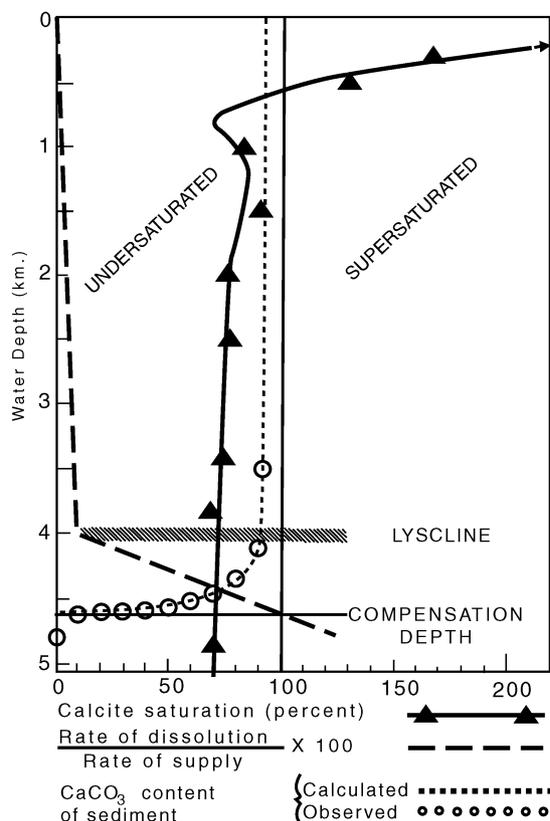

Figure C1 Characteristics of the oceanic water column that affect the dissolution of calcium and the level of the CCD (from van Andel *et al.*, 1975, figure 24).

studies must take into account the partitioning of carbonate deposition between epiric seas and continental margins, carbonate platforms and atolls, and the deep sea, all of which affect the level of the calcite compensation depth. The refinement and extension of these kinds of studies is a fruitful area for future research.

CALICHE – CALCRETE

Calcrete, a term effectively now synonymous with caliche, refers to near surface, terrestrial accumulations of predominantly calcium carbonate within soil profiles, the vadose zone or associated with shallow groundwaters, where waters are saturated with respect to calcium carbonate (Wright and Tucker, 1991). In the past these terms have been used in a much more general way to describe any surface or near surface type of carbonate occurrence. There are problems with the currently used definition and the terms are not used to describe tufas, travertines, beachrocks or cemented dunes even though all these could be regarded as falling into the basic definition. Suggestions have been made to limit the usage of the terms to carbonate accumulations in soil or paleosol profiles, however the similarities between many pedogenic (soil formed) calcretes and ones developed in the phreatic zone indicate that the mechanisms of formation are so similar that to restrict the term to one type of setting would be wholly artificial. Goudie (1973) provides a detailed review of terminology and Milnes (1992) gives an historical review of the ideas on calcrete development. Dolocretes are calcretes in which the dominant mineral is dolomite, typically as a primary precipitate, although it can be replacive after calcite.

The terms are most commonly used for indurated materials but many forms are only weakly cemented, and powdery and granular types are known. During the development of calcrete horizons or profiles there is a tendency toward induration and increase in the bulk content of carbonate as a result of progressive cementation, coupled and displacive and replacive introduction or redistribution of calcium carbonate into a host material. That host could be soil, sediment (including carbonate sediments), or bed rock.

Morphology

A very wide range of morphologies are known from laminar, nodular, powdery, mottled, massive, rhizcretionary (composed wholly or partly of the calcareous remains or coatings around roots), pisolitic, prismatic, platy, and brecciated (Netterberg, 1967, 1980; Goudie, 1983). The term 'hardpan' is commonly used to describe highly indurated horizons. Laminar forms are particularly distinctive, and can form in a variety of settings (Wright and Tucker, 1991).

Classification and development

The simplest way to classify calcretes is to use their morphology and many calcretes exhibit only one or two basic morphologies. However, it is common to see regular relationships between the morphology and the amount of secondary carbonate in the calcrete, such that it is possible to define profiles with two or more horizons which exhibit different

morphologies (Gile *et al.*, 1965). It has long been known that calcretes exhibit a progression in development from small, dispersed concentrations to massive horizons, especially in pedogenic forms, and this has been used as the basis for widely used classifications by Gile *et al.* (1966) and Machette (1985). These classifications are particularly useful for describing calcretes developed in siliciclastic sediments where the growth of carbonate nodules is a distinctive feature. However, calcretes formed in carbonate hosts develop differently and lack distinct nodules but commonly display sub-horizontal to sub-vertical sheets of secondary carbonate known as stringers (Wright, 1994). The growth of discrete carbonate nodules requires some element of displacive growth, which is triggered in non-carbonate hosts by the inability of calcite to form adhesive bonds with non-calcitic grains such as silica. However, in carbonate-rich hosts calcite forms cohesive bonds with other carbonate crystals (Chadwick and Nettleton, 1990). A slightly modified version of the Machette classification is used to describe calcretes produced largely or wholly by roots (Wright *et al.*, 1995).

The progressive, time dependent development of the features in these calcretes can be used to define chronosequences. By dating the geomorphic surfaces associated with the different stages of calcrete development, it has been possible to identify time ranges required for their development. These approximate time intervals can even be used, with care, to identify relative (not absolute) time relationships in ancient successions (Leeder, 1975; Wright and Marriott, 1996).

A critical distinction must be made between pedogenic and groundwater calcretes. The former, more easily studied in soil pits and excavations, and widespread in the stratigraphic record in red bed successions, are what most sedimentologists will encounter and for which we have well documented modern analogues. What is less well appreciated is that in many regions, especially Australia and Oman, there are extensive areas of carbonate cemented alluvium, petrographically similar to some forms of pedogenic calcrete, produced by cementation and replacive growth of carbonate from shallow groundwaters (Arakel, 1986). Few ancient examples have been documented but more remain to be discovered and Pimentel *et al.* (1996) provide criteria for their recognition.

Most calcretes do form in soils yet there are no soils called calcretes. Accumulations of calcium carbonate are prominent features of several major soil orders including the aridisols, alfisols and vertisols. Pedogenic calcretes form horizons (ca horizons) within soil profiles, but in many cases they are sufficiently prominent to develop several horizons constituting a sub-profile within the main profile. These can be referred to a K horizons with various sub-horizons designated K2, etc. (Gile *et al.*, 1965). Thus it is technically incorrect to refer to calcrete soils or calcrete paleosols, when what is meant are calcrete-bearing soils (e.g., aridisols or alfisols).

Distribution

Calcretes occur in almost all climatic regions. A net moisture deficit is required whereby soil solutions become concentrated enough for carbonate precipitation to be triggered (commonly biogenically). If the moisture regime is arid or hyperarid there may be too little moisture to generate and transport the carbonate in solution. Climates with a strong seasonally moisture regime, with a prolonged dry season, are the ones most likely to produce soil carbonates. However, if the

through put of soil water in the wet season is too great, the precipitates of the dry season may be leached away. There is a relationship between the depth of carbonate accumulation in a soil and the mean annual rainfall (Retallack, 1994). Clear proof that calcretes are unreliable climate indicators comes from their occurrence in cold or cool temperate climates, and even free draining limestone gravels in northern England can develop meter-scale horizons with fabrics identical to calcretes formed in Mediterranean climates such as north-east Spain and South Australia (Strong *et al.*, 1992). Groundwater calcretes appear to also develop in areas where there is a strong moisture deficit such that shallow, alkaline groundwaters become highly concentrated.

Sources of carbonate and mechanisms of formation

Pedogenic carbonates are illuvial in origin, meaning that the carbonate is leached from the upper soil horizons, transported in solution and reprecipitated at depth. There are several likely sources for the carbonate; wind blown dust is the most likely source (Machette, 1985), especially in carbonate-poor hosts. Evaporation, evapotranspiration, and degassing are regarded as major mechanisms causing carbonate precipitation in soils. In the case of groundwater calcretes precipitation by the common ion effect is a contributory process. Precipitation triggered directly or indirectly by biological processes is widespread, with fungi playing a key role in the indirect precipitation of carbonate. Plant roots act in a variety of ways to fix carbonate in soils. Surprisingly, despite bacteria having the potential to precipitate calcite in soils, there are very few records of such a process having contributed to calcretes. There is a growing body of evidence that specific vegetation types can produce different calcretes, for example, the distinctive calcretes of north-east Spain appear to be produced by fungal activity associated with pine tree root mats (Wright *et al.*, 1998).

Uses

Calcretes have been used in many countries for road construction. Groundwater forms are the hosts for extensive vanadium and uranium deposits (Arakel, 1982). They have been used extensively in paleoclimatic reconstruction, and studies of their O and C stable isotopes have proved invaluable for such diverse purposes as determining paleovegetation, paleotemperatures and paleoatmospheric composition (Cerling, 1999). Calcretes can present problems for soil management as hardpans can prevent infiltration by water and promote soil erosion.

Controversies and future research

There are many unresolved issues relating to calcretes. We understand little about the actual causes of precipitation in many cases. The origin of the ubiquitous laminar calcretes is still debated (Verrecchia *et al.*, 1995). The exact origin of calcrete structure *Microcodium*, which constitutes the bulk of many Cainozoic paleosols in Europe, is still unresolved and hotly disputed (e.g., see Freytet *et al.*, 1997). We need a much better understanding of the rates of formation of calcretes before we can use them for time resolution in the fossil record. A problem is that even where we have age ranges for individual stages of calcrete development from Quaternary deposits we

cannot simply extrapolate because even though a calcrete occurs beneath a surface that is 150 K years old it does not mean that calcrete formation was continuous and uniform over that interval of time. Considering the complexities of climate and vegetation change during the Quaternary calcrete growth may have only taken place during a small part of that time interval. Whereas progress has been made in understanding the diversity of biogenic fabrics in many calcretes, we understand little about the crystalline textures typical of calcretes found in modern deserts and in ancient red bed successions. Of critical importance is a better appreciation of the link between the characteristics of calcrete profiles and specific vegetation types, as this could provide a new approach to using calcretes for paleoenvironmental reconstruction.

CARBONATE DIAGENESIS AND MICROFABRICS

The four decades from about 1950 are of interest because they encompassed a flowering of our understanding of the carbonate fabrics we see with the microscope. The history of this period is dealt with in greater detail in Bathurst (1993: errors no fault of author) with extensive references. This growth from a topic that was almost unheard of in universities (my “sedimentary petrology” lessons in the postwar years were limited to the optical identification of sand grains) was much helped by funding from the oil industry.

The use of the microscope is only a natural extension of field work. What insight had William Blake when he wrote “To see a world in a grain of sand”. Until the 1950s, the study of sedimentary petrology (as it was then known) was rare, and that of diagenesis virtually unknown. However, by then, the economic importance of underground sources of water and hydrocarbon was clearly apparent and the study of sedimentology took wing. The foundations upon which post-World War II researchers had to build were noble but scant. Sorby (see *Sedimentologists*), in his paper to the Geological Society of London in 1897, had grasped the skeletal composition of limestones, also the dissolution of aragonite with simultaneous precipitation of calcite, as space filler or replacement. Cullis, in his communication to the Royal Society in 1904, had described the cores of the Pacific Funafuti Atoll, much helped by the two stains, Meigen and Lemberg, to distinguish aragonite, calcite, and dolomite (see *Stains for Carbonate Minerals*). Vaughan (see *Sedimentologists*), in 1910, publishing from the Laboratory on Dry Tortugas (all that remains now is a memorial plaque on the beach) had analyzed a variety of marine sediments, and Black (who taught sedimentary petrology in the University of Cambridge) had, in 1933, revealed the importance of

cyanobacteria in the Bahamas. Cayeux (see *Sedimentologists*), in 1935, had provided a superb range of black and white photomicrographs. Sander in 1936 (English version 1951) in a book remarkable for its scientific discipline, had given us the terms “geopetal”, “internal sediment”, and “fabric” (from “gefüge”). Hadding (1941–1959) had written superb analyses of Swedish Paleozoic limestones.

The first sign of a new start came from work in the universities. From Cambridge, in 1954, Illing made a major lithofacies study of the sediments on the Great Bahama Bank. From Liverpool, Bathurst, in 1958 and 1959, offered criteria, based on metalurgical fabrics, for distinguishing space-filling from replacement calcite. At much the same time, in the University of Texas, Austin, Folk (see *Sedimentologists*) gave us in 1959, the extremely successful system for recognizing limestone types, such as biomicrite and biosparite. An extraordinary group of workers in Shell Development Company were producing innovative ideas: for example Ginsburg, in 1956, continuing his earlier research done in the University of Miami, published an extensive study of the Florida seafloor. Murray, in 1960, examined a range of porosity-forming processes and Dunham, in 1962, 1969, and 1971, compiled a classification of allochems involving the valuable concepts of “grain-supported” and “mud-supported”, also “vadose silt” and “meniscus cement”.

Now a search could be made for diagenetic environments. Where had lithification taken place? Ginsburg in 1957, showed that the Pleistocene Miami Oolite, while friable in seawater, was cemented with calcite in freshwater. The supply of carbonate for the calcite came from dissolved aragonite. Schlanger in 1963, confirmed that freshwater lithification had taken place just below unconformities. Research on the Pleistocene of Bermuda in the 1960s, by Friedman, Gross, Land, Mackenzie, and Gould, led to a concept of freshwater lithification, the new calcite being regarded as either sparry cement or neomorphic replacement. All sparry calcite was assumed then to be of freshwater origin. The idea of meteoric lithification had great appeal—no heat, no pressure. The interpretation of process was aided by the new alliance between fabric and analysis of elements and isotope ratios. The concept of changing composition of pore water was clarified by the development of stains in the 1960s by Evamy, Shearman and Dickson. Cathodoluminescence (CL) was applied by Sippel and Glover following the pioneer work of Amieux.

Marine diagenesis was examined as well. Illing in his 1954 paper recorded beach rock and Bathurst in 1966 described micritization of shells by boring cyanobacteria followed by cementation. Yet, far from today’s seas, in New Mexico, Pray was mapping Mississippian bioherms with clastic dikes of syndimentary origin which were clearly in a marine cemented substrate.

Indeed, in the 1970s a new world of submarine cementation was opening up with the work of Schroeder and Ginsburg on Bermuda reefs and on other reefs off Jamaica by Land and Goreau. In the Persian Gulf cemented crusts in shallow water had been located by Shinn, Taylor, and Illing. Evidence of cementation in deep sea sediments in dredged blocks was revealed by Fischer and Garrison in 1967.

Older marine cemented limestones were recorded too by Purser in Jurassic hardgrounds in the Paris Basin and by Zankl in the Jurassic and Trias of Germany and Austria. Void-filling cements were found in Devonian reefs in Germany by Krebs.

Further support came from Bromley’s Chalk hardgrounds in Denmark.

The study of the finer fabrics was greatly helped by use of the transmission electron microscope, as in the book by Fischer, Honjo, and Garrison, and even finer detail was revealed by the scanning electron microscope pioneered especially by Alexandersson and Loreau.

A most valuable international conference on carbonate cements took place on Bermuda in 1969 when four diagenetic environments were distinguished: the intertidal marine, the submarine, the vadose freshwater, and the phreatic freshwater. Many of these were later described from Belize by James and Ginsburg in 1979.

An understanding of aquifer hydrology became increasingly pressing and was helped by work such as that by Back and Hanshaw published in 1970. There was thus a successful Penrose Conference in Vail, Colorado, combining hydrologists with sedimentologists. At that meeting a significant leap forward was taken by Meyers who introduced the use of CL zoning to reveal cement stratigraphy.

The study of freshwater aquifers led to the recognition of caliches by Esteban, Read, and Klappa and a range of soil textures.

Now some consolidation of ideas was necessary and five important books appeared: Bathurst on carbonate sediments and their diagenesis, Wilson’s great summary of carbonate lithofacies in the Phanerozoic, Flügel’s acute study of microfacies, with visual identification of allochems supported by the books of Majewske, and of Horowitz and Potter.

The deformation of carbonate sediments during burial was being revealed by Mossop’s research on pressure-dissolution in Devonian reefs, by Mimran in steep limbs of folded Cretaceous Chalk, and by Dickson and Coleman in 1980 who showed with isotopic analysis of calcite cement zones a long history of growth during burial. The later cement zones are commonly ferroan.

It was becoming clear that the amount of calcium carbonate required to fill the pores with cement must have been considerable, even exceeding the original mass of the sediments as proposed by Choquette and Pray in 1970. The importance of a local source through pressure-dissolution was suggested by Hudson in 1975. Calcite cementation in some Jurassic limestones is late burial because it post-dates fracture of micrite envelopes, as demonstrated by Emery, Dickson, and Smalley in 1987. A useful terminology for pressure-dissolution fabrics was presented by Buxton and Sibley in 1981, i.e., “fitted fabric”, “dissolution seam”, and “stylolite”. With the author’s permission Bathurst in 1991 tightened up their definition of “fitted fabric”. Lithification of coccolithic chalk by pressure-dissolution over tens of millions of years was demonstrated by Matter, and by Scholle, in 1974. Bathurst in 1983 dealt with burial calcitization in terms of compaction fabrics.

Dolomite, too, could have a deep crustal origin, both as replacement and cement. Choquette found it could be a fracture fill, as did Grover and Read, Moldovanyi and Lohmann, and Dorobek. Mattes and Mountjoy found dolomite related to pressure-dissolution. Wardlaw revealed fine detail by using resins to make pore casts.

The role of early cementation in preserving sediment from compaction was emphasized for Jurassic hardgrounds by Purser in 1969, for the Jurassic Smackover by Swirydzuk in 1988 and for the Carboniferous Limestone of England by Hurd and Tucker in 1988. James and Bone in 1989 showed

how, in the Cenozoic of South Australia, two grain-stones with identical burial histories were pressure-welded or cemented depending on the content of aragonitic molluscan debris.

Interest in the chemistry of the new microfabrics grew also, it being clear that whole rock analysis was of little use. The road to success lay in selective analysis of different components identified with the microscope, as by Hudson in 1977 and Lohmann in 1988. Marshall and Ashton exhibited the dual use of trace elements and stable isotope ratios, a study elaborated by Moldvanyi and Lohmann. Dickson and Coleman, in 1980, as already mentioned, had identified their zonal sequence by staining.

Another interesting diagenetic environment received attention in the 1970s. This was the early subsurface sediment, isolated from the overlying seawater. Chemical reactions continue in a closed system where sediments are buried with their original seawater, bearing a mixture of solid carbonate debris with organic material containing microorganisms. In 1980 Berner published a book on the early diagenesis of sediments within the first 100 m or so of burial. This exposed a new world of sulfate reduction, fermentation, redox potential and reactions of methane. Here was a framework for the growth of concretions investigated by Berner, Raiswall, Hudson, Curtis, Irwin and Marshall. This work provided an essential background for understanding how concretions coalesce to form lithified beds. It has become clear that many marine sediments, especially fine-grained, were buried in this way. Their development was treated in a remarkable book by Einsele and Seilacher in 1982 and its successor by Einsele, Ricken and Seilacher (1991).

The importance of a late diagenetic overprint, giving rise to new bedding, though always in response to a generally unknown but fluctuating syndepositional signal, has been treated in both books and by Simpson in 1985, by Ricken in 1986, and Bathurst in 1987 and 1990.

Important advances were made in understanding the calcitization of aragonite in the 1970s and 1980s. Relics of aragonite are commonly preserved inside the neomorphic calcite spar. These were revealed using SEM by Sandberg, Schneidermann and Wunder, and by Hudson. Using this information Lasemi and Sandberg were able to characterize micrites and microspars as ADP (aragonite-dominated precursor) or CDP (calcite-dominated precursor). The ability to distinguish ADP and CDP made it possible for Sandberg to recognize more surely periods of aragonite or calcite precipitation in seawater and to relate these to Fischer's secular variations of icehouse and greenhouse—or to a mixture of these as shown by Wilkinson, Buczynski, and Owen.

In conclusion, the principles followed by Sorby remain the same. We still need to look, describe, identify and find geometric relations. The complexity has been explored by Schroeder and Purser. We can now make out at least four major diagenetic environments: (1) the near subsea (first 40 cm or so), (2) the first 100 m or thereabouts which is a closed system, (3) the freshwater vadose and phreatic, and (4) the deep burial affected by high pressure and temperature. In addition there are the various lacustrine situations.

We still need to grasp more clearly just how pores in so many limestones are almost totally filled with cement. Vast volumes of water must pass through a pore in order that enough ions arrive to fill it with cement—some 10,000 to 100,000 pore volumes. What stimulates all this water to be supersaturated throughout such large volumes of sediment? We

need more help from sympathetic geochemists such as Morse and Mackenzie and their "Journey of a rain drop".

CARBONATE MINERALOGY AND GEOCHEMISTRY

Introduction

Sediments and sedimentary rocks contain a variety of carbonate minerals. Calcite (trigonal CaCO_3) and dolomite [trigonal $\text{CaMg}(\text{CO}_3)_2$] are by far the most important carbonate minerals in ancient sedimentary rocks. Aragonite (orthorhombic CaCO_3) is rare and other carbonate minerals are largely confined to special deposits such as evaporites or iron formations or present as minor minerals. Calcitic and dolomitic sedimentary rocks constitute 10–15 percent of the mass of sedimentary rocks and approximately 20 percent of the sedimentary rock mass younger than 600 Ma (the Phanerozoic). Carbonate rocks are important reservoirs of oil and gas and contain commercial ore bodies and in the form of biological, chemical, mineralogical, and isotopic signatures, important information concerning the evolution of the Earth. Thus, the mineralogy and geochemistry of the carbonate minerals constituting carbonate sediments and rocks have been investigated in great detail.

There are three polymorphs (similar composition, different crystal structure) of CaCO_3 that are found in sediments and in the structures of organisms. The rhombohedral mineral *calcite* is the most abundant and is thermodynamically stable. *Aragonite*, the orthorhombic form, is also abundant but found primarily in young sediments and the skeletal structures of marine organisms. *Aragonite* is the more dense form and hence

Table C1 Some properties of the carbonate minerals. ΔG_{f298} is the standard Gibbs free energy of formation, and K_{sp} is the solubility product of the phase. Full references for the data cited are found in Morse and Mackenzie (1990). (after Morse and Mackenzie, 1990)

is the CaCO₃ phase stable at high temperature but metastable relative to calcite at low temperature. It is about 1.5 times more soluble than calcite. *Vaterite* is the third anhydrous CaCO₃ phase, has a hexagonal structure, and is metastable relative to aragonite and calcite under the environmental conditions found in sediments and sedimentary rocks. It is approximately 3.7 times more soluble than calcite and 2.5 times more soluble than aragonite. In addition to the anhydrous CaCO₃ minerals found in sediments, there are scarce occurrences of hydrated CaCO₃ minerals, such as ikaite (CaCO₃·(6H₂O)).

Dolomite is one of the most abundant carbonate phases found in carbonate rocks. However, it does not occur as a skeletal component of organisms as do calcite and aragonite. Even after years of study, the mode of formation of dolomite remains controversial. Its properties under the environmental conditions at and near the surface of the Earth are less well-known than those of calcite and aragonite. This is partly a reflection of the fact that the synthesis of dolomite in low temperature laboratory experiments has proven to be difficult.

Table C1 lists the variety of carbonate minerals found in nature and some of their properties. In this article because of

the abundance of calcite and dolomite in the sedimentary rock record, their mineralogy and geochemistry are discussed in some detail.

Calcite

Calcites are very important biogenic and inorganic constituents of modern marine sediments and Pleistocene rocks. They are complex minerals containing up to 30 mole percent MgCO_3 . Calcites containing more than a few percent MgCO_3 are usually referred to as magnesian calcites. Generally, for the same MgCO_3 content, the biogenic calcites have greater concentrations of sodium, sulfate, water, hydroxide, and bicarbonate and tend to have larger cell volumes and greater carbonate positional disorder in their structure than natural or synthetic inorganic phases. Chemical and microstructural heterogeneities characterize biogenic magnesian calcites, and dislocations and plane defects are common in magnesian calcites. All of these characteristics may affect the thermodynamic and kinetic properties and reactivity of these phases in aqueous solution. In contrast to younger sediments, calcites found in Paleogene and older rock units commonly contain only a few percent MgCO_3 . This contrast in composition and its interpretation have been the principal driving force behind studies of the basic crystal chemistry, thermodynamic, and kinetic properties of calcites. The literature concerning these properties is substantial and is summarized in Mackenzie *et al.* (1983), Morse and Mackenzie (1990), Tribble *et al.* (1995), and Arvidson and Mackenzie (1999).

Crystal structure and chemistry

During recent years, a number of new observations concerning the crystal structure and chemistry of calcites has been made. These observations have proved useful in interpreting the experimental data on the solubility of calcites in aqueous solution, and in turn, the behavior of calcites during diagenesis and their usefulness in environmental interpretation. The following is a summary of the more important recent conclusions:

(1) Unit cell parameters of synthetic calcites vary smoothly as a function of MgCO_3 content. These phases have larger c/a axial ratios than those obtained from a straight line connecting the c/a axial ratios of calcite and magnesite or disordered dolomite (Figure C2(A)). Furthermore, the synthetic phases exhibit negative excess cell volumes in the composition range 0–20 mole percent MgCO_3 and positive excess volumes for MgCO_3 contents greater than 20 mole percent (Figure C2 (B)). In contrast, the unit cell parameters of biogenic calcites do not vary smoothly as a function of MgCO_3 content, and their axial ratios and cell volumes are larger than those of synthetic solids of the same MgCO_3 content (Figure C3).

(2) The excess c/a axial ratios in synthetic calcite phases are the result of the positional disorder of the CO_3 -anion group in the vicinity of Mg^{2+} ions. In essence, the anion group becomes progressively more inclined to the c crystal axis with increasing magnesium concentration in the calcite phase. This phenomenon has been documented in Raman spectroscopic studies of calcites that show an increase in the halfwidths of Raman spectral bands with increasing magnesium concentration (Figure C4). Single crystal X-ray refinements of two biogenic magnesian calcites have confirmed the hypothesis of positional disorder in these phases with increasing Mg content (Paquette

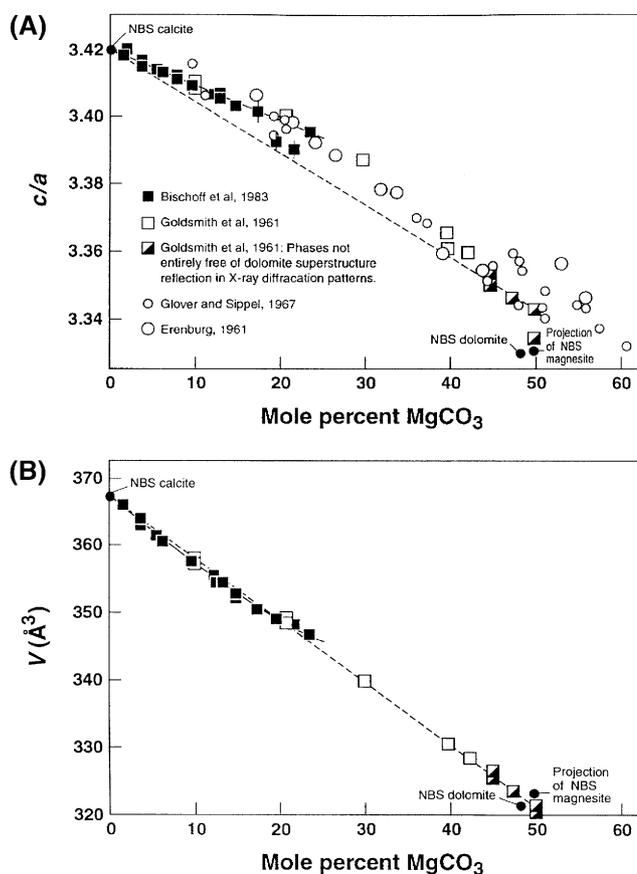

Figure C2 Unit cell axial ratios (A) and volumes (B) versus composition for synthetic magnesian calcites. Solid line is quadratic, least-squares fit for synthetic phases. The dashed line connects pure calcite and least-ordered dolomite (after Mackenzie *et al.*, 1983).

and Reeder, 1990). Furthermore, Paquette and Reeder have shown that this disorder is not simply limited to the CO_3 group but also affects the cation positions.

(3) In general, biogenic calcites exhibit a greater degree of heterogeneity with respect to the distribution of magnesium in their structure than synthetic phases. Furthermore, some biogenic calcites and synthetic calcites precipitated at high supersaturations from multicomponent aqueous solutions contain trace amounts of Na^+ and SO_4^{2-} owing to point defects and dislocations. It is likely that some substitutions of Na^+ for Ca^{2+} in the calcite lattice are balanced by incorporation of HCO_3^- into the structure.

(4) Busenberg and Plummer (1989) modeled the solid solution behavior of calcites based on experimentally obtained dissolution data. Compositionally pure binary solid solutions of CaCO_3 and MgCO_3 that include metamorphic and hydrothermal phases, synthetic phases prepared at high temperatures and pressures, and synthetic phases prepared from aqueous solution at low temperatures and very low calcite super-saturations were modeled as sub-regular solid solutions between calcite and dolomite or disordered dolomite. For the biogenic calcites and synthetic calcites synthesized at high calcite supersaturations from aqueous solution, a

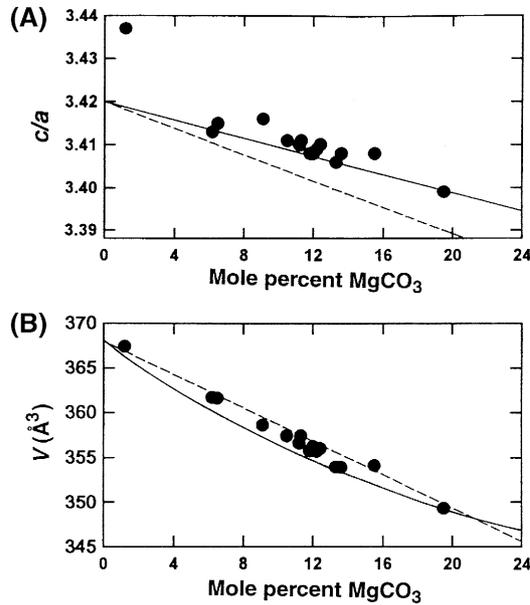

Figure C3 Unit cell axial ratios (A) and volumes (B) versus composition for biogenic magnesian calcites. Solid line is quadratic, least-squares fit for synthetic phases. The dashed line connects pure calcite and least-ordered dolomite (after Bischoff *et al.*, 1983).

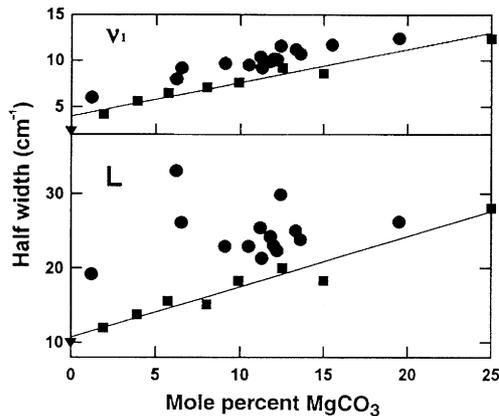

Figure C4 Halfwidths of the ν_1 and L Raman modes versus composition for synthetic (squares) and biogenic (dots) magnesian calcites. The triangle represents pure calcite. The straight line is the least-squares fit to the synthetic phase data (after Bischoff *et al.*, 1985).

sub-regular solid solution between defective calcite and disordered dolomite appeared to fit best the experimental data.

The solubility of a calcite in aqueous solution depends significantly on its physical and chemical characteristics. These characteristics must be defined and quantified before one can interpret the laboratory solubility or kinetic data necessary to studies of the reactivity of calcites in natural environments.

Solubility and solid solution behavior

The solubilities of magnesian calcites as a function of their MgCO_3 content have been a subject of considerable debate.

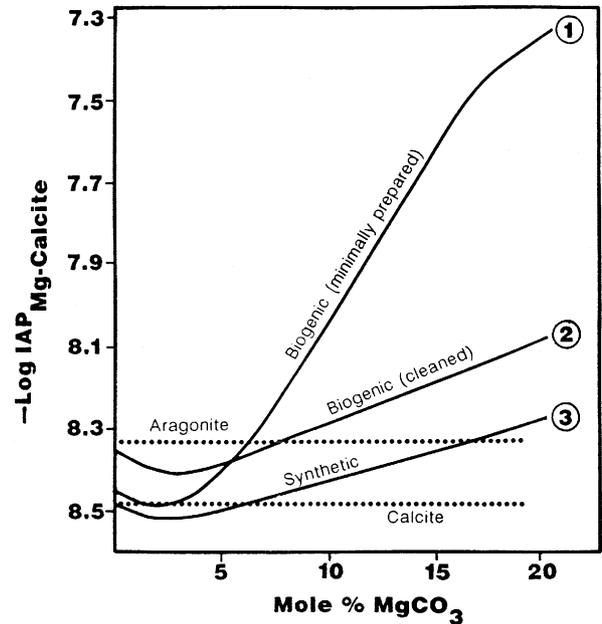

Figure C5 Solubility of magnesian calcites as a function of the MgCO_3 in the phase. See text for further explanation (after Bischoff *et al.*, 1993).

However, with the work of Bischoff *et al.* (1987, 1993), Busenberg and Plummer (1989), and Bertram *et al.* (1991), the solubility trend with composition of these phases at 25°C and 1 atmosphere total pressure appears reasonably well defined (Figure C5). The solubilities of these phases are expressed as a function of their MgCO_3 content and the ion activity product (IAP) of a solution in equilibrium with the solid:

$$\text{IAP}_{\text{calcite}} = K_{\text{sp}} = [\text{Ca}^{2+}]^{1-x} [\text{Mg}^{2+}]^x [\text{CO}_3^{2-}]$$

where brackets denote the activity of the ion in aqueous solution, x is the mole fraction of MgCO_3 in the solid, and K_{sp} is the solubility product.

The solubilities of magnesian calcites exhibit a minimum around two mole percent MgCO_3 , beyond which they increase nearly linearly. There appear to be two trends in the solubility-composition data; one for inorganic solids that are well crystallized, compositionally homogeneous, and chemically pure (Figure C5, curve 3) and the other for biogenic phases and inorganic solids that exhibit substantial lattice defects, carbonate positional disorder, and substitution of foreign ions like sulfate and sodium (Figure C5, curve 2). A third solubility-composition curve is shown in Figure C5, that of Plummer and Mackenzie (1974) for biogenic materials subjected to minimal cleaning procedures in the laboratory before use in dissolution experiments designed to determine the solubilities of these phases (Figure C5, curve 1). This curve probably reflects primarily kinetic rather than thermodynamic factors, a result of the lack of annealing of the biogenic materials and the non-removal of fines from the reactant solids used in these experiments.

As can be seen in Figure C5, biogenic and some inorganic calcites (Figure C5, curve 2) are relatively more unstable in aqueous solutions than synthetic phases of similar MgCO_3

content (Figure C5, curve 3). Their solubilities differ by roughly 0.15 pIAP units (pIAP = $-\log$ IAP) or about 4.6 kJ/mole. This difference arises because of physical and chemical differences between the two types of solids. The complicated microarchitecture, greater positional disorder of the CO_3 anion group, and chemical impurity of the biogenic phases and some inorganic calcites result in higher solubilities of these solids. It is likely that the solubility-composition curve 3 (Figure C5) for pure, compositionally homogeneous and structurally well-ordered calcite phases represents the true metastable equilibrium solubility of magnesian calcites in aqueous solution at 25°C and 1 atmosphere. This difference between the equilibrium and biogenic solubilities of calcite phases of the same MgCO_3 content has important implications for diagenesis of the metastable assemblage of carbonate minerals deposited on the seafloor today and in the geologic past.

Dolomite

The mineral dolomite, $\text{CaMg}(\text{CO}_3)_2$, is a major constituent of carbonate rocks. For geologists dolomite has been the center of an enduring debate regarding its mode of formation in surface environments, its past abundance relative to other sedimentary carbonates, and its overall significance in the geologic record (Machel and Mountjoy, 1986; Hardie, 1987; Mackenzie and Morse, 1992). This debate has motivated the search for a modern analogue to the surface or near-surface environment that is capable of producing large quantities of dolomite, whether as a primary precipitate, or (as is more commonly seen in ancient carbonate rocks) an early diagenetic phase replacing primary CaCO_3 . Although this labor has yielded possible scenarios in which certain sedimentary dolomites no doubt formed, it has failed to offer a reasonable model for the formation of *massive* dolomite in the geologic record. This lack of a modern analogue for such an important mineral has challenged experimentalists to observe and measure directly the physicochemical conditions and rates under which dolomite precipitation and replacement reactions occur.

Mineralogy and phase relations

Dolomite is distinguished from calcite and the other rhombohedral carbonates by its stoichiometry, ideal dolomite having equal numbers of Ca and Mg atoms, and by the segregation of Ca and Mg in distinct lattice planes. These planes are oriented normal to the *c*-axis, each alternating with *c*-normal trigonal CO_3 groups, that are also in essentially planar orientation. This cation ordering results in a coupled rotation of the carbonate groups and a reduction of symmetry relative to calcite from R3c to R3. Each cation is octahedrally coordinated by six oxygen atoms, which are themselves threefold coordinated with a calcium, magnesium, and carbon atom.

Determination of the univariant temperature- CO_2 curve for the calcite-dolomite-magnesite system was made by Harker and Tuttle (1955a) at high to moderate temperatures and pressures. The order of decomposition with increasing temperature was shown to be magnesite, dolomite, and calcite. The location of calcite-dolomite and dolomite-magnesite solvi along the CaCO_3 - MgCO_3 binary join (Figure C6) was established through the collective work of Harker and Tuttle (1955b), Graf and Goldsmith (1955, 1958), and Goldsmith and Heard (1961). Lattice constants for Ca-Mg carbonates have

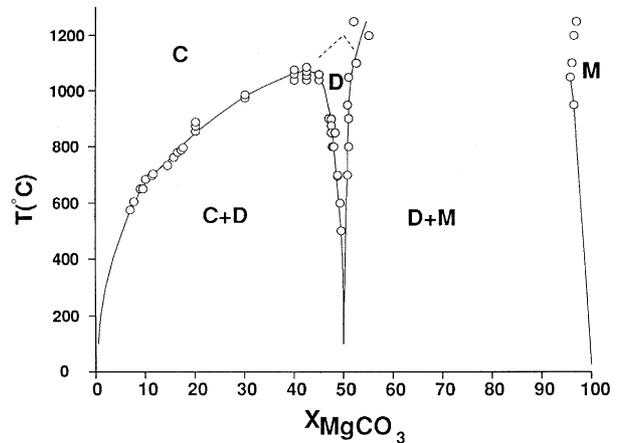

Figure C6 Subsolvus relationships for the CaCO_3 - MgCO_3 join. The top of the calcite-dolomite immiscibility gap occurs at 1075°C, at this temperature, the phase composition is $\text{Ca}_{57.5}\text{Mg}_{42.5}(\text{CO}_3)_2$. Dotted line represents limit of detectable ordering in the dolomite structure. C = calcite; M = magnesite; and D = dolomite [after Tribble *et al.*, 1995; data from Goldsmith and Graf (1958) and Goldsmith and Heard (1961)].

also been determined by Goldsmith and Graf (1958), Goldsmith *et al.* (1961), and Graf (1961). Those of Goldsmith and Graf have been abandoned.

The top of the calcite-dolomite solvus was located by Goldsmith and Heard (1961) at 1075°C, giving a composition of $\text{Ca}_{57.5}\text{Mg}_{42.5}(\text{CO}_3)_2$ (Figure C6). Above this temperature, complete solid solubility is seen between calcite and a carbonate of dolomite composition. However, a phase change must still separate the disordered Mg calcite (R3c space group) from ordered dolomite (R3). To distinguish this phase change as discontinuous (first order) or continuous (order ≥ 2) is problematic: a first-order transition would demand coexistence of ordered and disordered phases at the temperature of transition. Goldsmith and Heard (1961) observed a continuous increase in disorder from $\sim 1000^\circ\text{C}$ through 1150°C , based on the decreasing intensity of cation ordering reflections. The intensity of ordering reflections depends on the difference between *average* scattering factors for the atoms occupying distinct sites. Thus, Goldsmith and Heard concluded that the phase change is high order, with the caveat that a two-phase field, if present, may be so narrow as to have eluded detection.

With decreasing subsolvus temperatures, the amount of excess CaCO_3 that can be accommodated in stable dolomite is greatly reduced (Figure C6). Dolomites formed at temperatures $< \sim 500^\circ\text{C}$ with more than one mole percent excess CaCO_3 must thus be regarded as metastable. Goldsmith and Graf (1958) recognized the difficulty in accommodating this excess Ca in Mg sites, and showed that natural dolomites whose compositions deviate from stoichiometric proportions ($0.49 \leq X_{\text{CaCO}_3, \text{dol}} \leq 0.57$) also showed evidence of some cation disorder.

Early work on synthesis and mechanism

The work of Graf and Goldschmidt (1956) was one of the first experimental attempts to obtain information on the rate and mechanism of dolomite formation as a function of temperature

and reactant composition. Important conclusions of this work are:

(1) Ordered, stoichiometric dolomite similar to natural samples can be readily synthesized under dry conditions during brief reaction times at temperatures of 500°C to 800°C using a variety of reactants. However, the reaction below 400°C is so slow that no dolomite product is identifiable after reaction times of thousands of hours.

(2) Dolomite can be synthesized in hydrothermal (wet) conditions over a range in temperatures. The phases formed at a given temperature depend on the partial pressure of CO₂ and H₂O. At temperatures down to 200°C, ordered, stoichiometric dolomite can be synthesized. At lower temperatures or for shorter reaction times, the product dolomites may exhibit 1 : 1 Ca : Mg ratios, but cation ordering is usually incomplete.

(3) At temperatures less than 100°C, regardless of reaction time, dolomite-like materials are formed having compositions that deviate significantly from ideal and are typically calcium rich. These Ca-rich dolomites completely lack evidence of ordering. The term *protodolomite* was introduced by Graf and Goldschmidt (1956) to describe Ca-Mg carbonates that deviate from stable, ordered, stoichiometric dolomite. Protodolomite can transform to dolomite with sufficient time or temperature.

Since Graf and Goldschmidt's pioneering work, subsequent experimental work focused on the stability relations in the CaCO₃-MgCO₃ system under hydrothermal conditions in chloride solutions (Rosenberg and Holland, 1964; Rosenberg *et al.*, 1967; Gaines, 1974, 1980; Katz and Matthews, 1977). Gaines (1974) was able to produce ordered, stoichiometric dolomite from calcite and aragonite at 100°C reacted in Ca-Mg chloride solutions for only ~200 hours. He demonstrated qualitatively that the dolomite reaction rate depended on temperature, ionic strength, Mg : Ca ratio in solution, and the mineralogy of the reactant carbonate solid (calcite, magnesian calcite, and aragonite increasing in respective reactivity). The activation energy of the formation reaction of an ordered dolomite recalculated from Gaines' experiments by Arvidson and Mackenzie (1997) was found to be 42.1 kcal mol⁻¹.

Recent and current work in mineralogy and synthesis

Sibley (1990) produced stoichiometric, well-ordered dolomite from calcite at 218°C. Intermediate products included various fractions of magnesian calcite and non-stoichiometric dolomite whose compositions and rate of formation were apparent functions of the Mg/Ca ratio in solution. Sibley concluded that the reaction sequence of magnesian calcite → Ca-rich dolomite → dolomite is controlled by the relative (decreasing) nucleation and growth rates of these phases.

Lumsden *et al.* (1989) synthesized ordered, stoichiometric dolomite from calcite in Mn-doped MgCl₂ solutions at 192°C and 224°C, with magnesite (MgCO₃) and brucite [Mg(OH)₂] appearing as reactive intermediates. At a given temperature, Mn addition apparently decreased the reaction rate. Cation ordering in product dolomites appeared to decrease with increased residence time (coincident with an increase in $X_{\text{CaCO}_3, \text{dol}}$); however, these data are not well constrained, and the problems inherent in intensity ratio measurements are well-known. It is thus difficult to ascertain whether this trend in order/disorder reflects Mn substitution (Peacor *et al.*, 1987).

Schultz-Guttler (1986) explored the relationship between disordering in dolomite and the $X_{\text{MgCO}_3, \text{cal}}$ in coexisting calcite at relatively high temperatures and pressures, using pure

dolomite and calcite reacted in water with Ag oxalate over long reaction times (~100 hours). Schultz-Guttler documented a positive relationship between isothermal MgCO₃ solubility in calcite and the disorder of coexisting dolomite, and suggested that discrepancies among previous data in the location of the calcite limb of the solvus may reflect the time required to achieve a completely ordered structure, even at high temperatures and pressures. One would expect this effect to be exacerbated at lower temperatures.

Although cation disorder in dolomite has typically been estimated from intensity ratios of ordering versus nonordering reflections, structural disorder resulting from other defects may play a critical role in reactivity. Wenk *et al.* (1983) summarized the occurrence of a diverse set of features known collectively as *modulated structures*. These are seen as diffuse intensity contrasts in TEM images of a variety of carbonates, including dolomite (particularly Ca-rich varieties, although often absent in stoichiometric dolomite). The role of these microstructures and their relationship to cation ordering is not yet understood, but this area holds potential in terms of documenting the relationship between dolomite of replacement origin and the carbonate precursor, and thus yielding insight into the reaction mechanism. The most common microstructure is a modulation parallel to (1014) having a wavelength of 200 Å.

Wenk *et al.* (1993) recently reported possible evidence of direct precipitation of ordered dolomite in a modern sabkha facies at Abu Dhabi. TEM images and electron diffraction data were used to differentiate coexisting aragonite, disordered magnesian calcite (grading to partially ordered calcian dolomite), and ordered dolomite. Despite the coexistence of these phases, Wenk *et al.* argued that there is no evidence to suggest that the ordered dolomite formed as a result of ordering of a calcite precursor, and thus must have formed by direct precipitation, possibly with concurrent aragonite dissolution. If this observation is correct, it suggests that dolomite growth can occur at low to moderate temperatures on relatively short timescales, given an appropriate solution chemistry.

Finally, Arvidson and Mackenzie (1997, 1999, 2000) showed from theoretical considerations and continuous flow, dolomite-seeded, reactor experiments that the dolomite precipitation reaction rate is strongly dependent on temperature and moderately dependent on the saturation state of the solution from which the dolomite is forming. The dolomite produced in their experiments was variable in composition but typically was a calcium-rich protodolomite that formed syntaxial overgrowths on the seed material. The activation energy for this protodolomite precipitation reaction was found to be 31.9 kcal mol⁻¹, lower than that for reactions involving ordered dolomite. In addition, Arvidson and Mackenzie (2000) found that the energy required to convert a calcium-rich protodolomite to an ordered dolomite is about 5.5 kcal mol⁻¹.

Some geological considerations

Questions concerning the diagenesis of calcites in carbonate sediments and rocks and the occurrence and mode of formation of dolomite have plagued geologists for nearly a century. Our knowledge of the mineralogy, chemistry, and phase relations of these minerals acquired from experimental work has formed the necessary foundation to obtain answers

to some of the questions. For example, the finding that calcites rich in magnesium are not stable relative to pure calcite and dolomite is the principal reason that the former phases convert to the latter with increasing age of the sedimentary rock in which the minerals are found. Modern calcareous sediments of shallow-water origin are characterized by a metastable assemblage of calcites and aragonite, primarily of biogenic origin, and sparse inorganic dolomite. With time and burial, this metastable assemblage generally will be converted to the stable assemblage of calcite and dolomite; aragonite will alter to calcite, the stable dimorph, and magnesium-rich calcite will lose magnesium and be converted to nearly pure calcite and contemporaneously, or later in the history of the sedimentary deposit, dolomite. Evidence for the diagenetic stabilization of aragonite and magnesian calcite is ample, particularly from limestones subjected to vadose and phreatic meteoric diagenesis.

In general, the alteration of magnesian calcite to calcite is petrographically described as a pseudomorphic replacement, in which the original skeletal or non-skeletal materials retain their original microarchitecture. The original fabrics are retained because the chemical reactions that transform magnesian calcites to calcite probably occur along a microscopic diagenetic front. Incongruent reaction is the reaction mechanism most commonly invoked to explain the retention of microarchitecture in stabilized magnesian calcite skeletal materials or other substrates. The reaction involves dissolution of the magnesian calcite accompanied by precipitation of calcite with a lower concentration of magnesium than that of the initial solid. Based mainly on experimental and theoretical arguments, Bischoff *et al.* (1993) showed that there are several potential stabilization pathways by which a magnesian calcite is converted to calcite. However, these pathways are poorly documented in the rock record because of lack of adequate field studies.

The mineral dolomite and the uncertainties surrounding its origin have attracted the attention of earth scientists for more than a century. The core of the dolomite problem is the apparent paradox posed by the paucity of dolomite in modern marine depositional environments and its relative abundance in the sedimentary rock record. There are two major contrasting paradigms that have been promoted to explain this observation. The first is that most dolomite is not primary in nature but forms over time from the alteration of the other principal carbonate phases of calcite and aragonite. The second is that the atmosphere/ocean environmental conditions of today are not favorable to dolomite precipitation but were at times during the geologic past. This latter paradigm requires changes in seawater chemistry during geologic time (see *Sea water: Temporal changes to the major solutes*). To obtain further insight into this latter paradigm, Arvidson and Mackenzie (1999) studied the rate of dolomite precipitation in a steady-state, dolomite-seeded, reflux reactor over a range of temperatures at fixed bulk composition of the reacting solution and at variable temperature and solution composition. They found that the rate was a strong function of temperature and the degree of saturation of the solution with respect to dolomite, as has been shown with calcite and aragonite. The strong dependence on temperature and saturation state observed in the experiments led the authors to conclude that it is the overall rate of dolomite precipitation relative to competing carbonate phases of calcite and aragonite at surface temperatures that determines dolomite's abundance in the

sedimentary regime. They also concluded that small changes in temperature can substantially affect the dolomite precipitation rate. Thus, it is possible that the abundance of dolomite in the sedimentary rock record reflects its absolute precipitation rate in the environment, the rate being controlled by the environmental variables of temperature and solution composition, i.e., the saturation state of seawater. There is little doubt that the global mean temperature of the planet has varied over geologic time as has the chemistry of seawater. Thus, the abundance of dolomite might reflect to some degree these changes. This assertion is currently being debated (Holland and Zimmermann, 2000) and further investigated, as is the role of bacteria in the dolomite precipitation reaction (Warthmann *et al.*, 2000).

CARBONATE MUD-MOUNDS

Mud-mounds (also mud mounds, and mudmounds) are important geological bodies in the carbonate system. Wilson (1975) is the one who used the term most extensively. His conception of mud mounds had a profound influence on subsequent perception of this type of carbonate body, particularly through the last chapter of his book where he refers to "foreslope mud mounds" on type I carbonate shelf margin profile (Wilson, 1975, 361, and Figure XII-3, a widely cited figure in subsequent geological literature). For most workers then, mud-mounds became these geological structures found associated with basin-type facies.

Definition

There is no widely accepted definition of mud-mound. Several have been proposed (e.g., several papers in Monty *et al.*, 1995), based on various parameters such as percentage of mud versus organisms, presence or absence of specific elements such as stromatolites, relief above seafloor at time of deposition, or type of organisms controlling surface accretion. On a strictly descriptive base, mud-mound can be broadly defined as a rock or sediment body, having a mound or lens shape, massive to crudely bedded, within which finely crystalline carbonate predominates (without connotation on the origin of the last), and more commonly associated with deep water facies (modified from Bourque, 2001). This roughly corresponds to the objects described by Wilson (1975) as mud-mounds. It excludes mudbanks that are shallow water structures (AGI Glossary of Geology), like for instance those of the Florida Bay and Shelf.

A key point of this definition is that mud-mound is a geological object that resulted from a more or less modified primary depositional structure which did not necessarily have an important relief above the seafloor at time of deposition (even if the object exhibits today a mound or lens shape), nor a mud content equal to the present finely crystalline carbonate content.

Facies spectrum and origin of mud-mounds

The origin of mud-mounds is controversial. First of all, there is an inherent ambiguity related to the term itself: the "mud" part of it, which is the fundamental component of

Bioclasts

mud-mounds, evokes a primary composition of loose lime mud. However, most studies during the last two decades stressed the necessary role of soft-bodied and/or poorly fossilizable organisms in mound accretion, in particular that of the microbes and the sponges, and showed that a significant portion of the finely crystalline material may correspond to an early lithification of these organisms or parts of them. An important character of mud mounds is the multigeneration nature of the finely crystalline material (polymuds of Lees and Miller, 1985): the first generation corresponds to the primary, early cemented, often pelleted mudstone, whereas the subsequent generations correspond to geopetal muds originating from collapse of uncemented material and/or internal sedimentation, all types of generation forming a highly structured mosaic.

On the one hand, several workers put forward an all-microbial origin of mud-mounds following Monty (1976, and in Monty *et al.*, 1995). In particular, the pelleted nature of the finely crystalline carbonate is viewed as the product of *in situ* calcifying microbes and therefore considered as diagnostic for a microbial origin of the mound (several papers in Monty *et al.*, 1995). This view is emphasized by the mud-mound spectrum proposed by Bosence and Bridges (*in* Monty *et al.*, 1995) who recognized only two types of mud-mounds: the microbial mud-mounds, and the biotrital mud-mounds, leaving no room for other builders than the microbial community.

On the other hand, several studies have shown that most Paleozoic mud-mounds are not made up of a single component, but rather of a mosaic of facies (e.g., James and Bourque, 1992). For one, the red stromatactis facies commonly found in the basal part in Paleozoic mud-mounds has been shown to be very rich in sponge bodies and/or in sponge spicules everywhere it has been studied (references in Bourque and Boulvain, 1993). The facies has been interpreted to have originated from the calcification of a primary sponge network through microbial decay during early diagenesis, destroying the original shape of the sponges and much of the spicules, and ending with a finely crystalline limestone having a pelleted texture (Bourque and Boulvain, 1993).

There is no doubt that microbial communities may have acted as primary builders in mud-mound accretion, for instance in trapping and binding allochthonous mud, producing *in situ* loose lime mud or mediating pelleted micrite-microspar precipitation *via* their vital activity (e.g., by photosynthesis). They may also have acted as the main agent of transformation of a primary organic-rich substrate into micrite-microspar *via* organic matrices. For instance, decaying

former microbial community (Défarge *et al.*, 1996) or decaying sponges (Reitner *et al.*, 1995) may be used as substrate for calcite nucleation. In both cases, the end product is a pelleted finely crystalline limestone (micrite-microspar), a situation that renders difficult the recognition of the primary community.

Figure C7 presents a genetic classification of mud-mounds that account for the primary facies spectrum found in mud-mounds. Microbial and skeletal mud-mounds are those which were primarily accreted by microbial communities or skeletal organisms (sponges, bryozoans, delicate corals, etc.), respectively. Detrital mud-mounds are those which resulted from the piling up of biotrital material and/or loose lime mud.

The above discussed types of mud-mounds were built mainly by autotrophic and/or heterotrophic communities. These last years, ancient mud-mounds related to chemosynthesis have been described, and we should expect that more will be recognized in the future. In this case, deciphering which group of organisms is involved in chemosynthesis is not readily achieved.

Gaps in current knowledge

Beyond the controversies on the origin of mud-mounds, two main gaps in the current knowledge of mud-mounds are particularly teasing. Firstly, the origin of the enormous amount of marine cement and the driving mechanism for marine fluid circulation remain poorly understood. For instance, the stromatactis facies into which early marine cement may constitute more than half of the rock volume testifies to rapid, massive cementation. An enormous volume of water supersaturated with respect to CaCO_3 is needed. The mechanisms that drive the necessary fluids to the sites of early cementation in relatively deep-water mounds are presently poorly circumscribed.

Secondly, mud-mound workers can rely on a very limited number of modern analogs for mud-mounds. One of the strengths that lead to satisfactorily understand the ancient reef system through geological time is the actualistic approach favored by the accessibility of the modern reef system. This is far from being the case for the mud-mound system. The only modern objects that may represent analogs to mud-mounds are the deep-water mud-rich ahermatypic coral mounds. These can be classified as skeletal and/or detrital mud-mounds. Obviously, they represent only a very small portion of the mud-mound spectrum in the geological record, and therefore carbonate mud-mounds are geological bodies important for our understanding of the past carbonate system and life.

CATHODOLUMINESCENCE (applied to the study of sedimentary rocks)

Introduction

Cathodoluminescence (CL) is the term used to describe the emission of light from crystalline materials caused by irradiation with high energy electrons emitted from a cathode source. The detailed physical principles of CL are explained in Walker (1985). When a beam of electrons impinge on a solid material a variety of interactions take place. Some energy is absorbed, some transmitted (but only through very thin sheets of matter) and some is reflected in both particulate and wave forms. It is the light emission that constitutes CL. This light is not always emitted in the visible region of the spectrum, although there are few studies in sedimentology of CL in the UV or IR portions of the electromagnetic spectrum.

Sedimentologists use CL extensively in clastic and carbonate petrography to reveal fabric and paragenetic information not apparent with other imaging techniques. CL is now an established routine tool that provides qualitative information on grain provenance, sediment fabric, compaction processes, cement growth fabric, and by inference, diagenetic history. It also enables more precise quantification of constituents and fabrics. CL petrography is an important prerequisite to reconstructing paleo-fluid evolution of carbonate and sandstone aquifers in order to define the relationship between growth zones or healed fractures and multiple generations of fluid inclusions.

Analytical techniques

The basic requirements for recording CL in sediments are detailed in Marshall (1988). In essence, a source of high energy electrons generated under near vacuum is focused onto a polished thin section causing excitation of atoms in the surface layers of the mineral lattice. CL is emitted as the excited

electrons fall back to their ground state. The emission can be recorded photographically, digitally or spectroscopically. Levels of CL emission are commonly very low so efficient light transfer instrumentation has been developed to optimize capture of CL emissions. Several complicating factors arise. Firstly, electron irradiation damages some minerals (especially quartz) resulting in changes to or destruction of the CL emission. To record the initial state of luminescence either low energy electron beams or short exposure times are required (Ramseyer *et al.*, 1989). Instruments with scanning beams and low beam energies that operate at high vacuum (and thus produce fewer damaging negative particles) provide the best results with quartz. Secondly, the character of the CL emission changes with temperature so instruments with cold stages enabling cooling of the sample to liquid N or He temperatures have been developed. Moreover, color as observed with the eye is a subjective description of overlapping spectral bands so accurate determination of CL emission can only be conducted if spectra are measured. Commercial 'cold cathode' instruments are available and are adequate for the study of CL in carbonate minerals, whilst either so-called 'hot cathode' research instruments or CL attachments for the SEM are required if accurate information is to be collected on CL in quartz (Walker and Burley, 1991).

The nature of CL emission

The characteristics of CL in many common minerals encountered in sediments are well documented, although some important questions remain. Luminescence emanates from emission centers. These are an expression of changes from an ideal, perfect lattice structure (Walker, 1985), usually grouped as either: (i) intrinsic centers, effectively structural imperfections of the lattice, alternatively referred to as 'defect centers'; and (ii) extrinsic centers, the result of trace elements being incorporated into the crystal reflecting the composition of the solution or melt from which the mineral crystallized, commonly referred to as 'impurity centers'. Defects can be growth distortions, 'holes' in the lattice or particular vibrational states of atoms, whilst impurities can behave as activators, sensitizers or quenchers of CL. However, the distinction between these two categories is artificial as many defect centers occur as the result of an impurity. Most natural crystalline materials exhibit some CL (see the compilation in Marshall, 1988), unless they contain significant amounts of Fe²⁺, an effective quencher of CL when incorporated into the mineral lattice. Carbonate cements (aragonite, calcite, dolomite, magnesite, but not siderite or ankerite), quartz, detrital and authigenic quartz and feldspars, authigenic clay minerals (kaolinite but not illite or chlorite), sulfates (barite and anhydrite) and phosphates (apatite) all exhibit significant CL emissions.

The nature of the emission depends on the interaction between the CL center and the vibrational energy of the lattice, which is strongly temperature dependent. The number and type of both emission and quenching centers present determine the nature of the emission spectrum and color observed. An emission spectrum reveals how many spectral bands contribute to the overall color but also resolves the nature and number of emission centers present (Walker and Burley, 1991). This is particularly important in determining the cause of CL in a mineral. Without spectroscopy, CL remains a poorly constrained tool for describing fabrics.

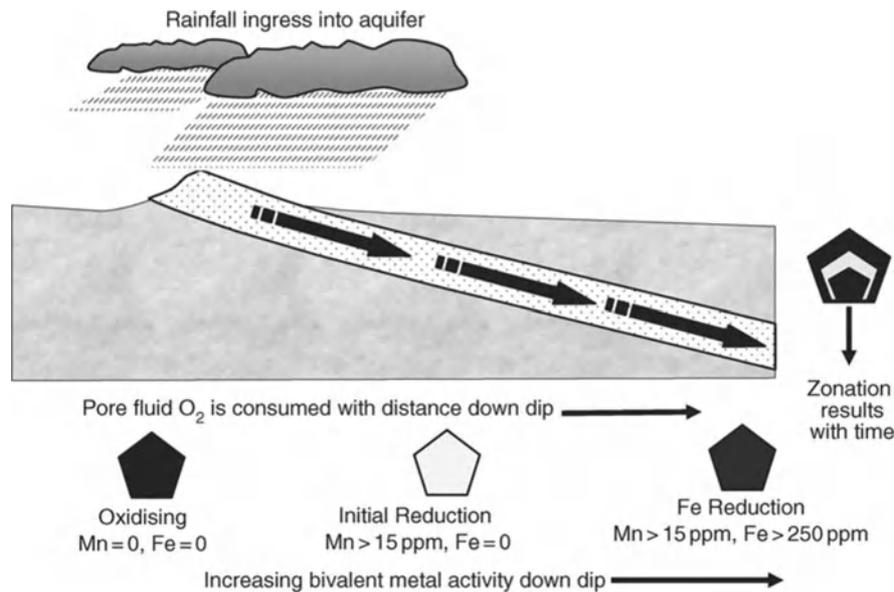

Figure C8 The evolution of carbonate CL fabrics during gradual burial as Mn and Fe become available for incorporation into cement. Nonluminescent cement precipitated near a source of oxygenated fluid recharge may be the lateral correlative of bright cement some distance down-aquifer, and low intensity CL cement further into the subsurface (based on Hendry 1993).

CL of carbonates

Sedimentary carbonates of different major and trace element composition exhibit distinct CL emission spectra and resulting colors, revealing a variety of growth fabrics. Activators in sedimentary carbonate minerals are mostly transition metals (especially Mn²⁺) and rare earth elements. Intrinsic CL in carbonates is a low intensity dark blue emission, that is swamped if more than a few ppm of Mn²⁺ are present. Mn²⁺ produces a yellow CL emission in calcites when substituted in Ca²⁺ sites. Substitution of Mn²⁺ into Mg²⁺ lattice sites shifts the emission to longer wavelengths. Thus Mn²⁺ activated Mg-calcites are characterized by more orange CL than yellow and dolomite is bright red, whilst Mn²⁺ substitution into a dolomite Ca²⁺ lattice site produces yellow CL emission. Some dolomites exhibit a luminescence that is green to the eye but when resolved spectroscopically is shown to be a combination of the intrinsic blue and a low intensity yellow emission. Fe²⁺ is the dominant quencher in carbonates, and at concentrations of ca >250 ppm shifts the yellow-orange red luminescence emission toward longer wavelength resulting in brown-appearing emissions that become less intense as the Fe²⁺ content increases.

CL color in carbonates depends on both absolute concentrations of Mn²⁺ and Fe²⁺ and the ratio between them (ten Have and Heijen, 1985). The maximum CL intensity is controlled by the Fe/Mn ratio, whilst the CL intensity below the maximum is a function of the absolute amounts of Mn²⁺ for a given Fe/Mn ratio (Hemming *et al.*, 1989). Incorporation of Mn²⁺ and Fe²⁺ into carbonates is thus largely controlled by the redox state of the diagenetic environment (Barnaby and Rimstidt, 1989). Oxidized Mn³⁺ and Fe³⁺ are both insoluble in aqueous fluids, but as the oxygen content decreases, first Mn³⁺ and then Fe³⁺ are reduced to their soluble bivalent form, successively becoming available for incorporation into the carbonate lattice. If calcite is precipitated during burial its CL

emission character tends to evolve from nonluminescent (although with intrinsic blue emission being much more common than reported because of its low emission intensity) through bright yellow to dull brown (Figure C8).

CL of quartz

CL emissions in quartz are much more variable, and are ascribed to a variety of emission centers (Table C2). Additionally, the spectrum and resulting CL color of some types of quartz changes drastically during irradiation, indicating that an emission center is created during the excitation process, although this center remains poorly understood. The CL characteristics of quartz crystallized from a melt are different to that precipitated from an aqueous fluid, such as authigenic quartz in sandstones and some veins. Anhydrous, magmatic quartz is characterized by two broad emission bands, one in the blue, and one in the red range of the visible spectrum. In fact the broad blue emission is considered by solid state physicists to represent two, and possibly three, separate but overlapping intrinsic center emissions (Gorton *et al.*, 1997). The visible CL colors of quartz, ranging from bright blue, through purple to red, reflect variation in the relative intensity of these emission bands. The red peak also has a long tail that extends into the infrared, and this peak increases in intensity at the expense of the blue peak with electron irradiation, producing a range of reddish 'brown' colors.

Work on authigenic quartz precipitated from aqueous solutions has demonstrated that hydrous quartz exhibits a wide variety of other CL emission bands that include relatively low intensity, short lived blue, green, yellow and red colors as well as combinations of these (Ramseyer and Mullis, 1988). The blue emissions also extend into the UV range (Demars *et al.*, 1996). Microprobe analysis and spectral studies suggest that these transient emissions are impurity-related and

Table C2 Summary of suggested CL emission centers in quartz

CL emission center	CL color	Wavelength	Quartz Type
Electron irradiation	red	650	Magmatic and α -quartz
Lattice defects	Broad red	650–690	Magmatic and α -quartz
Defect center	blue	430	Anhydrous quartz
O ₂ vacancy	UV	260	Anhydrous quartz
SiO ₄ tetrahedra	blue	455	Anhydrous quartz
Self trapped excitons	blue	430–450	Anhydrous quartz
Structural water	Green-blue	510	Diagenetic α -quartz
Li-compensated Al ³⁺	UV	340	Diagenetic α -quartz
Interstitial Li ⁺	Blue, green, yellow	440–580	Diagenetic α -quartz
Interstitial Na ²⁺	UV	290	Diagenetic α -quartz
Fe	red	640	Magmatic quartz

Figure C9 Complex CL zoning patterns in calcite. Early non-luminescent cements are followed by cyclical banding whilst final pore fills are brightly luminescing suggestive of initial burial followed by unconformity related meteoric recharge.

Figure C10 'Hot-CL' photomicrograph of plutonic detrital quartz grains enclosed in zoned syntaxial quartz overgrowths.

correlate with abundance of lithium-compensated aluminum substitution in the quartz lattice, and with the abundance of structurally bound water in the lattice. This raises the possibility that CL in quartz may record pore fluid changes or specific pore fluid conditions, much as CL fabrics do in carbonates.

Applications of CL in sedimentology

CL is routinely used as a qualitative tool to reveal details of sediment texture. In carbonates depositional grains and bioclasts are easily distinguished from cements, in some cases even when recrystallization has taken place. In sandstones, the contrast in CL character between detrital quartz of various origins and authigenic quartz overgrowths enables accurate quantification of cement abundance and determination of porosity-loss processes (Houseknecht, 1988), including mechanical compaction and pressure dissolution. Zinkernagel (1978) was the first to demonstrate that the various CL colors of quartz grains can be related to their geological history, making quartz CL a very powerful provenance tool. Magmatic α -quartz with dominant blue emission is typical of plutonic environments, volcanic quartz is dominated by red CL whilst reddish 'brown' colors are typical of metamorphic terrains.

Figure C11 SEM-CL showing compactional microfracturing of a detrital quartz grain in a quartz cemented sandstone. Note that overgrowths postdate fracturing.

CL of both carbonate and quartz cements reveals details of growth fabric and growth processes (Figures C9 and C10). These fabrics include zonation, dissolution events and microfracturing. Concentric zonation consists of parallel bands of different CL emission colors indicative of growth through time. Discontinuities and irregular crosscutting surfaces in these

Table C3 Compilation of CL characteristics of growth zone patterns in carbonate cements and their CL hydrological interpretation. Fluctuations in redox state that produce cyclical non-bright luminescent zoning are a strong indicator of active but near surface fluid flow conditions prior to fluid-rock stabilization. They most commonly form in shallow groundwater aquifers that respond to recharge. In contrast, poorly zoned, low-luminescent sparry cements indicate stagnant anoxic conditions that typify deeper burial

Zoning pattern		Environment	Hydrology	Examples
Intrinsic blue or nonluminescent, almost always unzoned		Hardgrounds, shallow sub-surface, marine or meteoric	Oxygenated, open to seawater circulation, active to stagnant aquifers	Syn-depositional calcite marine cements; tufa; unconformity cements
Concentric non (or intrinsic blue)—bright—low intensity luminescent zones		Shallow burial, marine or meteoric aquifer	Falling oxygenation, active or stagnant aquifers	Gradual burial in stagnant or slow moving aquifer
Nonluminescent with multiple bright concentric subzones		Shallow burial meteoric aquifer	Fluctuating oxygenated to suboxic, active recharge	Transient fresh water lenses beneath emergent shoals or cyclothems
Concentric non, bright and low intensity luminescent zones		Deeper burial or distal aquifer	Low but fluctuating oxygenation levels, active aquifer	Major unconformity sourced meteoric phreatic cements
Dominantly low intensity luminescence, with sector zoning, cements tend to be coarsely crystalline; recrystallization may obliterate early fabrics		Deep burial beneath influence of active surface hydrology	Variably anoxic, typically stagnant, with slow cementation	Typical of burial cements formed in chemical compaction regime or from dewatering of mudstones and organic matter-rich source rocks

zones document intervening episodes of dissolution or replacement. Sector zoning comprises polygonal to irregular zones representing adjacent crystal faces that result from differential trace element up-take (Reeder, 1991). Microfracturing may record compactional processes or tectonic events (Boiron *et al.*, 1992; Figure C11). CL of cements is thus most powerful as a means of resolving fine scale detail of textural fabrics and determining paragenetic relationships between successive cement generations, and gave rise to the term 'cement stratigraphy', the study of spatial relationships of coeval cement generations (Meyers, 1991). As a consequence of changing redox relationships, growth fabrics of carbonate cements revealed by CL are often related to paleohydrology, burial and uplift history (Table C3). However, although CL emission is qualitatively related to geochemistry, there are many other factors that contribute to CL color and intensity (Machel and Burton, 1991). In practice, therefore, erroneous inferences can be made unless other geochemical techniques, such as fluid inclusions and stable isotope analysis, are used to fully characterize cements. Equivalent zoning patterns, for example, may be produced by different processes or be diachronous, even in closely spaced samples. Cement stratigraphy of quartz overgrowths is less well documented, largely because the relationship between pore fluid conditions and resulting CL fabrics is less well understood (but see Demars *et al.*, 1996). CL fabrics in quartz overgrowths were used by Burley *et al.* (1989) to establish a detailed cement and fluid inclusion paragenesis, enabling burial diagenetic histories to be reconstructed.

Future research directions

CL petrography is now an established routine tool in sedimentology because of its value in distinguishing depositional

from authigenic components, revealing cement fabrics, and in reconstructing diagenetic histories. However, the use of CL in providing quantitative constraints on paleo-pore fluid geochemistry requires a more complete understanding of the nature of CL centers, especially in silicates. Quantitative spectroscopic studies are required, linked with geochemical analysis of cements, if CL emissions and cement growth fabrics are to provide more useful information on lattice defects, trace element compositions and pore fluid evolution.

CATION EXCHANGE

Cation exchange is a process by which cations are reversibly adsorbed on charged surfaces of sediments from solution. Isomorphous substitution and broken edges in the phyllosilicates, and deprotonation of acid groups in the organic matter provide net negative charge. The negative charge is balanced by the electrostatic attraction of cations. Cation exchange is a rapid and reversible process, and cations are exchanged on an equivalent charge basis. All components of sediments contribute to some extent to cation exchange. However, minerals in the clay fraction (<2 μm) and organic matter are the most important components involved in this process.

Because of their charge and size, the alkaline earth and alkali metal cations (Ca^{2+} , Mg^{2+} , Na^+ , and K^+) do not form stable secondary minerals and are left in the solution phase to

neutralize surface charge of sediments. Under acidic conditions Al^{3+} (and monomers of Al) and H^+ are also present on the exchange sites. Since the cations are held by a weak electrostatic force by sediments and are easily exchangeable, they are called exchangeable cations. The total amount of exchangeable cations that can be held by sediments is called the cation exchange capacity (CEC). The CEC and exchangeable cations are expressed in mmoles of charge kg^{-1} ($\text{mmol}_c \text{kg}^{-1}$). The CEC values of some common clay minerals in sediments are given in Table C4.

Historical development

Following Thompson's (1850) discovery of the cation exchange phenomenon, Way (1850) conducted the first comprehensive studies of cation exchange in Rothamsted, England. He concluded that cation exchange is instantaneous, cations are exchanged on equivalent basis, adsorption of cations increases with increasing concentration of added salt and clays are responsible for cation exchange reactions. Way also made some wrong conclusions including that organic matter takes no part in cation exchange and cation adsorption is irreversible. Several scientists reviewed the work by Way and the two wrong conclusions were corrected by Johnson (1859). Van Bemmelen (1888) presented a more complete picture of the cation exchange process and demonstrated that cation exchange is not restricted to Ca^{2+} in the soil, but other cations also participate in the process. The controversy about the nature of exchanging materials was resolved after the advent of X-ray diffraction when Hendricks and Fry (1930), and Kelley *et al.* (1931) independently established the crystalline nature of the clay particles. Within next 20 years, structures of phyllosilicates, which are the major components of the clay fraction of sediments, and their cation exchange were well established.

In the cation exchange process, there is selectivity or preference for smallest hydrated radius among cations of the same valence and for cations of different valencies generally the higher valence cations are preferred. The nature of sediments and the amount of CEC also influence the relative replacing power of cations on sediments. There is no single universal order of replacing power of cations on sediments. For high charge sediments the relative order of cation replaceability (lyotropic series) is $\text{Li}^+ \approx \text{Na}^+ > \text{K}^+ \approx \text{NH}_4^+ > \text{Rb}^+ > \text{Cs}^+ \approx \text{Mg}^{2+} > \text{Ca}^{2+} > \text{Sr}^{2+} \approx \text{Ba}^{2+} > \text{La}^{3+} \approx \text{H}^+ (\text{Al}^{3+}) > \text{Th}^{4+}$ (Bohn *et al.*, 1985).

Table C4 Cation exchange capacities of some common clay minerals found in sediments

Clay mineral	Cation exchange capacity ($\text{mmol}_c \text{kg}^{-1}$)
Kaolinite	30–150
Mica	100–400
Vermiculite	1200–2070
Smectite	800–1350
Chlorite	100–400
Palygorskite-sepiolite	50–450
Allophane-imogolite	100–400
Zeolites	2200–4600

Cation exchange equations

Several cation exchange equations have been derived to obtain an equilibrium constant since such a parameter would be useful to predict the exchangeable cation composition at different ion concentrations. It has been observed in several studies that the equilibrium constant derived from these equations are not constant over a range of conditions, and therefore they are called selectivity coefficients. The cation exchange selectivity coefficients for the exchange of mono–monovalent cations and mono–divalent cations are given in Table C5. Kerr (1928) applied the principles of chemical equilibrium to cation exchange. Vaneslow (1932) represented cation exchange in thermodynamic terms and modified Kerr's equation to include activity of cations in solution and on the exchange sites. He considered the exchanging surface to be an ideal solid solution so that the activity of adsorbed cations on exchange phase could be equated to its mole fractions. Krishnamoorthy and Overstreet (1949) used a statistical thermodynamics approach and developed an equation similar to Vaneslow's, except that a multiplier factor of 1.5 for mono–divalent exchange and 2 for mono–trivalent exchange. Gaines and Thomas (1953) introduced the equation, which was based on the affinities of cations for clays over a range of cation ratios. Gapon (1933) used the equivalent (mol_e or $\text{mol}(+)$) rather than moles to represent cation concentrations on the exchange sites. Due to its simplicity, the Gapon equation has been most commonly used in cation exchange studies even though there has been some criticism on the use of equivalent charge.

Empirical exchange equations

In addition to the equilibrium exchange equations, significant efforts have been made to develop mathematical relationships between the amount of a cation on exchange sites and the concentration of that cation in the equilibrium solution. The best known and most widely used of these are the Freundlich and Langmuir equations (White and Zelazny, 1986). The Freundlich equation, $x/m = KC^{1/n}$ relates the concentration of a given cation in equilibrium solution (C) to the amount adsorbed (x/m) leading to the coefficients K and n derived from experimental data.

The Langmuir equation originally invented for the adsorption of gases can be expressed as $x/m = \frac{KCb}{1+Kc}$, where K is a constant related to bonding energy, and b is the maximum amount of adsorbate that can be adsorbed. Both of the derivations are essentially empirical and no information about the actual adsorption mechanisms of cations can be derived from these equations.

Kinetics of exchange reactions

Cation exchange reactions occur almost instantaneously and therefore, the rates of these reactions often are transport controlled, i.e., film and/or particle diffusion and not reaction controlled (Sparks and Suarez, 1991). In general, sediments with large specific surface favor film diffusion mechanism whereas in sediments with microporous surfaces intraparticle diffusion is more prevalent. The type of cations also has a significant influence on the rate of exchange. Exchange of cations with lower hydration energies, i.e., smaller hydrated radii such as K^+ , NH_4^+ , and Cs^+ is often slower than hydrated

cations like Ca^{2+} , Mg^{2+} , and Na^+ . Cations with smaller hydrated radii fit well in the interlayer of swelling minerals, which results in the collapse of interlayer space and exchange is slow and controlled by particle diffusion.

Diffuse double layer models

The colloidal properties of clays, such as flocculation, dispersion and swelling, are influenced by the distribution of cations in the vicinity of negatively charged clay surfaces. Gouy (1910) and Chapman (1913) independently derived an equation to describe the ionic distribution in the diffuse layer formed adjacent to a charged surface. The theory has limited quantitative application due to the assumption that cations behave as point charges, which result in their accumulation in excessively high concentration adjacent to the negatively charged surface. In this model, there is no provision for surface complexation, which is common in adsorption of ions on variable charge surfaces. Stern (1924) suggested appropriate corrections to Gouy–Chapman theory by accounting for finite size of ions and the possibility of surface complexation reactions. In Stern's theory, diffuse layer is divided into two parts: the first layer close to the surface where cations are tightly retained and the remainder of the model comprises of Gouy–Chapman layer. Grahame (1947) made further refinement to diffuse double layer theory, by splitting the Stern layer into two layers to allow for consideration of two types of strongly adsorbed ions. Closer to the surface, Grahame recognized an inner Helmholtz plane where adsorbed ions lose some of their water of hydration and an outer Helmholtz plane that contains normally hydrated ions close to the colloid surface. Bolt (1955) introduced corrections in the Gouy–Chapman theory to account for the cation size, dielectric saturation, polarization energies of the ion, Coulombic interaction of the ions, and the short-range repulsion between cations. The corrected diffuse double theory has been useful in calculations of overall cationic distribution in the diffuse double layer and exclusion of anions near constant charge surfaces.

Due to deficiencies in diffuse double models, in recent years surface complexation models have been used to describe the retention of cations on sediments. Surface complexation models often are chemical models, which are based on molecular description of the electric double layer using equilibrium adsorption data (Goldberg, 1992). The best way to glean the information about the mechanism for ion exchange is to study the surface chemistry using direct spectroscopic techniques, such as, X-ray photoelectron spectroscopy, nuclear magnetic resonance spectroscopy, electron spin resonance spectroscopy and X-ray absorption spectroscopy (XAS). The synchrotron based XAS has been successfully applied in recent years to obtain information on the mechanism of cation exchange and adsorption processes (Fendorf and Sparks, 1996).

CAVE SEDIMENTS

Introduction

Cave sediments are found in modern (e.g., Ford, 1988) and ancient (e.g., Jones, 1992a) karst terrains throughout the world. Although commonly ignored, these sediments are very important because "... once formed they are more protected from subsequent erosion than the contemporaneous surface sediments. They may thus preserve sediments and faunal remains for periods from which all other records are lacking" (Smart *et al.*, 1988, p. 159).

There are three types of cave sediment (Figure C12). Exogenous (allochthonous) sediments that come from various sources and are formed by processes that are external to the bedrock in which the cave is found. Endogenous (autochthonous) sediments are derived from the bedrock in which the cave is found. Biological sediments are formed by animals that live in or close to the caves.

Exogenous sediments

The composition and characteristics of exogenous sediments is controlled by the area from which they originate and the mechanism by which they are transported to the cave (water, ice, wind) in which they are deposited. In continental settings, fluvial siliciclastic sediments are the most common void-filling allochthon (Ford, 1988). Marine sediment are rare simply because most caves are located inland and are far removed from the ocean. In Ingleborough Cave, Yorkshire, for example, passages are completely filled with fluvial gravels, sands, and silts (Ford, 1988).

In coastal regions and on oceanic islands exogenous sediments may be of marine and/or fluvial origin (Jones, 1992a). Hurricanes, for example, commonly generate huge waves that can carry vast amounts of marine sediment onshore. As the waves move over the coastal areas they may entrain sediment from coastal swamps, fresh or brackish water ponds, and soils. Once onshore, wave energy will start to diminish and the sediment-laden water will drain into the karst terrain via solution-widened joints and fissures. Upon reaching a cave, the decrease in flow velocity will cause sediment deposition. In those settings, sediments may include marine sands, marine muds, swamp muds, and terra rossa (e.g., Jones, 1992a). In many cases, these sediments will be intercalated with speleothems.

Exogenous and endogenous sediments are commonly characterized by sedimentary structures that include imbrication of pebbles (Ford, 1988), cross-bedding, and graded bedding (Ford, 1988; Jones, 1992b). In some cases, complex mound-like structures, such as those found in "caymanite" in paleocaves on the Cayman Islands may evolve (Jones, 1992b). Drying of the sediment after deposited may lead to the formation of desiccation cracks.

Endogenous sediments

Despite Dunham's (1969) classic description of "vadose silt", relatively little is known about endogenous sediments because they are commonly mixed with exogenous sediments which are compositionally and morphologically similar.

Cave breccia is one of the most obvious examples of endogenous sediment. The clasts in these breccias may be derived from the bedrock that forms the walls and roof of the cave or from the speleothems that commonly adorn the caves. Less obvious, is the endogenous micrite that forms as a residue from the breakdown of spar calcite crystals (sparmicrite), by the calcification of microbes, by the breakdown of calcified microbes, or by precipitation from cave waters (Jones and Kahle, 1995). Insoluble residues (e.g., quartz grains, clay) left from the dissolution of the bedrock may also be incorporated into the cave sediment.

Biological sediments

These sediments include bat and bird guano, and various bone accumulations. Many caves are the home to a diverse array of

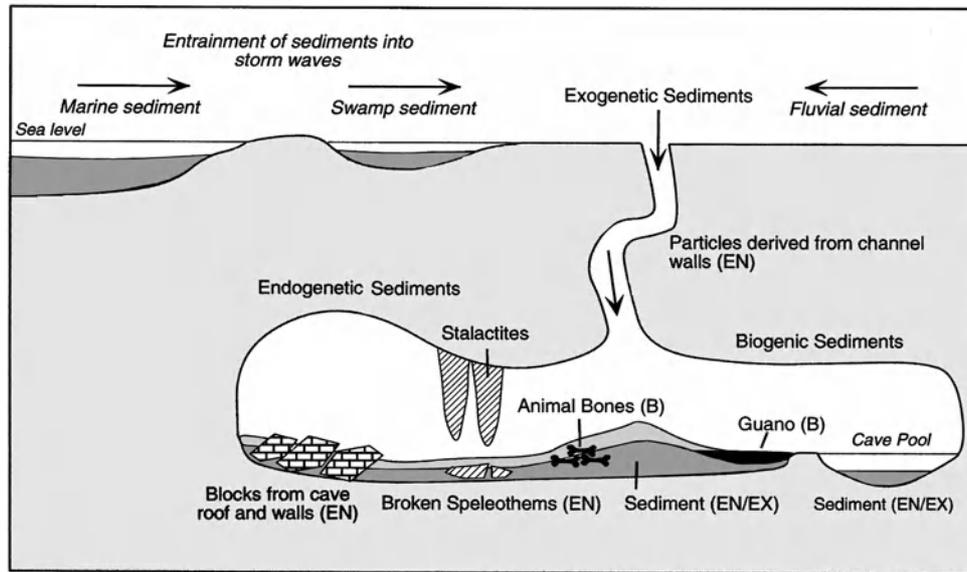

Figure C12 Schematic diagram showing potential source areas for cave sediments. EN = endogenic; EX = exogenic; B = biological.

invertebrates and vertebrates that are adapted to life in these dark environs. Bones or waste products from these animals may become an integral and important component of cave sediments. The bones may also serve as nuclei around which speleothems are precipitated. Guano, which is common in some caves, is formed by bats, birds, and even cave crickets (Jefferson, 1978).

Summary comments

Cave sediments are formed of sediments derived from many different sources (Figure C12). Determining the origin of the sediment may be difficult because grains of the same composition, size, and composition may be exogenetic or endogenetic in origin. Nevertheless, study of these sediments is important because they may provide evidence of deposits that are not preserved elsewhere in the succession.

CEMENTS AND CEMENTATION

Introduction

Cementation is the process of precipitation of mineral matter (cements) in pores within sediments or rocks. It is one of several processes, including mechanical and chemical compaction and mineral replacement, that constitute diagenesis and, taken collectively, produce progressive porosity reduction and lithification of sedimentary strata with increasing age and/or depth of burial. Cementation occurs in open intergranular or intragranular pores (i.e., between or within grains), and also takes place in larger openings such as vugs, caves or fractures. Cements even form crusts on surfaces at sediment-water or sediment-air interfaces. Precipitation of cements can occur at any stage from deposition, through burial, to uplift and re-exposure.

Cements occur in all types of siliciclastic, carbonate and evaporite strata and include an enormous variety of minerals. The most common cements are carbonates (especially calcite, aragonite, dolomite, and siderite), silicates (primarily quartz, opal, clay minerals, and zeolites), sulfates (especially gypsum and anhydrite) and chlorides (mainly halite). Cement morphologies vary widely, and morphological description, coupled with detailed geochemistry, may yield information on timing of precipitation as well as the physical and geochemical conditions under which cements formed.

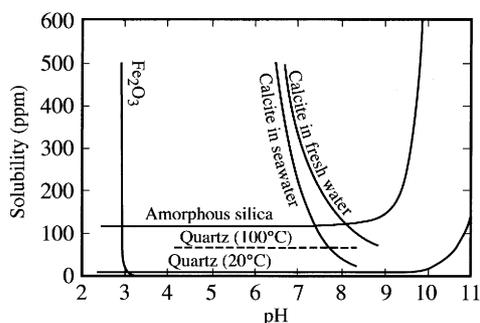

Figure C13 Solubility curves at approximately 25°C for hematite (Fe_2O_3), amorphous silica, quartz and calcite in marine and fresh waters as a function of pH. Dashed line shows quartz solubility at 100°C. (Adapted from Correns, 1950; Blatt *et al.*, 1972; Rosler and Lange, 1972).

Precipitation of cements is controlled by a variety of physical, chemical and biological factors. Crystallization kinetics, Eh, pH, P_{CO_2} , temperature-pressure conditions, and ionic concentrations and interactions of dissolved chemical constituents are common physiochemical controls. For example, Figure C13 illustrates the effects of pH on the solubility of a variety of common cementing agents. For calcite and dolomite, as temperature and pressure increase, aqueous solubility decreases, favoring precipitation at higher temperatures (Mackenzie and Bricker, 1971; Holser, 1979). Calcite and dolomite solubilities also increase with increased P_{CO_2} and decreased pH. Ions that appear to inhibit calcite precipitation include magnesium, sulfate, chloride and phosphate.

For quartz (and its polymorphs), solubility increases slightly with temperature, therefore decreasing the likelihood of significant quartz precipitation at very high burial temperatures (Mackenzie and Bricker, 1971). The pH of diagenetic fluids exerts a major influence on the formation of quartz and amorphous silica (Figure C13), with pH levels below 9 favoring precipitation.

Anhydrite solubility decreases with increasing temperatures, and gypsum solubility increases slightly to a maximum at approximately 40°C, but decreases at higher temperatures (Holser, 1979). Halite solubility increases with temperature. Pressure affects the solubility of halite slightly, but affects anhydrite more substantially. Elevated levels of sodium, potassium, and magnesium appear to decrease solubilities of gypsum/anhydrite and thus enhance its precipitation (Holser, 1979).

Iron oxides, sulfides and some carbonates (siderite and ankerite) are strongly controlled by Eh and pH conditions. Under oxidizing conditions, iron oxides form whereas under reducing conditions, pyrite or siderite are formed, depending on the relative sulfide and carbonate concentrations in the solution. Acidic pore fluids increase the solubility of any iron-bearing minerals present.

Biological metabolism and decay affect physiochemical conditions and mineral precipitation. Furthermore, because cementation involves precipitation from aqueous solutions, the presence of hydrophobic organic coatings (such as hydrocarbons) on grains can inhibit dissolution and retard or prevent cement formation.

Rates of cement precipitation vary greatly. The presence of suitable substrates for mineral precipitation plays a major role

in determining rates, because crystal nucleation is kinetically more difficult than continued growth on an already-nucleated crystal. Where suitable substrates exist, cementation by minerals that are compositionally similar or identical to the substrate may proceed rapidly (Wollast, 1971), commonly producing overgrowths that are in optical continuity with substrate crystals.

Some strata are completely cemented in as little as a few years after deposition; others retain as much as 40–50 percent porosity after tens to hundreds of millions of years and hundreds to thousands of meters of burial. An enormous body of research has focused on the factors that promote or inhibit cementation as well as controls on rates of precipitation (e.g., Moore, 1989; Bjørkum *et al.*, 1998). Such extensive studies were conducted not only to gain a general understanding of the post-depositional history of sedimentary strata, but also because such knowledge is essential for proper evaluation of hydrocarbon and metallic mineral prospects.

Cements in carbonate rocks

The dominant cements in most carbonate rocks are, not surprisingly, carbonate minerals. Aragonite and high-Mg calcite are the dominant precipitates in modern marine carbonate sediments. Both minerals are unstable under most non-marine conditions, however, and so undergo rapid alteration when removed from a marine setting. Aragonite normally is dissolved in meteoric fluids; high-Mg calcite most commonly converts to low-Mg calcite during meteoric or burial diagenesis. Low-Mg calcite is the most common cement in surficial, non-marine carbonate settings and is also the dominant cement in subsurface settings along with dolomite and, far less commonly, siderite. Carbonate cements (see Folk, 1965, for shape classification) are precipitated in a variety of diagnostic fabrics and crystal morphologies that may or may not survive later diagenesis—the most common of these are illustrated in Figure C14 (see also Scholle, 1978).

Sulfate or chloride cements, especially gypsum-anhydrite and halite, are additional important cements, especially in carbonate deposits from arid to extremely arid climates. Silica forms cements in carbonate rocks under some limited conditions, as do phosphate and glauconite.

Syn depositional (eogenetic) cements in marine carbonate settings

Synsedimentary carbonate cements are widespread in modern oceans and are volumetrically important in a number of settings ranging from coastal areas to oceanic depths. The main controls on marine carbonate cementation are sedimentation rates, degree of carbonate saturation, and rates of water exchange through the sediment. Where water throughput is high (because of a strong pumping mechanism coupled with permeable sediment) and saturation levels are high, cementation is extensive. Cementation also occurs, however, where water throughput is low, provided that sedimentation rates also are very low. Areas of extensive water throughput occur mainly where wave energy or tidal pumping force seawater through the sediment—such areas include windward reef fronts and beaches. In such settings, even though they are environments with high sedimentation rates, enough new carbonate is added from seawater that cement precipitation and lithification occur quite rapidly. Many tropical carbonate

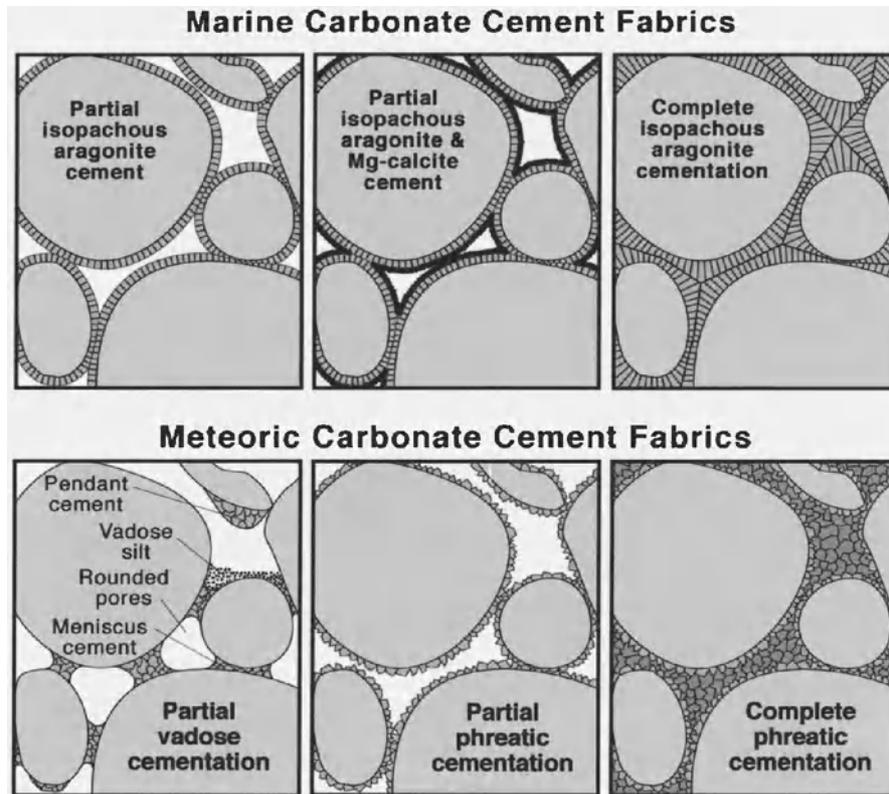

Figure C14 Sketches of typical shallow marine and meteoric (eogenetic) carbonate cement fabrics found in modern sediments. The marine cements are aragonite and high-Mg calcite; the meteoric cements are all low-Mg calcite.

beaches, for example, are armored by lithified carbonate sand, termed *beachrock* (*q.v.*), that forms in years to tens of years, based on the presence of incorporated modern artifacts such as coins (Scoffin and Stoddart, 1983). Although primarily a marine process, beachrock formation may involve mixing with coastal groundwaters in some areas. Subtropical to tropical platform or shallow shelf settings also are sites in which extensive syndepositional carbonate cements are widely distributed and volumetrically abundant, typically forming grapestone deposits or hardground layers.

Several time periods in the geologic record (e.g., the late Precambrian and late Permian) appear to have had widespread conditions that were especially favorable for syndepositional shallow-marine and coastal cementation (Grotzinger and Knoll, 1995). Large botryoids of aragonite and/or high-Mg calcite formed as seafloor crusts by direct precipitation from seawater during those time intervals (Mazzullo and Cys, 1979).

Modern shallow marine carbonate cements are mainly aragonitic with subordinate high-Mg calcite (James and Choquette, 1983). This probably results from inhibition of low-Mg calcite formation by one or more ions in seawater and pore waters including Sr, Mg, and PO_4 (e.g., Folk, 1974; Burton and Walter, 1990). Aragonite cement is found mainly as isopachous (uniform thickness) crusts or palisades of fibrous crystals (Figures C14 and C15*). Coarser botryoids of bladed

aragonite are known from large voids in reef-front settings (James and Ginsburg, 1979). High-Mg calcite cements typically occur as peloidal micritic precipitates with crystal sizes of less than 1–2 μm . Because aragonite and high-Mg calcite cements are unstable during later burial, recognition of syndepositional cementation may depend on recognition of remnants of primary fabrics, the occurrence of intraclasts (syndepositional rock fragments), borings that crosscut grains and cements, or attached/encrusting organisms. Several studies indicate that the mineralogy of inorganic marine precipitates has varied through geologic time as a function of a number of large-scale climatic and oceanographic variables (e.g., Sandberg, 1983).

Syndepositional marine cementation also occurs in finer grained and deeper water carbonates, especially nannofossil oozes or chalks. Although deeper ocean waters generally are undersaturated with respect to calcium carbonate, precipitation still can occur interstitially below the sediment-water interface where biological processes, decomposition of organic matter, and diffusive exchange of seawater and pore waters can lead to carbonate supersaturation. Enhanced water exchange and bacterial activity in burrows, leads to preferential cementation of these structures. In areas or times of essentially zero sediment accumulation (hiatus zones), such cementation may extend beyond burrows and become pervasive within a sediment layer, leading to the formation of firmgrounds or, with more extensive cementation, hardgrounds (Kennedy and Garrison, 1975) in both shallow and deep-water marine settings. True hardground creation can take

* Figures C15, C17, C18A and C18B appear on Plate I, facing page 114.

as little as a few years to hundreds of years in lagoonal or open shelf settings, but may require hiatal periods of tens to hundreds of thousands of years in outer shelf to deep ocean floor settings.

The most common cement in such deeper-water settings is extremely finely crystalline high-Mg calcite that is very difficult to differentiate optically from the sediment matrix. Non-carbonate precipitates such as calcium phosphates and glauconite (glaucony) are also common, and many hardgrounds are typified by a yellowish-brown or greenish coloration where such non-carbonate minerals are present. Other factors aiding hardground recognition are the presence of synsedimentary clasts, borings, and encrusting or attached fauna.

Early diagenetic (eogenetic) cements in non-marine carbonate settings

Nonmarine carbonate cements are produced in terrestrial settings both above and below the water table (that is in undersaturated or vadose zones as well as saturated or phreatic zones). Such cements typically form as a result of: (1) degassing of CO₂-rich groundwaters emerging at the surface or in caves, (2) by evapotranspiration of carbonate-bearing surface waters and near-surface groundwaters, or (3) by mixing of near-surface waters of different compositions. Travertine deposits forming at hot- and cold-springs exemplify the first process; these deposits include substantial amounts of interstitial carbonate cement as well as surficial cement crusts. Likewise, cave *speleothems* (*q.v.*) (stalactites, stalagmites, flowstone) represent cements formed in caves and solution-enlarged fractures from meteoric waters that lose CO₂ as they emerge into large, partially air-filled cavities. Most speleothems are composed of low-Mg calcite; although a few examples include aragonite, dolomite, or gypsum. Most speleothems have distinctive palisades of coarse crystals oriented perpendicular to the sequential growth banding that reflects the frequently changing conditions that characterize vadose to shallow phreatic settings.

Nonmarine cements resulting from evapotranspiration of near-surface waters are common in soils formed on carbonate or siliciclastic sediments and extend from the soil zone down to the water table and below. Such exposure-related carbonate precipitates include root coatings (rhizoliths), soil nodules, and massive calcrete or caliche horizons. Cements produced under freshwater vadose conditions consist of low-Mg calcite with distinctive structures (Figure C14), including meniscus, needle-fiber, and pendant fabrics, and may be associated with vadose silt (James and Choquette, 1984).

Non-carbonate cements and crusts can also be formed at nonmarine exposure surfaces, including precipitates of iron oxides (ferricretes: see *Laterites*) and of silica (silcrettes). In most cases, the cementing agents in such crusts are derived by local dissolution and reprecipitation of primary constituent grains and thus form mainly on siliciclastic substrates.

Exposure surfaces associated with hypersaline waters have very different cementation patterns. In particular, areas with intense evaporation of marine-derived waters (e.g., areas of coastal sabkhas or salinas such as the Persian Gulf or southern and western Australia) have a wide variety of carbonate and evaporite cements (see *Sabkha*, *Salar*, *Salt Flat*). Aragonite and high-Mg cements are common in such settings, as are evaporite minerals such as gypsum, anhydrite, and halite. The removal of calcium from pore waters by carbonate and sulfate

precipitation, in turn, leaves a dense residual brine depleted in calcium and enriched in magnesium. Such brines can replace primary aragonite crystals with dolomite and perhaps also form dolomite cements (McKenzie, 1981). Typically, such penecontemporaneous dolomites are non-stoichiometric, aphanocrystalline, and contain numerous solid inclusions.

Pore fluids that form as a result of evaporative concentration of seawater or waters of mixed continental/seawater origin can be extremely saline—commonly as much as 8 times normal seawater concentration. In sabkha and playa environments, these waters precipitate euhedral, tabular to lenticular gypsum crystals that displace or engulf the carbonate and siliciclastic sediments in which they form. Anhydrite typically occurs as displacive nodules or contorted layers composed of white, felted masses of lath-shaped crystal fragments (Kinsman, 1966). Kinsman (1974) described primary anhydrite precipitates as well as anhydrite formed by syndepositional dehydration of gypsum. Climate cycles now are known to cause calcium sulfates to undergo multiple episodes of dehydration and rehydration prior to significant burial, making evaluation of primary fabrics and mineralogies difficult.

At the landward edges of coastal sabkhas, pore water salinity dilution through influx of continental groundwater commonly leads to dissolution and reprecipitation of early-formed anhydrite and gypsum as clear, poikilotopic gypsum that can completely cement sabkha and playa sands (carbonate or siliciclastic). However, as sabkha and playa sediments undergo deeper burial, increasing temperatures and pressures result in reconversion of gypsum to anhydrite.

The third process leading to cementation in nonmarine to marginal marine settings, the mixing of waters of dissimilar compositions is widespread, but not yet well understood. This process can involve mixing of marine with fresh or saline meteoric waters as well as mixing of purely terrestrial waters of different compositions (e.g., vadose and phreatic waters or groundwaters from two different sources). Mixing can lead either to dissolution or precipitation, even when two undersaturated fluids are mixed. The main cements attributed to this process are low-Mg calcite and dolomite. Low-Mg calcite forms in the mixing zone in fabrics similar to normal phreatic precipitates—i.e., as isolated euhedral crystals that coat grains and that generally are randomly oriented unless substrate microstructure influences orientation. Modern mixing-zone dolomite commonly consists of bands of euhedral, limpid, pore-lining dolomite crystals, interlayered with bands of syntaxial calcite (Humphrey, 2000).

In situations in which mixing of marine with fresh or brackish water takes place under locally reducing conditions, siderite (FeCO₃) cements can form (e.g., Mozley and Burns, 1993). Siderite cements, however, also form in deep marine settings lacking water mixing, but where bacterial processes provide reducing conditions.

Most early diagenetic carbonate cements, other than those formed in such unusually reducing conditions, have a common set of trace-element geochemical characteristics. In particular, virtually all have low iron and manganese concentrations (and thus are non- or weakly-luminescent under cathodoluminescence *q.v.*); they are pale pink to red when stained with Alizarin Red-potassium ferricyanide solutions—see Stains, and Dickson, 1966). The low iron and manganese concentrations result from the fact that these elements are substantially incorporated into calcium carbonates only under reducing conditions.

Distinguishing carbonate cements formed in marine environments from those formed in meteoric settings is complex. Cement fabrics and morphologies, discussed above, are most effectively used when combined with relevant isotopic information. Marine cements typically are relatively enriched in ^{18}O and ^{13}C , which helps to distinguish them from isotopically much “lighter” cements formed from low salinity meteoric fluids or under deeper burial conditions.

Burial-stage (mesogenetic) cements

Most porosity loss in carbonate strata occurs during progressive burial at depths well below the environment of near-surface water circulation (e.g., Schmoker and Halley, 1982). Although physical and chemical compaction account for some of the porosity reduction, much of the loss (especially in grainstones) results from carbonate cementation. The subsurface precipitation of up to 30–40 percent cement in carbonate rocks creates a substantial mass transport problem if the material is imported from external sources. In most instances, however, burial-stage cements are derived primarily by dissolution of primary carbonate grains or unstable eogenetic carbonate cements, either locally or in nearby strata. Dissolution can occur at high-pressure grain contacts, along solution seams and stylolites, or in associated shales, marls or other organic-rich strata. Elevated temperatures and pressures, forced fluid movements due to subsidence and compaction, a variety of diagenetic changes in associated siliciclastic rocks or organic deposits, changes in Eh (generally to progressively more reducing conditions), and many other factors affect burial cementation (Scholle and Halley, 1985; Choquette and James, 1987).

Low-Mg calcite is the main mesogenetic cement in most carbonate rocks; dolomite and quartz cements (in several varieties) also are common. Evaporite cements (especially anhydrite) or hydrothermal precipitates (e.g., fluorite and barite) are important in some special settings.

Most mesogenetic calcite cements, like many meteoric phreatic cements, have equant to bladed crystals that increase in size toward the centers of large pores. The crystal size and orientation of substrate grains and eogenetic cements can affect mesogenetic cement morphologies. Echinodermal bioclasts exert especially strong substrate control because each grain is a single crystal of calcite. This encourages the formation of very large cement overgrowths, which may obliterate all surrounding pore space, a common situation in pelmatozoan limestones. In some cases, single-crystal overgrowths surround several framework grains, producing a “poikilotopic” fabric. Overgrowth cements also are found at much smaller scales. In chalks and other micritic carbonate deposits, calcite overgrowths are documented on sub-micron-sized material, including the individual elements of coccolith “shields”. Such overgrowths are only discernable using scanning electron microscopy (Figure C16).

Many, but not all, burial-stage calcites are compositionally zoned (Figure C17). Recognition of zonation typically requires observations using staining techniques (Dickson, 1966), cathodoluminescence microscopy (Miller, 1988; Reeder, 1991), or backscattered electron or microprobe mapping (Reed, 1989). Zonation provides evidence of fluctuating geochemical conditions during an extended period of crystal growth. Corrosion zones preserved between stages of crystal

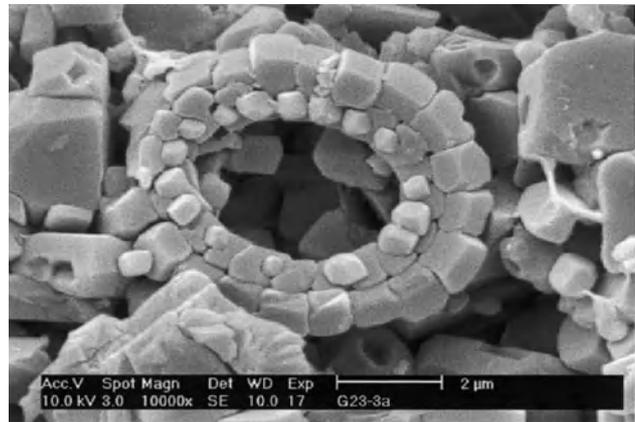

Figure C16 Scanning electron photomicrograph of a Maastrichtian pelagic chalk from the Danish North Sea. The large coccolith shield (probably *Cribrosphaerella ehrenbergii*) has multiple calcite overgrowths formed in optical continuity with individual crystal elements (note irregular sizes of individual elements indicating variable overgrowths). Scale bar = 2 μm .

growth may reveal episodes of crystal growth alternating with dissolution and therefore even greater geochemical variations.

Burial-stage dolomite also is common, resulting from either deep reflux of surface-derived brines or remobilization of Mg^{2+} from precursor high-Mg calcite or earlier-formed non-stoichiometric dolomite at the higher temperatures and pressures encountered at depth. In general, dolomite is far more common as a replacement than as cement, but dolomite cements do occur, especially in strata where the rock framework has already been largely or completely dolomitized. Burial-stage dolomites commonly are stoichiometric, zoned, relatively inclusion free, and medium to coarsely crystalline. They typically show substantial amounts of iron substitution and may be termed ferroan dolomite or ankerite, depending on iron content (see *Ankerite*).

Dolomites formed at temperatures of about 60–150°C and higher, especially from hydrothermal fluids, hydrocarbon-bearing brines, or waters associated with sulfate reduction, have distinctive morphologies. They are coarsely crystalline, rich in fluid inclusions, and have curved crystal faces, curved cleavage planes, and undulose extinction due to lattice deformation as a result of calcium enrichment. These are termed “saddle”, “baroque”, or “hydrothermal” dolomites (Radke and Mathis, 1980; and see *Dolomite Textures*). Unlike other dolomites, saddle dolomites occur with roughly equal frequency as cements and replacements, and commonly are accompanied by a suite of associated precipitates, including fluorite, metallic sulfides (e.g., sphalerite, galena), and barite.

Evaporite minerals, especially gypsum and anhydrite, may be remobilized during burial (mesogenetic) and uplift (telogenetic) phases of basin history. Where primary or eogenetic evaporite minerals are present in arid-region deposits, they can be dissolved and reprecipitated. In some cases, substantial subsurface transport occurs, allowing mesogenetic evaporite cements to precipitate in strata that were not directly associated with arid climates, and therefore, carbonate rocks, irrespective of their original depositional environments, may undergo filling of primary or secondary porosity by remobilized evaporite minerals. Anhydrite commonly precipitates

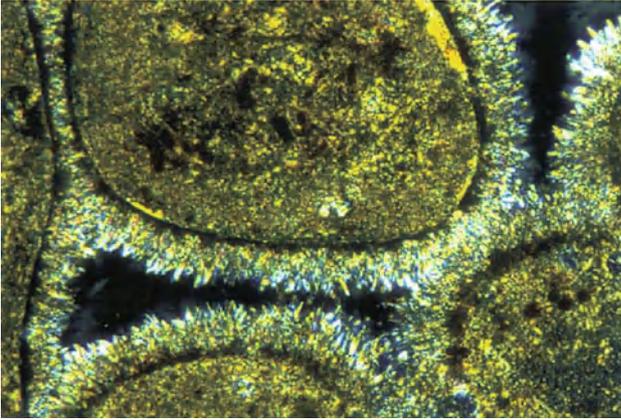

Figure C15 Thin-section photomicrograph (cross-polarized light) of modern beachrock at Salt Cay, Bahamas Islands. Dark, lumpy material surrounding grains is peloidal high-Mg calcite cement; it is followed by isopachous rim of fibrous, aragonitic, marine cement. Long axis of photo = 0.52 mm.

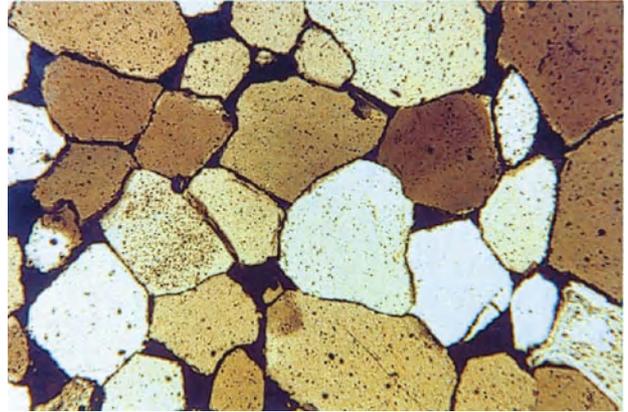

Figure C18A Thin-section photomicrograph (plane-polarized light) of a quartz arenite from the Devonian Hoing Sandstone in Illinois. Note the apparent interlocking, closely-packed fabric of sand grains with sutured grain boundaries possibly indicating substantial grain-to-grain pressure solution (but see Figure C18B for clarification). A few quartz overgrowths are weakly visible (e.g., lower left). Long axis of photo = 0.9 mm.

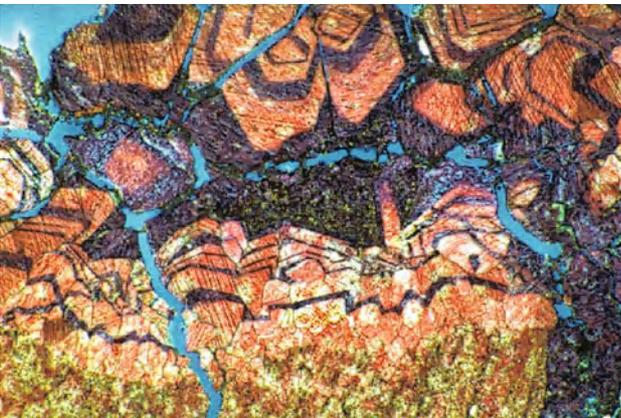

Figure C17 Thin-section photomicrograph (plane-polarized light; Alizarin-Fe stained) showing the value of staining in recognizing cement generations. This fracture in a Permian limestone from East Greenland is filled with successive bands of ferroan (blue stained) and non-ferroan (pink stained) calcite indicative of fluctuations in redox conditions during precipitation. Long axis of photo = 4.5 mm.

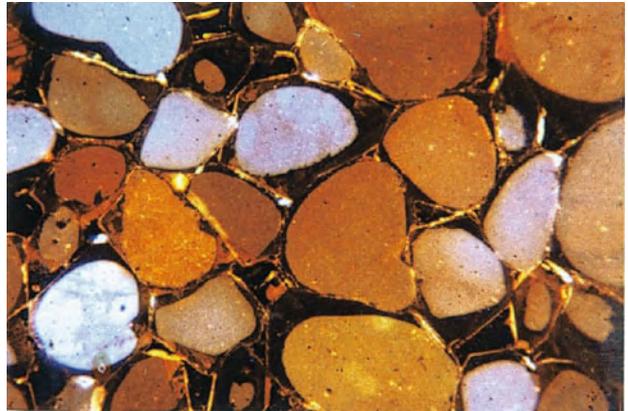

Figure C18B Photograph of same area as Figure C18A but under cathodoluminescence and using very long time-exposure. Detrital quartz cores appear blue-white or orange, and well-defined quartz overgrowths (transparent) surround virtually every grain. Boundaries between overgrowths are not sutured, and sandstone is clearly not pressure dissolved. From Scholle (1979, p. 114, photographs by Robert Sippel).

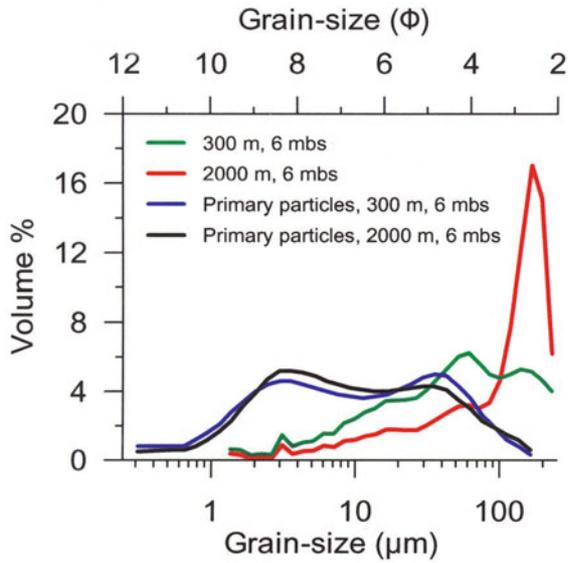

Figure F15 *In situ* grain size spectra of inorganic lime particles from a dredging plume measured with a LISST-100 *in situ* laser 300 m and 2000 m from the dredging site respectively. The grain size spectra of the primary particles have been analysed in the laboratory by use of a Malvern MasterSizer/E laser. The spectra indicate the significance of pure salt flocculation because no organic material was present in the sediment plume (Mikkelsen and Pejrup, 2000).

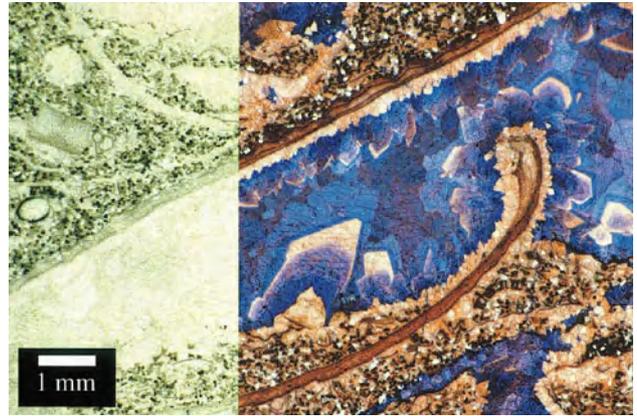

Figure S37 Photomicrograph of grainstone from the Derbyhaven Formation, Carboniferous Limestone, Isle of Man. Stain highlights the distribution of detrital quartz (unstained) in peloidal sediment caught between calcite strophomenid brachiopods that have pseudopunctate shell structure stained orange/red. The differentiation of early non-ferroan calcite cement (pink) from later zoned ferroan calcite cement (blue and mauve) is only visible in the stained segment of this photomicrograph.

from hot, geochemically evolved, basin-derived brines. Unlike the felted masses of crystals that form under near-surface conditions, mesogenetic hydrothermal anhydrite forms as large, blocky crystals that may also replace the carbonate host rock.

Silica cements can form at relatively early stages of burial where primary opal (opal-A) is present in the form of siliceous fossils (diatoms, radiolarians, siliceous sponges) or volcanic ash. Small particle sizes, high surface areas, high solubility of opal relative to quartz, and increasing temperatures with depth all drive opal alteration (Williams *et al.*, 1985). Opal-A may undergo diagenetic alteration to opal-CT, a transformation that can yield cement *lepispheres* (*q.v.*). However, the ultimate transformation product normally consists of one or more forms of quartz: megaquartz, microquartz (chert), or chalcedony that form either as replacement of carbonate grains or as cement. Fibrous quartz (chalcedony) occurs in both length-fast (chalcedonite) and length-slow (quartzine and/or lutecite) forms; the presence of length-slow chalcedony can indicate a possible association with evaporites or former evaporites.

Understanding the formation of burial-stage cements depends largely on observations of the sequence of cement formation (paragenesis) coupled with geochemical information. Paragenetic determinations show the relative temporal relationships between any given cement and a variety of other geological events, the absolute timing of which may or may not be known. Such events can include earlier cementation episodes, compaction effects (including stylolitization), uplift and possible exposure, development of fractures or other deformation features, hydrocarbon emplacement, and hydrothermal mineralization.

Several types of geochemical information are used to assist in the recognition of burial-stage cements. Trace-element data is useful mainly because most near-surface cements are produced in oxic environments and many burial-stage cements are formed at lower Eh levels. Thus, Fe, Mn and other metals concentrations typically are elevated in burial cements relative to earlier-formed precipitates. Stable isotope geochemistry (primarily $^{16}\text{O}/^{18}\text{O}$) is widely applied to the study of timing of carbonate cementation because $^{16}\text{O}/^{18}\text{O}$ ratios depend, in part, on temperature of precipitation. Thus, burial-stage cements typically are enriched in ^{16}O (and, largely as a result of organic matter alteration, ^{12}C) relative to most marine precipitates. Unfortunately, the isotopic composition of waters from which precipitation occurs also strongly affects the isotopic ratios of the cement, making it impossible to determine uniquely the temperature of formation from isotopic measurements alone on a single precipitate. The same "light" O and C ratios that characterize burial cements are also found in many near-surface meteoric precipitates. Analyzes of two or more minerals (e.g., calcite and quartz) precipitated at the same time and from the same waters can resolve the problem of dealing with two "unknowns", but proving simultaneous precipitation is difficult.

Homogenization measurements on *fluid inclusions* (*q.v.*) incorporated within cements can be used to directly determine precipitation temperatures, and thus, their time of formation if the geothermal history is well constrained (Goldstein and Reynolds, 1994). In addition, freezing-point determinations on the fluid inclusions can provide data on the chemical composition of precipitating fluids. Such studies have been applied very successfully to a variety of minerals, but should be approached with care for several reasons. Inclusions can be

incorporated into crystals when they are precipitated but also at later stages through the healing of fractures, cleavages and other dislocations. Only "primary" inclusions provide accurate temperatures and fluid chemistries of initial crystal formation; thus, their proper recognition is critical, but often difficult. In addition, some minerals, especially calcite, are unlikely to maintain intact primary fluid inclusions during deeper burial and elevated temperatures. Several studies have shown that as little as 15°C of "overheating" can cause primary inclusions in calcite to re-equilibrate, thus altering their apparent formation temperatures (Goldstein and Reynolds, 1994).

In recent years, $^{87}\text{Sr}/^{86}\text{Sr}$ determinations have been applied to carbonate cement studies. Compilation of a seawater $^{87}\text{Sr}/^{86}\text{Sr}$ secular variation curve for the Phanerozoic (Burke *et al.*, 1982) can aid in the identification of unaltered marine precipitates. Many burial cements, by contrast, have $^{87}\text{Sr}/^{86}\text{Sr}$ ratios far more radiogenic than marine cements in the same rocks, largely through incorporation of strontium derived from subsurface alteration of feldspars, clays and other clastic terrigenous minerals.

Absolute age determinations using a variety of radiometric methods (^{14}C , Th/Th, $^{230}\text{Th}/^{234}\text{U}$, ^{238}U , $^{238}\text{U}/^{206}\text{Pb}$, and others) have been used to constrain the timing of carbonate cement formation and continue to be perfected. Additional dating techniques (K/Ar, Ar/Ar, U-Th, and others) are applicable to non-carbonate precipitates, such as authigenic clays or feldspars.

Uplift-stage (telogenetic) cements in carbonate rocks

Uplift typically leads to reduced temperatures and pressures and may be accompanied by substantial changes in pore fluid composition due to deep penetration of meteoric fluids from elevated recharge areas. This generally leads to substantial dissolution, with generation of solution-enlarged fractures, vugs and caves. Carbonate cements precipitated during this stage are volumetrically subordinate to earlier precipitates and are difficult to distinguish from either early meteoric or burial cements except by their paragenetic relationships. Thus, they are discussed only very briefly here.

Carbonate cements normally remain unaltered or may undergo partial dissolution during telogenesis, but evaporite cements may undergo dramatic transformations. Anhydrite cements, because of their high solubility in meteoric waters, may be extensively dissolved and reprecipitated as gypsum or may be leached entirely during uplift. Calcite cements commonly fill some of the porosity that is newly generated by such dissolution (Scholle *et al.*, 1992).

Cements in sandstones and other siliciclastic strata

Cementation of siliciclastic sandstones and conglomerates can be quite complex—where siliciclastic strata have a diverse primary mineralogical composition, they also undergo complex subsurface alteration processes. Many of the varied detrital grains in siliciclastic strata act as substrates for the precipitation of overgrowth cements. Other grains are unstable in surficial or shallow- to moderate-burial conditions and dissolve to yield a variety of complex aqueous solutions capable of precipitating a diverse range of cements.

Three precipitates account for the vast majority of cementation in clastic terrigenous strata: various forms of silica (quartz and opal), carbonate minerals (mainly calcite),

and authigenic clay minerals. Many other minerals, including carbonates (dolomite and siderite), evaporites, zeolites, iron oxides, iron sulfides, and feldspars occur as cements in lesser volumes or under specialized conditions; many of these cements are illustrated in Scholle (1979).

Syndepositional to early diagenetic (eogenetic stage) cements in siliciclastic deposits

It is uncommon for siliciclastic sediments to be extensively cemented during eogenetic diagenesis, especially as compared to their carbonate counterparts. Some hardgrounds, especially phosphatic ones, are known from modern siliciclastic shelf sands in areas of very low sediment accumulation rates. Beachrock cementation occurs on siliciclastic shorelines in areas of marine carbonate formation (e.g., the Red Sea and Gulf of Elat/Aqaba) and carbonate cementation of shelf sands occurs in extensive areas of methane seepage. Aragonite and high-Mg calcite are the predominant marine carbonate cements in modern marine siliciclastic settings, as they are in carbonate environments.

The most common sites of eogenetic cementation of siliciclastic deposits are surficial to shallow subsurface meteoric environments. In surficial settings, calcium carbonate-bearing waters are drawn to the surface by capillary forces and evaporatively concentrated. This leads to precipitation of micritic low-Mg calcite cements forming highly lithified calcretes and caliche crusts. This process occurs primarily in areas of shallow water tables in semiarid to arid settings and, in some instances, is substantially influenced by transpiration (sometimes yielding cemented root structures, termed "rhizocretions"). Dissolution and reprecipitation of silica- and/or iron-bearing minerals by surface evaporation creates siliceous or ferruginous surface crusts, termed silcretes and ferricretes, respectively. In arid regions, it is even more common to observe near-surface dissolution, evaporative concentration, and reprecipitation of sulfate evaporites, producing surficial layers of siliciclastic sediment that are completely cemented by coarsely crystalline, poikilotopic gypsum (gypcretes).

Influx of calcium carbonate-rich groundwaters in tectonically active basins occurs by subsurface flow from adjacent highlands that may contain carbonate strata undergoing surficial weathering or subsurface dissolution. Surface re-emergence and evaporation of those waters produces spring-fed low-Mg calcite travertines as well as interstitial cementation and surface coating of fluvial sediments downstream from groundwater emergence sites.

Early diagenetic infiltration and lateral flow of groundwaters can also lead to localized concretionary cementation of siliciclastic sediments. Carbonate concretions are most common, but iron oxides and hydroxides, iron sulfides, silica, barite, and gypsum also form concretions. Concretions are spherical or elongate masses of sediment cemented by finely crystalline precipitates. Septarian concretions (see *Septarian Concretions*) are precipitated carbonate nodules that also have fractures filled with coarse, multigeneration carbonate. Individual concretions can range from millimeters to several meters in length, and these sometimes coalesce to form larger sheets or irregular masses. Most concretions are syngenetic to very early diagenetic precipitates, although some have long precipitation histories or form during late diagenesis.

Carbonate concretions normally are composed of multiple generations of non-ferroan low-Mg calcite, reflecting the

consistently high Eh and compositional variability of near-surface waters. However, where eogenetic reducing conditions exist, siderite and/or ferroan calcite form concretionary precipitates. Root traces or other permeability corridors, localized concentrations of organic matter, distribution of carbonate fossil fragments, and other factors play roles in localizing sites of concretion formation, and the directions of groundwater flow may control the elongation of concretions.

Siliceous cements also are formed in early diagenetic settings, especially in volcanoclastic rocks. Amorphous silica (opal) is a common precipitate in sandstones that have volcanic glass as a primary constituent. Near-surface devitrification of glass shards proceeds rapidly in meteoric waters and the increase in aqueous silica concentrations is followed by opal precipitation. The opal cements, however, normally are transformed to one or more forms of quartz (chert, chalcedony, or megaquartz) at the increased temperatures encountered during deeper burial. Zeolites (especially analcime, clinoptilolite, laumontite, and phillipsite), clays (especially smectite and kaolinite), and calcite are other common cementing agents in early- to intermediate-stage diagenesis of volcanogenic sediments.

Iron oxide grain coatings, once considered entirely detrital, in many cases now are recognized to be early diagenetic precipitates (Walker, 1976). Amorphous or extremely finely crystalline hematite and hematite precursors (mainly goethite) form as grain coatings in oxidizing near-surface settings, producing reddened sediments (redbeds, *q.v.*). The iron is derived from dissolution of unstable iron-bearing minerals, including amphiboles, olivene, and magnetite.

Burial (mesogenetic stage) cements in siliciclastic deposits

Much more extensive cementation of siliciclastic strata takes place during moderate burial and commonly is dominated by quartz precipitation, especially in strongly quartzose sediments (quartz arenites, orthoquartzites). Mesogenetic sources of silica for cementation are varied, but pressure solution of detrital quartz grains was once considered to be the primary source. That importance is now questioned, and other sources of silica are considered to be more significant by many authors (e.g., Land, 1984). Alternative silica sources include dissolution and reprecipitation of less stable forms of silica (especially opal from radiolarians, diatoms and volcanic glass, and extremely fine-grained quartzose eolian dust), subsurface alteration or dissolution of amorphous aluminosilicates, feldspars, and other silicate minerals, and diagenetic transformations of clays (especially conversion of smectite to illite) within sandstones or associated shales (Füchtbauer, 1978). Hot waters from deep basinal sources that cool as they move upward can also precipitate quartz, because silica solubility decreases with decreasing temperature. Although such basin-scale fluid movements may be slow, the tens to hundreds of millions of years over which burial diagenesis can act allows extensive quartz cementation of siliciclastic strata (Sibley and Blatt, 1976).

Quartz cements form primarily on detrital quartz grains and almost always grow as syntaxial overgrowths (i.e., in optical continuity with the substrate). Monocrystalline quartz grains have single-crystal overgrowths; polycrystalline detrital grains can have more complex overgrowths. A variety of sedimentary or early diagenetic coatings on detrital grains (including iron

oxides or hydroxides, organic films, and clays) can inhibit formation of quartz overgrowths and help to preserve porosity in quartz-rich sandstones, but such coatings rarely completely cover the surface of grains. Overgrowths thus may be initiated at breaks in the coatings, initially forming as small protrusions from the detrital grain surface. Multiple initial growths may eventually coalesce into a complete overgrowth with euhedral crystal outlines or may completely fill pore spaces, forming compromise boundaries with overgrowths on adjacent grains. Extensive overgrowth precipitation yields a completely cemented fabric of interlocked quartz grains that can erroneously appear to be the result of extensive compaction and grain-boundary suturing (Figure C18A). The presence of visible grain coatings surrounding the detrital quartz grains, where they have not inhibited cementation, are a great aid in the proper identification of overgrowths as the cause of porosity destruction. They can clearly delineate the contacts between detrital cores and overgrowths, even though both act as a single crystal. Where such “dust rims” are absent, cathodoluminescence microscopy may aid in the recognition of overgrowths (Figure C18B), through accentuation of trace-element variations between detrital and authigenic constituents (Sippel, 1968; Miller, 1988).

Other forms of silica—mainly chalcedony and chert (microquartz)—can also cement siliciclastic strata in mesogenetic settings, especially where detrital quartz substrates are relatively scarce or where silica precipitation rates are very high. Chalcedony is a fibrous growth form that typically forms palisade rims and radiating, spherulitic growths in interstitial pores. Microquartz form as tiny, equant, often inclusion-rich crystals, with anhedral to subhedral morphologies, commonly increasing in crystal size from pore wall to pore center.

As with carbonate cements, fluid inclusion geothermometry and stable isotope geochemical studies are very useful in determining the temperature and geochemical conditions of quartz cement formation. Because of the physical strength and lack of cleavage in quartz, fluid inclusions studies of this mineral are far more reliable than those done on calcite, dolomite or most evaporite minerals.

Burial-stage calcite is an important mesogenetic cementing agent in many siliciclastic strata and can form throughout the history of mesogenetic alteration. Early-stage calcites form predominantly where a significant volume of unstable carbonate (commonly aragonitic shell fragments) was present in the original sediment. These grains are readily dissolved during early diagenesis in the presence of nonmarine or low-salinity (mixed) pore fluids. The presence of calcitic shells or other carbonate grains can provide isolated nucleation sites for the growth of calcite cements from carbonate-saturated pore waters. These isolated sites of cement formation allow nucleated crystals to grow unimpeded by competition from neighboring precipitates. This commonly produces coarsely crystalline cements and even poikilotopic fabrics in which single calcite crystals engulf several detrital grains. The force of crystallization of such early mesogenetic calcite can lead to displacement or fracturing of detrital grains and produce apparently undercompacted or “floating” fabrics.

Late-stage calcite cements typically postdate quartz overgrowths and authigenic clays. They result from the fact that calcite solubility decreases at increased temperatures and basinal brines may have elevated pH and high Ca and CO₃ concentrations. In addition, under most deep burial

conditions, waters are strongly reducing, and late-stage calcites therefore are characterized by elevated iron and manganese concentrations.

Mesogenetic dolomite and siderite cements can be locally important in siliciclastic deposits. Dolomite cements can be anhedral to euhedral, generally are zoned and tend to be ferroan, reflecting reducing conditions during formation. Siderite cements tend to be finely crystalline with yellow-brown flattened rhombs; they too require reducing conditions for formation.

Clay minerals in siliciclastic rocks were once considered to be entirely detrital. In recent decades, however, numerous studies have demonstrated that authigenic clays are extremely common and precipitate under a variety of conditions (Blatt, 1979), in some cases substantially affecting the petrophysical properties of sandstones (Bjørlykke, 1988). Illite, smectite, and mixed-layer smectite-illite and smectite-chlorite and kaolinite all occur as pore-filling and grain-coating cements and can be difficult to distinguish from detrital counterparts. Some authigenic clays, especially smectite-illite grain coatings, clearly predate all other cements and may be of eogenetic origin. As such, these clays can inhibit later quartz or calcite cementation and thus help to preserve sandstone porosity. Other clays form later in the cementation history. Kaolinite (or its polymorph, dickite) occurs as authigenic vermicular stacks (“books” of mica-like plates) that generally postdate eogenetic cements. Because kaolinite precipitation is favored by low pH conditions, its formation sometimes is associated with decomposition of organic matter or meteoric water influx. Alteration and recrystallization of both detrital and authigenic clays during progressive burial can further complicate recognition of primary versus secondary origins or timing of precipitation.

A number of other cements, including authigenic feldspar overgrowths, pyrite and other iron sulfides, barite, fluorite, sphalerite, and other hydrothermal minerals, can form during various stages of siliciclastic diagenesis. However, they normally have only local importance in controlling rock properties and so will not be detailed here.

Summary

Many cements and cement fabrics are known from carbonate and siliciclastic strata. In combination, they occlude 20–40 percent porosity in many sedimentary rocks and contribute substantially to sediment lithification. The fabrics and paragenetic relationships of cements provide important clues to the time and conditions under which they were formed. Those interpretations are strengthened when done in combination with trace-element analyzes, isotopic studies, and fluid-inclusion geothermometry. Absolute age determinations on cements are becoming more precise and as techniques are perfected for analyzing small, *in situ* samples, such determinations will substantially improve our understanding of cementation. Future studies may clarify the poorly understood role of microbial activity in mediating cementation, especially in the subsurface. Likewise, refining our understanding of the factors that prevent or retard cementation remains of fundamental importance, because it aids in predicting the location and quality of possible unconventional oil and gas reservoirs and economic mineral deposits.

CHALK

The Ocean Drilling Program defines chalk as a firm pelagic sediment composed predominantly of calcareous pelagic grains (e.g., Kroenke *et al.*, 1991, see *Oceanic Sediments*). Calcareous pelagic grains comprise calcareous nannofossils of silt size and calcareous microfossils of mm size, as well as fine fossil debris. The term chalk can also refer to a calcareous nannofossil-rich facies irrespective of induration. The grains are mixed into sediments of mudstone, wackestone, or packstone texture (see *Classification of Sediments and Sedimentary Rocks*). Calcareous nannofossils include coccoliths which originate from spores of golden brown algae, and are found in sediments ranging from Late Triassic to present (Siesser and Winter, 1994). Microfossils are typically foraminifers.

Chalk facies sediments contain varying amounts of siliceous micro- and nannofossils which upon burial may form chert (see *Siliceous Sediments*). Similarly, chalk also contains varying amounts of clay which upon burial may form stylolites or flaser structures (Garrison and Kennedy, 1977, see *Diagenetic Structures*).

Oceanic chalk deposits form in areas where terrestrial input is low, and where the seafloor is above the carbonate compensation depth, typically on deep sea plateaus (see *Oceanic Sediments*). These sediments are almost exclusively of Cretaceous age or younger. Upon the large transgression in Upper Cretaceous, chalk facies sediments accumulated on the continental shelf (Håkansson *et al.*, 1974). The Chalk Group of the North Sea Basin is primarily composed of chalk sediments of Upper Cretaceous and Paleocene age.

Freshly deposited chalk facies sediments have porosities around 70 percent; and porosities of around 35 percent may be

maintained to an effective burial of *c.*1 km (Scholle, 1977, Figure C19). This preservation of porosity probably reflects that the fossils constituting the chalk are mainly composed of chemically stable low Mg calcite (see *Carbonate Mineralogy and Geochemistry*).

Chalk is utilized as a source of lime and for improvement of acid soils. In North West Europe it is a reservoir for groundwater (Downing *et al.*, 1993) and in the Central North Sea for hydrocarbons (Andersen, 1995). Chalk is used for rinsing smoke after coal combustion in power plants and as a raw material for production of pure calcite or aragonite for industrial purposes: pigment in paper, plastic and paint. Indurated chalk has been used as building stone (a beautiful example is the cathedral of York, England).

Until the 1960s chalk was seen as a uniform white powder, possibly formed by precipitation of calcite in the seawater, and when studied in exposures, the purpose was mainly extracting macrofossils. With the introduction of electron

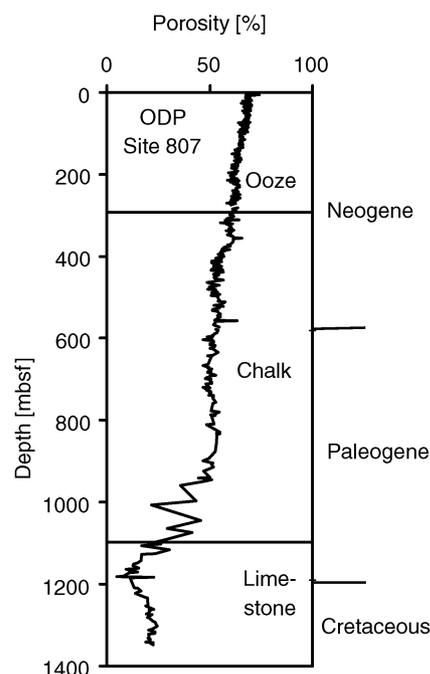

Figure C19 Chalk facies sediments on the Ontong Java Plateau at a water depth of 2,805 m, investigated by the Ocean Drilling Program (Kroenke *et al.*, 1991). Laboratory porosity versus depth in meters below sea floor (mbsf). With burial, the soft calcareous ooze grades into firmer chalk and this again to hard limestone. Compaction experiments indicate that the gradual porosity loss through ooze and chalk is a consequence of physical compaction (Lind, 1993, see *Compaction of Sediments*), whereas geochemical data indicate that the limestone is formed via porosity reducing precipitation of calcite caused by diffusion of ions from where flint or stylolites form or from the basement (Delaney *et al.*, 1991; see *Cements and Cementation*). The small scale porosity variation in the chalk section primarily reflects varying proportion of carbonate mud and hollow microfossils (Masters *et al.*, 1993), whereas the more dramatic porosity shift within the limestone reflects an upper wackestone interval rich in cemented microfossils overlying an interval of re-crystallized carbonate mudstone (Borre and Fabricius 1998; see *Fabric, Porosity and Permeability*). The interval from 970 mbsf to 1100 mbsf is rich in flint beds (see *Siliceous Sediments*).

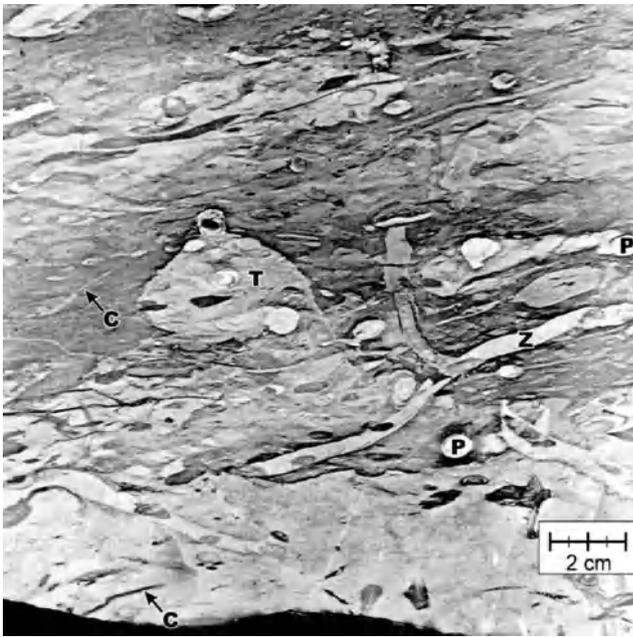

Figure C20 White chalk containing about 5–10% clay minerals, Maastrichtian, from the quarry “Dania” in northern Jutland, Denmark. The chalk has been sectioned vertically and smoothed. The surface has been lightly oiled with common lubricating oil (see Bromley, 1981). The treatment greatly increases the visibility of the sediment structures. The sediment has been fully bioturbated by burrowing animals. The trace fossils represented are: (T) *Thalassinoides*, (Z) *Zoophycos*, (P) *Planolites* and (C) *Chondrites* (see *Biogenic Structures*). R. G. Bromley.

Figure C21 Electron micrograph of Maastrichtian chalk from the central North Sea. The sample has a mudstone texture, a calcite content of 98.8 wt.% and a porosity, \emptyset , of 37%. The mud is composed of coccoliths and fossil debris. All calcite particles are apparently thoroughly re-crystallized and because the clay content is low, the specific surface, s , as measured by BET is relatively low ($1.6 \text{ m}^2 \text{ g}^{-1}$), and the resulting gas permeability 4.3 mD. Chalk is petrophysically an exceptionally simple sediment which obeys Kozeny's equation relating permeability, specific surface, and porosity: $k = C \emptyset^3 / S^2$, where S is the specific surface relative to bulk volume, k is the Klinkenberg corrected gas permeability (in m^2) and C is near constant, varying from 0.21 for a porosity of 20% to 0.24 for a porosity of 40% (Mortensen *et al.*, 1998).

microscopy it became clear that the white powder is composed of nannofossils and fossil debris; and the expansion of drilling activity in the oceans and in the North Sea directed the scientific interest to the study of nanno- and microfossils with the purpose of establishing a biostratigraphy usable on drilling cores and cuttings. In the sixties and seventies scientists intensified the study of sedimentary structures and it appeared that chalk as a rule is bioturbated (Figure C20). It was also found that chalk may contain re-sedimented chalk-clast bearing intervals (e.g., in the central North Sea, Nygaard *et al.*, 1983). Chalk may exhibit cyclicity in silica content (frequently seen as series of chert beds) or clay content (reflected as series of marl beds). By some researchers this was seen as a signature of geochemical segregation from an originally more homogeneous sediment, but from studies of the pattern of bed thickness variations and oxygen isotopic variations (see *Isotopic Methods in Sedimentology*) it became more and more probable that the cyclicity reflects an original sedimentary variation which from the eighties have been related to paleo-climatic fluctuations (e.g., Gale, 1989; and see *Cyclic Sedimentation, Milankovitch Cycles*).

Major constructions in chalk (e.g., the Channel tunnel between England and France) and the search for and production of hydrocarbons from chalk reservoirs has in the nineties directed research attention to the mechanical, hydraulic and petrophysical properties of chalk (e.g., Burland *et al.*, 1990; Maliva and Dickson, 1992; Megson and Hardmann 2001; Figure C21). Specific current research questions are how the porosity loss proceeds in geologic time in the sedimentary basin, and the rock mechanical behavior during hydrocarbon production and by the change in pore fluid from oil to water.

CHARCOAL IN SEDIMENTS

Definition

When plant material is burnt by fire there is often an incomplete combusted residue known as charcoal. All plant organs, from leaves to flowers to wood, may be preserved as charcoal. During the charring process wood may break up into characteristic sizes and shapes. It has been shown that wood fragments may typically be about 1 cm cubed. The charcoal is brittle (getting hands dirty upon touch) and relatively inert with the cell walls being converted to almost pure carbon (Scott, 1989). Charcoal usually shows exceptional anatomical detail when seen, for example, under the scanning electron microscope (Scott and Jones, 1991) (Figures C27, C28, C29). Even small flowers may be preserved as charcoal (Scott *et al.*, 2000).

Transport

During wild fires small particulate fragments (around 1–10 µm, including charcoal and soot particles) may be blown

away from the fire sites. These small particles may enter lakes and other wetland environments or into the sea and be incorporated into accumulating sediments (Clark and Patterson, 1997). In contrast, larger charcoal fragments may either, in the case of fires within mires, be incorporated into peat or else be transported by water (Scott, 2000). Severe fires may destroy plants which help bind soil and it is possible that rainstorms following major fires may result in significant erosion of the fire site. Sediment and charcoal may be washed into a depositional site (Nichols and Jones, 1992). It has been shown, for example, that major alluvial fans may be triggered by fires, such as in Yellowstone National Park (Meyer *et al.*, 1992).

Macroscopic charcoal fragments usually float in water. The length of time for a charcoal fragment to be waterlogged depends on a series of variables from size, temperature of charring, organ and species (Nichols *et al.*, 2000).

Deposition

It has been argued that larger charcoal fragments in a sediment implies a nearby fire (Clark and Patterson, 1997). Whilst this may be the case for classes of windblown microscopic charcoal, however, it is not necessarily true for larger macroscopic charcoal fragments. Charcoal may be incorporated into bed load sediments. Flume experiments have shown that charcoal may be entrained in sand ripples of velocities around 35 cms⁻¹ (Nichols *et al.*, 2000). Marine sediments may also yield charcoal fragments (Bird, 1997; Scott, 2000).

Sedimentary distribution

Macroscopic charcoal when encountered in fossil deposits is often called fusain (Scott, 1989). This is one of the four fundamental lithotypes of coal described by Marie Stopes. In the Quaternary there has been a number of significant studies of microscopic charcoal from lake and peat sediments to help unravel more recent fire histories (Patterson *et al.*, 1987). In marine clastic sediments also most research has centered upon microscopic charcoal and soot particles which are likely to record larger and more frequent regional fires (Bird, 1997). In contrast, studies of Pre-Quaternary charcoal has centered upon larger charcoal fragments that are visible in rocks (Scott, 2000). There is a good fossil record of charcoal from the latest Devonian and evidence of extensive wildfire from the Early Carboniferous (Scott, 2000).

Most often a geologist will encounter charcoal (fusain) fragments in terrestrial clastic rocks and also commonly they may be abundant in estuarine, deltaic and shallow marine deposits. These may be recognized as small black cubes with a lustrous sheen which marks the finger upon touch (Figures C22, C23). This is in contrast to coalified plant material, which is often black, shiny, having a concoidal fracture and is clean to touch. Charred leaf material may also be recognized (Jones and Chaloner, 1991) (Figure C24). Smaller charred plant fragments, which may include flowers, may be difficult to see on a bedding surface. In these cases only bulk maceration, using HF, or sieving of unconsolidated sediment, will yield the smaller charcoal fragments (Figures C25, C26).

Charcoal is often encountered within coal seams (Figure C22) where it may represent 10–50 percent of the

seam. Charcoal may also be encountered in volcanic rocks, especially pyroclastic deposits where charcoal has been entombed in hot lava or ash (Scott, 2001). Charcoal is often not recorded by sedimentologists in the field.

Implications

The recording of charcoal (fusain), as opposed to other forms of organic matter, has considerable implications for the interpretation of paleoenvironments and diagenesis. In addition, microscopic and isotopic studies of charcoal may yield data on

CHLORITE IN SEDIMENTS

Chlorite is a common phyllosilicate mineral found in all kinds of sediments and sedimentary rocks. In fact the name chlorite, derived from the green color of most specimens, encompasses a group of minerals characterized by a wide range of chemical and structural variation (Bailey, 1988a). In sediments, much chlorite falls by definition into the category of minerals known as “clay minerals” (see *Clay Mineralogy*). Small amounts of chlorite are common in many sediments and it may be both detrital or formed diagenetically. Overall, diagenetic chlorite is probably rarer than other diagenetic clay minerals but it is common in certain kinds of sedimentary rocks. To understand some types of diagenetic chlorite its relationship to serpentine minerals and to mixed-layer chlorite minerals must be considered (Reynolds, 1988). Indeed, the petrology of chlorite in the sedimentary realm is diverse. This contribution attempts to summarize what is known about the characteristics, occurrence, and origins of various kinds of chlorite in sediments.

Structure and composition

All varieties of chlorite have a common structure consisting of a negatively charged 2:1 layer and a positively charged ‘interlayer’ octahedrally coordinated hydroxide sheet (Bailey, 1988a). Most chlorites are trioctahedral and as such they are normally rich in Fe and Mg. Less commonly, chlorites may be dioctahedral in which case they tend to be enriched in aluminum. For many years the nomenclature and classification of trioctahedral chlorites was plagued by the existence of numerous species names. This has been greatly simplified with Fe-rich chlorites classified as chamosites, and Mg-rich chlorites as clinochlores, with suitable adjective modifiers used if necessary (Bayliss, 1975). The chemical compositions of chlorites are complex, but a generalized structural formula distinguishing octahedral and tetrahedral cations and encompassing both trioctahedral and dioctahedral species can be written as:

In this form, R²⁺ represents divalent cations, mainly Fe and Mg, R³⁺ represents trivalent cations mainly Al, and □

represents a vacant octahedral site. Fully trioctahedral chlorites do not have octahedral vacancies so that the octahedral cation total in the above formula is six. Dioctahedral chlorites, such as the species sudoite, have a dioctahedral 2:1 layer, and a trioctahedral interlayer hydroxide sheet. Thus in the general formula given above they have one vacant site and an octahedral cation total of five. Similarly a chlorite in which both the 2:1 layer and the interlayer octahedral sheets were both dioctahedral would have two vacant sites and thus only four octahedral cations.

In terms of crystal structure the 2:1 layer and the interlayer hydroxide sheet in chlorites may be stacked together in different ways so defining different chlorite polytypes. For some time it has been recognized that type I polytypes are common in sedimentary rocks formed at diagenetic temperatures whereas the IIb polytype is the common polytype for high temperature metamorphic chlorites. Recent summaries are provided by de Caritat *et al.* (1993) and Walker (1993).

In contrast to metamorphic chlorites formed at higher temperatures, recalculation of chemical analyzes to structural formulae for trioctahedral chlorites from sedimentary rocks often indicates the presence of octahedral vacancies, i.e., octahedral totals fall short of six cations. It is not yet clear, however, if such vacancies are present in the structure of sedimentary chlorites or are simply apparent due the assumptions made about the (usually unanalyzed) anions and/or analytical problems inherent in the analysis of clay minerals, e.g., avoiding contamination (Hillier and Velde, 1991; Jiang *et al.*, 1994).

Occurrence and origin

Much of what is known about chlorite in sediments can be rationalized into a number of broad categories or associations, each probably with some degree of genetic significance (Figure C30). These categories include detrital and weathered chlorite; the odinite-berthierine-chamosite shallow-marine association; the Mg-rich chlorite evaporite/dolomite association;

the aluminous dioctahedral chlorite red-bed association; the lithic/volcaniclastic sediment association, and the shale diagenesis/low grade-metamorphism association. However, the nature of chlorite in sediments is diverse, and undoubtedly many occurrences will not fall neatly into one of these associations; others, such as chlorites in limestones, have not yet received the study they deserve. Nonetheless, the use of these associations provides a conceptual framework to help understand the occurrence of chlorite in sediments in many instances.

Detrital and weathered chlorite

Detrital chlorite in sediments reflects provenance. In fact, chlorite is very easily weathered being one of the first minerals to disappear from soil profiles, even in temperate climates (Bain, 1977; Barnhisel and Bertsch, 1989). As a result it is quite unusual to find abundant detrital chlorite in sediments, unless they were deposited in close proximity to chlorite-rich parent materials. Nonetheless, small amounts of detrital chlorite can be found in many sediments. In modern oceanic sediments, chlorite is largely confined to, and concentrated in, sediments from high latitudes (Chamley, 1989; Weaver, 1989). This is undoubtedly a direct reflection of the fact that chlorite is such an easily weathered mineral. Indeed, estimates of its abundance in the clay size fraction of high latitudes oceanic sediment are only rarely more than 20–30 percent (Windom, 1976). The effect of weathering on the distribution of detrital chlorite in marine sediments is also evident from studies of oceanic sediments from dated cores of the western Atlantic region, which record a general increase in chlorite content from the Eocene to the Quaternary (Chamley, 1989). This appears to reflect the general pattern of global cooling over this time and consequent decrease in the intensity of chemical weathering in many source areas. To some extent it may also reflect a general increase in relief resulting from Alpine tectonism with the associated stripping of more mature soils and more widespread exposure of low-grade (chlorite-rich)

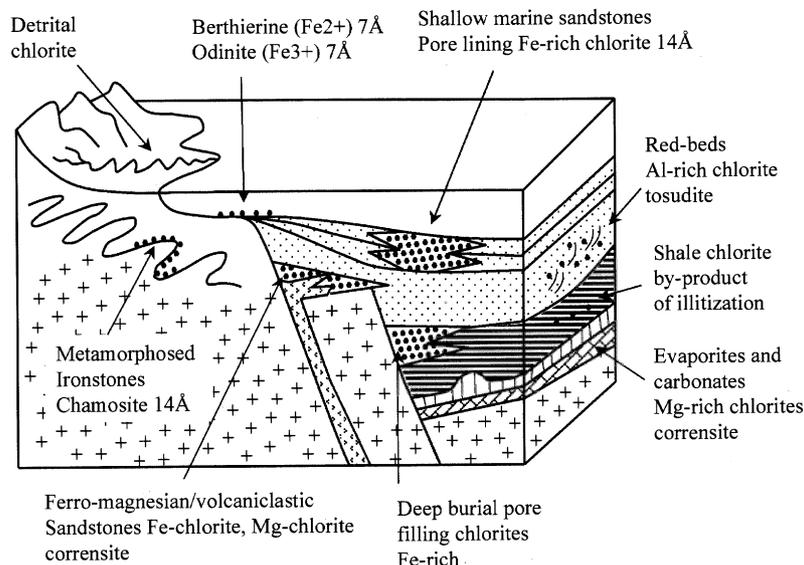

Figure C30 Common occurrences of chlorite and related minerals in sediments.

metamorphic rocks. In summary, the conditions necessary to supply detrital chlorite to sediments in great quantity are probably only rarely established. Therefore, the simple presence of abundant chlorite in sediments is more often than not an indication of its diagenetic formation, or at least that such an origin should be seriously investigated. Often it is assumed, quite correctly, that the presence of the I1b polytype in un-metamorphosed sediments indicates a detrital origin for chlorite. Caution must be applied, however, since the polytypic forms of chlorite are not entirely independent of compositional controls, for example Mg-rich chlorites formed at diagenetic temperatures, such as those in the evaporite/dolomite association described below, often crystallize as the I1b polytype (Hillier, 1993; Hillier *et al.*, 1996).

Odinite-berthierine-chamosite shallow marine association

The Fe-rich variety of chlorite known as chamosite is named after its occurrence in an oolitic ironstone, near the town of Chamoson in the French speaking part of the Swiss Alps. The ironstone at Chamoson has been affected by low-grade metamorphism and similar ironstones from other localities not so affected are characterized instead by the presence of the 0.7 nm (7Å) serpentine mineral berthierine (e.g., Hughes, 1989). Oolitic ironstones are deposited in shallow marine environments and increasingly the presence of Fe-rich chlorite (chamosite), often as a clearly authigenic isopachous pore-lining (Figure C31), has been recognized in sandstones deposited in similar shallow marine settings. Indeed, iron ooids are frequently present in small quantities in such sandstones (Ehrenberg, 1993). This evidence is enough to suggest that the geochemical conditions that lead to chlorite formation must be similar in both cases. In modern environments examples of berthierine formation in shallow marine tropical deltaic environments have been known for some time (Porrenga, 1967), although they have more recently been reinterpreted and the 0.7 nm (7Å) mineral renamed odinite (Odin, 1988; Bailey, 1988b). Reinterpretation rests largely on

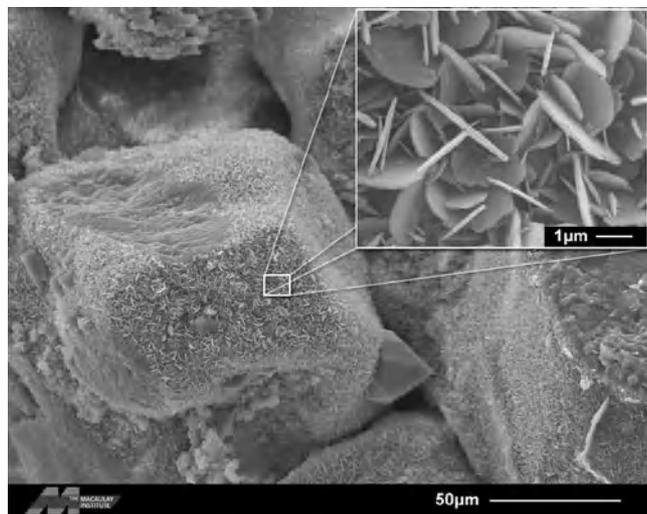

Figure C31 Diagenetic pore-lining chlorite from a shallow marine sandstone (Dogger beta Haupsandstein, see Hillier, 1994).

the basis that much of iron present is ferric rather than ferrous as in berthierine *per se*. Pore-lining chamosites from sandstones often show evidence for interstratification with a 0.7 nm (7Å) mineral, probably berthierine. Thus it has been suggested that odinite and/or berthierine may represent the precursors of diagenetic chamosite, since all appear to share a common depositional/geochemical environment characterized by a high supply of colloidal iron from a tropically weathered landscape. Taken together one may thus define an odinite-berthierine chamosite association. Although many questions have yet to be answered concerning the precise genetic links amongst these minerals and the precise conditions that promote their formation, the alteration of syn-sedimentary Fe-rich 0.7 nm (7Å) minerals to Fe-rich chlorite as a result of diagenetic processes is a common hypothesis.

Diagenetic alteration of chlorites from shallow marine sandstones has recently been studied in some detail for (Hillier, 1994) including the well-known Tuscaloosa sandstone of the US Gulf Coast (Ryan and Reynolds, 1996). Thus polytypes are known to change from 1b to 11b with increasing temperature of alteration, with the 1a polytype an intermediate step. Additionally, 0.7 nm (7Å) layers are eventually, if erratically, lost and crystal size may increase with temperature.

Mg-rich chlorites and the evaporite/dolomite association

It has long been known that Mg-rich chlorites and corrensite, (R1 trioctahedral mixed-layer chlorite(50)-smectite, see *mixed-layer clays*) are common in many dolomite and/or evaporite bearing rocks. Early work in both Europe and North America was summarized by Millot (1964) and later by Hauff (1981) who focused on occurrences of corrensite. Examples from Permo-Triassic rocks are well-known almost worldwide and it is probably fair to say that some of them may represent the most chlorite-rich sediments known. Generally, there is a consensus that occurrences of chlorite and corrensite in this category represent authigenic minerals, but there are still two schools of thought concerning the timing of the authigenesis. One hypothesis is that these minerals are syn-sedimentary, the other that they form as a result of burial diagenesis. Hillier (1993) summarized the arguments in favor of the role of burial diagenesis, such as the absence of any modern syn-sedimentary analogues. He also proposed that diagenetic reactions amongst dioctahedral clay minerals (the most common detrital clay mineral assemblage) and dolomite, may be an important but hitherto overlooked pathway for the formation of Mg-rich chlorites and corrensite in rocks that fall into this category. A further pathway is by the diagenetic alteration of precursor Mg-rich smectites that may be altered to corrensite and subsequently to chlorite with increasing diagenesis. This is analogous to the reaction pathways that have now been well documented from andesitic and basaltic volcanic rocks affected by low grade metamorphism (Frey and Robinson, 1999). The Mg-rich chlorites of the evaporite/dolomite association are rarely restricted to one lithology and may be as common in sandstones (Hillier *et al.*, 1996) as they are in mudstones.

Aluminous dioctahedral chlorites red beds association

In most types of sediments and sedimentary rocks dioctahedral chlorites are rarer than trioctahedral types. In some red beds,

however, this trend may be reversed. In fact the consistent and pervasive occurrence of dioctahedral chlorites in some red beds, as well as the allied mixed-layer dioctahedral chlorite-smectite mineral called tosudite, indicates a clear association which hitherto has not generally been recognized. Examples include the Triassic of the Colorado Plateau (Schultz, 1963), some Permo-Triassic sandstones of Germany e.g., Kulke (1969), and parts of the Old Red Sandstone of the United Kingdom (Garvie, 1992). One way to recognize dioctahedral chlorite is by an intense 003 peak in an X-ray powder diffraction pattern; this feature is directly related to the aluminous composition. Indeed, other features such as abundant kaolinite or dickite in association with dioctahedral chlorites indicates quite clearly that the type of reds beds in which they occur have aluminous diagenetic mineral assemblages. In red beds this might be related to widespread leaching and flushing by meteoric water during early diagenesis, with consequent alteration of feldspars and micas. Dioctahedral chlorites are also common in hydrothermal alterations of aluminous rocks and in sedimentary basins they can occur as a result of localized hydrothermal activity associated with fault systems. However, the pervasive nature of their distribution in some red beds argues against a localized hydrothermal origin. Pathways for their diagenetic formation have not yet been adequately established but might involve either a kaolin precursor, or perhaps a sequence beginning with aluminous (beidellitic) smectite that evolves to dioctahedral chlorite via tosudite as an intermediate step. Such a sequence would be entirely analogous to the well-documented saponite to corrensite to trioctahedral chlorite sequence in Mg-rich environments. Indeed, tosudite may be easily misidentified as corrensite when it occurs in red beds simply because the association of corrensite with red beds is more widely known. Any clay mineral identified as "corrensite" but associated with abundant kaolinite (aluminous system) in a red bed is certainly worthy of close scrutiny.

Lithic and volcanoclastic sediment association

One of the well-known pathways by which chlorite may form diagenetically is by the alteration of detrital ferromagnesian minerals, for example biotite is commonly altered to chlorite during diagenesis (Jiang and Peacor, 1994). Clearly, this process may operate in any sediment where detrital ferromagnesian minerals are present, but is particularly common in sediments that are mineralogically immature. Volcanoclastic sediments also are prone to the diagenetic formation of chlorite, often with associated formation of corrensite (Almon *et al.*, 1976; Stalder, 1979). In volcanoclastic sandstones there are undoubtedly many parallels with the low temperature formation of corrensite and chlorite in altered volcanic rocks (Frey and Robinson, 1999).

Shale diagenesis/low grade-metamorphism association

The smectite to illite reaction, or more generally illitization, is one of the most important reactions that occur during diagenesis. Although there are different ways to write the overall reaction, it is generally agreed that magnesium and especially iron are liberated and become available for chlorite formation. Thus in the classic study of Hower *et al.* (1976) of

shales from the Gulf Coast chlorite was first observed at 2500m, increased in abundance to 3700m and thereafter remained constant to the greatest depth examined at 5500m. Hower *et al.* (1976) interpreted all chlorite they observed as diagenetic and later TEM work by Ahn and Peacor (1985) supported the hypothesis that chlorite was formed diagenetically in Gulf Coast shales as a result of the illitization of smectite. Recalculation of the data of Hower *et al.* (1976) indicates the formation of between 5–7 percent chlorite by weight in the shales they studied. Formation of chlorite as a consequence of the processes of illitization is probably common place in mudrocks. Furthermore it has been suggested that this process may account for the observation that older rocks (e.g., Paleozoic shales) tend to have higher chlorite contents than younger rocks (e.g., Weaver 1989), simply because they are more likely (longer thermal histories) to have been affected by advanced diagenesis. This seems a logical explanation since sedimentary rocks that have entered the realm of low-grade metamorphism are typified by a phyllosilicate assemblage of white mica and chlorite, culminating in the greenschist facies. It is unlikely, however, that late diagenetic chlorite formation in mudrocks is entirely a consequence of illitization processes. More likely there is a spectrum of reactants that may be involved in chlorite formation depending on mudrock composition (Burton *et al.*, 1987). This spectrum may encompass many of the processes that characterize any of the different associations outlined above thereby resulting in Fe-rich, Mg-rich or Al-rich chlorite.

CLASSIFICATION OF SEDIMENTS AND SEDIMENTARY ROCKS

Sediments and sedimentary rocks may be divided into two kinds, intrabasinal or autochthonous and extrabasinal or allochthonous. Intrabasinal sediments and sedimentary rocks or autochthonous deposits are those whose particles were derived from within the basin of deposition. Most carbonate sediments and rocks (including limestones and dolomites or dolostones) were precipitated within a basin of deposition. Terrigenous particles or sedimentary rocks belong to the extrabasinal or allochthonous group and were derived from outside the basin of deposition; examples are sandstones and shales (Lajoie, 1979; Friedman *et al.*, 1992).

Intrabasinal or autochthonous deposits

Intrabasinal or autochthonous particles include various solids that grew biochemically or chemically in the waters of the depositional basin. These include carbonate biocrystals and other carbonate particles, silica biocrystals, particles composed of evaporite minerals, and certain authigenic minerals, such as glaucony (glauconite), that grew at the water/sediment interface.

Carbonate particles, sediments and rocks

Carbonate sediments and rocks are composed of carbonate particles and cement. They grew as solids in the depositional basin and include skeletal and non-skeletal calcium-carbonate materials. Carbonate skeletal debris includes whole skeletons of calcium carbonate-secreting organisms, as well as broken pieces of the hard parts secreted by organisms. Ordinarily, organisms must die to contribute their skeletal material to sediments. However, several exceptions are known. Ostracodes and trilobites discard their shells during molting and coccoliths shed plates during life.

The clay- and silt-size particles of carbonate sediments are collectively designated as lime mud. Lime mud for the most part consists of tiny needles and platelets of carbonate crystals. Organisms secrete the tiny solids that compose lime mud. Lime mud may form by the accumulation of tiny skeletal components secreted by algae. During the Cretaceous pelagic algae, known as coccoliths, were abundant enough to form an ooze that, when lithified, became chalk (*q.v.*).

The minerals secreted by organisms form biocrystals, that is, solids having the lattice properties of minerals but distinctive shapes that are not crystal faces. In the modern marine environment, widely varying groups of organisms produce skeletal debris. In the past, some groups of organisms that are now important sediment producers were insignificant, and some once-important groups are now minor or no longer exist at all.

In modern carbonate sediments the two principal minerals are calcite and aragonite. This fact was established in 1859 by Henry Clifton Sorby (1826–1908; see *Sedimentologists*), who also showed that calcite tends to predominate in sand-size skeletal debris, whereas aragonite predominates in lime mud.

Although the chemical formulas of both aragonite and calcite are the same, CaCO_3 , these minerals differ in

crystallographic arrangement, in density, in hardness along certain crystallographic directions, in their contents of trace elements, and in their solubilities in various fluids (see *Carbonate Mineralogy and Geochemistry*). One variety of calcite has been termed low-magnesian calcite and the other high-magnesian calcite. Modern skeletal carbonate particles consist mostly of high-magnesian calcite and aragonite, whereas ancient limestone consists of low-magnesian calcite. Low-magnesian calcite has less than 8 mol percent MgCO_3 . A calcite containing 8 mol percent to 10 mol percent MgCO_3 may be considered either high or low-magnesian calcite. The composition of the mineral calcite, which represents both kinds, can be given by the formula $(\text{Ca}_{1-x}\text{Mg}_x)\text{CO}_3$, where $0 < x < 0.30$ (Bathurst, 1975; Sanders and Friedman, 1967; Tucker and Wright, 1990).

Lime mud: silt- and clay-size

The silty- and clay-size components of carbonate sediments are collectively designated as lime mud. Most lime mud consists of tiny needles and platelets of carbonate crystals that are too small to resolve with binocular- or petrographic microscopes. Accordingly, interpretations of the particles of lime mud have been based on the notion that they shared a common origin, namely inorganic precipitation from saline water. Studies with the scanning-electron microscope have shown that, among the supposedly uniform constituents of lime muds, great variety exists. Three mechanisms for forming lime mud include: (1) inorganic precipitation, (2) biochemical secretion, and (3) breakup of sand-size (or larger) aragonitic skeletal debris.

Inorganic precipitation may be an important source of lime mud. According to an estimate of Shinn *et al.* (1989), the amount of lime mud precipitated inorganically on the Great Bahama Bank may be much greater than that secreted by algae. The tiny needles of aragonite precipitated inorganically are dispersed in the water and form drifting "clouds" of milky-white water called whittings. Sedimentation rates from whittings are high, yet the whittings appear to persist for months. This implies that, despite the losses from the fallout to the bottom, the components of the whittings are being renewed. A plausible mechanism for such renewal is rapid precipitation in the water column of aragonite needles (and possibly small particles of high-magnesian calcite). The tiny individual aragonite crystals precipitated by whittings are indistinguishable from aragonite biocrystal needles secreted by codiacean green algae.

Within their cells, certain algae secrete solid skeletal components that consist of tiny biocrystals of aragonite. Much lime mud forms by the accumulation of such tiny biocrystals, which are released onto the bottom when the algae die.

Codiacean or green algae, especially the alga *Penicillus* sp. which resembles a shaving brush and hence is popularly known as the shaving-brush alga, produce fine biocrystals (needles) of aragonite ($< 15 \mu\text{m}$) within the sheaths of their filaments. When the organism dies, the filaments disintegrate and release the needles to the sea, where they accumulate as lime mud. The modern-day rate of production of aragonite needles by *Penicillus* sp. alone can account for all the mud in the inner Florida Reef tract and one third of the mud in northeastern Florida Bay. Two more-or-less-equally abundant green algae (*Udotea* and *Rhipocephalus*) are likewise active contributors of lime mud in this area. Codiacean algae are

known in rocks as old as Ordovician, and they may have contributed aragonite needles to ancient lime muds.

Coralline red algae secrete skeletons composed of high-magnesian calcite. High-magnesian calcite, probably derived from the breakdown of red-algal skeletons, is abundant in carbonate muds in Florida Bay and on the Great Bahama Bank west of Andros Island. Red algae and serpulid worms living on leaves of the marine grass *Thalassia* may produce as much as or more lime mud than does *Penicillus*.

Some lime mud results from the physical breakage of sand-size- and larger aragonitic skeletal material. Such mud can originate by (1) decomposition of organic matter, such as conchiolin, which binds the small hard parts together; (2) weakening or comminution of the skeletal material by boring organisms such as fungi, algae or sponges, (3) feeding activities of predatory organisms, and (4) physical breakage by abrasion in agitated waters.

Intraclasts

The term intraclast refers to sand-size or larger particles, texturally analogous to rock fragments, broken from consolidated- or hardened materials in one locality and redeposited at another locality within the basin of deposition. "Intra" means within, in this context within the basin of deposition, and "clast" denotes broken. Many intraclasts are recycled fragments of coherent sediment. Intraclasts are of various sizes and shapes. Many are angular and their diameters may exceed 2 mm.

Micrite

Lithified lime mud that was deposited mechanically, and which may form a matrix among sand-size particles in limestone or be the only particle in a fine-textured limestone is known as a **micrite**. This term is a shorthand expression for microcrystalline calcium carbonate.

Pellets

Spherical- or ellipsoidal sand-size particles of calcium carbonate are called pellets. Internally, pellets are commonly homogeneous. Although they are of sand size, most pellets may be compared to tiny mudballs, and commonly consist of aragonite. Most pellets are formed by deposit-feeding organisms that eat the mud. These organisms digest organic matter from the mud and excrete the undigested lime mud in the form of fecal pellets.

Peloids

Peloids are particles that resemble pellets but for which no particular origin is implied. Not all pelletlike particles are of fecal origin; some are lime-mud aggregates that originated when lime mud dried out on exposure to the atmosphere. When lime mud is so exposed, desiccation cracks (the so-called mud cracks) and small chips of dried-out mud spall off. These particles may be larger than sand-size pellets, but they are very fragile, and are quickly comminuted to rounded, sand-size, pellet like particles. Many peloids are sand-size, rounded intraclasts. Fecal pellets and pellet-shaped mud aggregates commonly cannot be distinguished.

Ooids

The sand-size coated particles known as ooids derive their name from a Greek word which means egg or egglike because under the microscope these particles resemble the roe of fish. Ooids usually are spherical or elliptical.

The rims of most modern marine ooids consist of aragonite; a few are composed of high-magnesian calcite. In most modern aragonitic ooids the long axes of the individual aragonite crystals are tangential to the rims. This is known as concentric fabric. In some ooids the fabric is radial; the long axes of the aragonite crystals are normal to the rims and therefore diverge away from the center of the ooid. Modern ooids having radial fabric (mostly composed of high-magnesian calcite) occur in hypersaline waters, such as in the Great Salt Lake of Utah; in Baffin Bay, off Laguna Madre, Texas; or in thick accumulations of algal mats as found in sea-marginal ponds of the modern Red Sea and along the west coast of Australia. In addition to higher salinity, locations of formation of radial ooids are characterized by less-energetic water movement. It appears, therefore, that low-energy conditions favor growth of radial ooid fabric whereas high-energy conditions favor growth of tangential (concentric) ooid fabric. However, this applies only to aragonitic ooids; modern marine high-magnesian calcite ooids are exclusively radial (see *Oolites and other coated grains*).

On the basis of their internal fabric, most ancient marine ooids may be classified into two groups; (1) Group one consists of ooids having either (a) concentric aragonitic fabric or (b) coatings consisting of crystalline mosaics of calcite (or dolomite), commonly lacking any vestige of tangential or radial structure. These mosaics may consist of minute euhedral rhombs only a few micrometers across or of anhedral spar crystals nearly as large as the ooids themselves. The structures of these ooids have been substantially altered by diagenesis.

The ooids in algal mats may be precipitated by the algae themselves, yet the origin of most ooids is still problematic. Most modern ooids occur in or close to the intertidal position in a zone in which the waves break and pound. Many geologists consider that in this turbulent, shallow-water environment, ooids may form inorganically as the cooler water from adjoining deep zones spreads across the shoals, gives up some of its CO₂, and becomes warmer.

Pisolites

Spherical- or elliptical coated particles that exceed 2 mm in diameter are known as pisolites. The division between pisolites and ooids is one of size; ooids are smaller than 2 mm. Despite this seemingly arbitrary size differentiation, the origins of ooids and pisolites are not the same. Pisolites that are merely oversized ooids are not common, either in modern carbonate sedimentary environments or in ancient limestones. Three common kinds of pisolites are known: oncolites, caliche or vadose pisolites, and cave pearls or cave pisolites.

Oncolites (also known as algal pisolites) very closely resemble vadose pisolites. Their origins are, however, quite different. Oncolites consist of encrustations on various particles. When particles, commonly skeletal, roll about intermittently on the sedimentation surface, microorganisms, especially cyanobacteria, but also green algae, bacteria, and diatoms, attach themselves to and repeatedly coat these particles with concentric laminae by trapping and binding

sediment. The microorganisms coat the exposed portions of the oncolites during periods of quiescence, and may be partially abraded from the surfaces of the oncolites during the intervening periods of rolling. Thus oncolites commonly are composed of irregular-and incomplete laminae.

The most common pisolites are known as caliche- or vadose pisolites. Vadose pisolites form in the weathering zone as caliche (*q.v.*). Cave pearls, or cave pisolites, are pisolites that are true particles; they form in a manner analogous to ooids, but in pools of water in caves (Bathurst, 1975; Friedman, 1985; Friedman *et al.*, 1992; Shinn *et al.*, 1989; Tucker and Wright, 1990).

Limestones

Except for reefs which framework builders construct, for consolidated lime mud (micrite) and for limestones formed by the bacterial breakdown of calcium sulfate, the basic constituents of most limestones are recognizable sand-size particles and the spaces between these particles. The inter-particles spaces may be occupied by (1) micrite, (2) optically clear spar (calcite), and (3) void space, which may be filled with fluids, such as water or petroleum (oil or gas) (Friedman *et al.*, 1992; Scoffin, 1987; Jones and Goodbody, 1985; Tucker and Wright, 1990).

Dunham classification

Dunham (1962) recognized two first categories among limestones: (1) those in which the original particle components were bound together (named collectively as boundstones) and (2) those in which the original components were not bound together (no collective name) (Figure C32).

Boundstones are *limestones showing evidence that particles being deposited were bound by organisms or that they consist of frameworks constructed by organisms*. This group includes reefs, stromatolites, and travertine. Embry and Klovan (1971) have divided Dunham's boundstone group into subgroups according to the nature of the binding. Thus *limestones bound together with microbial laminae* are bindstones. *Limestones that originated in place* (autochthonous limestones) as *frame-built reefs* are framestones. *Limestones that consist predominantly of sediment trapped by baffling organisms* are bafflestones. This expansion of the Dunham classification is congruent with ecological classifications of dominant reef organisms into guilds (constructors, binders, bafflers).

Particle-supported rocks are subdivided into two further classes: (1) *particle-supported limestones devoid of lithified lime mud*, known as grainstones, and (2) *particle-supported limestones containing some lithified lime-mud matrix, but not enough to keep the sand-size particles from touching one another*; known as packstones.

Matrix-supported limestones are also subdivided into two classes; (1) *mud-supported limestones containing at most 10 percent sand-size- or larger particles*, known as mudstones, and (2) *mud-supported limestones containing at least 10 percent sand-size- or larger particles*, known as wackestones. Notice that in the Dunham classification the term micrite is not used. Instead, the fine- size carbonate rock is called mudstone (better, lime mudstone) (Figure C32).

The rationale of this classification is that it allows one to map gradients in rate of production of sand-size particles relative to rate of accumulation of lime mud. In calm waters,

DEPOSITIONAL		TEXTURE		
Original components not bound together during deposition				
Contains mud (particles of clay- and fine silt size)		Lacks mud and is particle supported		Original components were bound together during deposition as shown by intergrown skeletal matter, lamination contrary to gravity, or sediment-floored cavities that are roofed over by organic- or questionably organic matter and are too large to be interstices.
Mud supported		Particle supported		
Less than 10% particles	More than 10% particles			
<u>Mudstone</u>	<u>Wackestone</u>	<u>Packstone</u>	<u>Grainstone</u>	

Figure C32 Classifying and naming limestones according to depositional texture; the scheme of Dunham (1962).

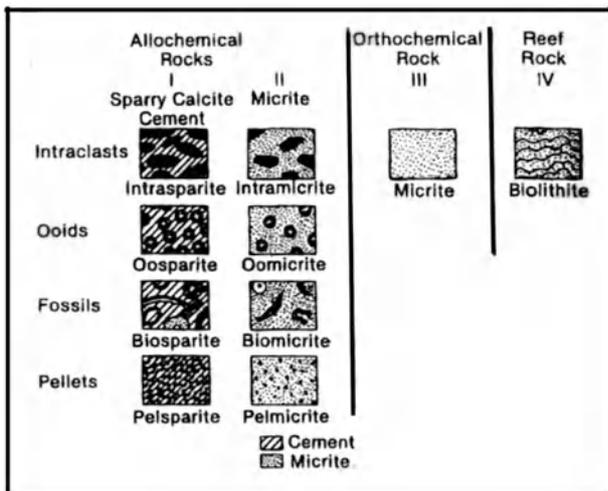

Figure C33 Classifying and naming limestones according to the scheme of Folk (1959) (modified by Friedman *et al.*, 1992).

lime mud, if present, settles on the bottom and remains there. Hence limestones derived by lithification of an original lime mud deserve to be contrasted with those derived by lithification of carbonate sediment devoid of lime mud. This relationship between sand-size particles and lime mud generally distinguishes an original sediment deposited in calm water from a sediment deposited in agitated water. This distinction is fundamental (Dunham, 1962).

Folk classification

R.L. Folk (1959) subdivided the constituents of limestones into two categories: (1) allochemical constituents or allochems (particles, meaning sand-size or larger), and (2) orthochemical constituents (collectively designated by the word orthochems and consisting of micrite, presumably lithified original lime mud; and cement, sparry calcite; Figure C33). Folk's classification lists four kinds of allochems (particles):

(1) intraclasts, (2) ooids, (3) skeletal particles and (4) pellets (including peloids).

The interstices among the allochems are filled with the orthochemical constituents (micrite or sparry calcite cement). Combinations of allochems and orthochems provide a basis for recognizing eight kinds of limestones. In addition, micrite may lack sand-size particles and hence stand alone as a ninth kind of limestone. Finally, a tenth kind is a reef rock (biolithite) (Figure C33).

Folk assigned names to eight of these ten kinds of limestone by using composite words consisting of two parts: (a) an initial abbreviated expression for the allochems, and (b) a word designating the orthochemical constituents, based on one of the two groups listed above. These words for the orthochems are (1) micrite, and (2) sparite (*limestones having a cement consisting of sparry calcite*). The prefixes for the allochems are abbreviated as follows: intraclasts = intra; ooids = oo; fossils = bio; pellets = pel.

Thus the names of these eight kinds of limestone are intrasparite, intramicrite, oosparite, oomicrite, biosparite, biomicroite, pelsparite, and pelmicrite. If several kinds of particles are important constituents of a limestone, their abbreviations are strung together in order of increasing abundance. For example, a limestone composed of micrite and having allochems composed of 10 percent intraclasts, 20 percent skeletal debris, and 70 percent peloids would be an intrabiopelmicrite.

The Folk classification allows for particles larger than sand size, which are however, not particularly common in limestones. For particles of pebble size, such as the intraclasts of flat-pebble conglomerates, the shells of lag concentrates, or the pellets of organisms having large anal diameter, Folk continued the tradition of one of Grabau's terms, rudite. A limestone composed of large pellets, if accumulated in a micrite, is known as pelmicrudite; flat pebbles in a micrite would be intramicrudite. If sparry cement occurs between these same pebble-size particles, the limestones would be designated pelsparrudite and intrasparrudite.

The distinctive aspect of Folk's classification (Folk, 1959) is its use of names for eight major kinds of limestone based on what lies between the particles (spar or micrite).

Dolostones

Dolostones are carbonate rocks consisting of the mineral dolomite $\text{CaMg}(\text{CO}_3)_2$. Two kinds of dolostone occurs: (1) Calcareous dolostones, carbonate rocks containing 50 to 10 percent of the mineral dolomite, and (2) Dolostones, carbonate rocks containing 90 percent or more of the mineral dolomite. Dolostones may or may not preserve the original texture of the antecedent limestone, such as skeletal particles or ooids, which they have replaced.

A dolomite fabric in which the predominant constituents are euhedral crystals is known as idiotopic. Idiotopic dolostone is one of the most-important carbonate reservoirs for oil and gas because it is abundant, porous, and permeable. Dolomite crystals partly bounded by crystal faces are subhedral. A dolomite fabric in which most of the constituent crystals are subhedral is hypidiotopic. Dolomite crystals bounded by anhedral crystal faces constitute a fabric known as xenotopic (Friedman, 1965).

Other crystals may be added to the name as modifiers. Such modifiers for crystal size include: micron-sized: $0\ \mu\text{m}$ to $10\ \mu\text{m}$ (0.001 to 0.01 mm); decimicron-sized: $10\ \mu\text{m}$ to $100\ \mu\text{m}$ (0.010 to 0.100 mm); centimicron-sized: $100\ \mu\text{m}$ to $1000\ \mu\text{m}$ (0.100 mm to 1.000 mm); millimeter-sized: 1 mm to 10 mm; centimeter-sized: 10 mm to 100 mm.

A further breakdown of the centimicron-size range may be made by using the terms fine crystalline ($100\ \mu\text{m}$ to $250\ \mu\text{m}$), medium crystalline ($250\ \mu\text{m}$ to $500\ \mu\text{m}$), and coarse crystalline (500 to $1000\ \mu\text{m}$). This further breakdown into three additional size classes is based on empirical observations of the distribution of crystal sizes in dolostones and recrystallized limestones and is therefore useful; it does not, however, follow the metric framework of the above-given size classification.

The naming and classifying of these various fabrics and size classes can also be extended to limestones that have undergone neomorphism or to precipitates, such as evaporites.

Dolostones may also be classified genetically into three major groups: (1) syngenetic dolostone, (2) diagenetic dolostone, and (3) epigenetic dolostone. Syngenetic dolostone is here defined as *dolostone that has formed penecontemporaneously in its environment of deposition*. This kind of dolostone contrasts with diagenetic dolostone, which is *dolostone formed by replacement of calcium-carbonate sediments or of limestones during or following consolidation, such as within beds of carbonate sediments or limestones*. In borderline cases, the distinction between syngenetic and diagenetic becomes difficult or impossible to make. Epigenetic dolostone is here defined as *dolostone that has formed by replacement of limestone along post-depositional structural elements, such as faults and fractures*. Many, but not all, epigenetic dolostones are genetically associated with metallic ore deposits, notably of lead and zinc minerals. These dolostones have recently become known as hydrothermal dolostones (Friedman, 1965; Friedman and Sanders 1967; Bathurst, 1975; Baker and Burns, 1985; Land, 1985; Hardie 1987; Tucker and Wright, 1990; Friedman *et al.*, 1992).

Authigenic rocks

Authigenic is a term designating rocks that have grown in place subsequent to the formation of the sediment or rock of which they constitute a part. The most-important kinds of authigenic rocks are (1) chert, (2) phosphate rock, and (3)

sedimentary iron ores. Evaporites formed by precipitation in the interstitial waters of a preexisting sediment likewise qualify as being authigenic.

Chert

Chert is a tough, brittle siliceous rock exhibiting a splintery-to conchoidal fracture and a vitreous luster. The silica to form most cherts is thought to come from the tests of siliceous organisms.

The tests of siliceous organisms, such as those of radiolarians and diatoms, as well as the spicules of sponges consist of opal. Likewise, siliceous shells in cherts of Tertiary age are mostly opaline. In contrast, nearly all silica in Paleozoic cherts occurs as quartz and chalcedony.

Silica minerals present in chert include quartzine and lutecline, which are fibrous varieties of quartz, and cristobalite (opal-CT). Quartzine and lutecline may form at the expense of sulfate minerals in evaporite deposits. These silica minerals may be the only testimony to the former presence of such sulfates, now replaced and vanished. These silica minerals may therefore be useful indicators of ancient environments.

The silica of chert may be (1) an alteration product of volcanic rock, such as smectite and volcanic glass, or (2) a precipitate derived from the dissolution of tests of siliceous organisms. The most-probable source of silica in the cherts of the central Pacific Ocean is dissolution of radiolarian tests. The silica in most oceanic cherts probably is of biogenic origin. Biogenic opal is dissolved and reprecipitated as finely crystalline cristobalite or opal-CT, which inverts to quartz. The end product is a classic dense, vitreous chert.

Chert occurs (1) in nodules, and (2) in strata (bedded or ribbon cherts). Common synonyms for chert or varieties of chert include jasper, flint, novaculite, and porcellanite.

Although the source of silica for many cherts evidently is the dissolved siliceous tests of marine organisms, many chert nodules are inferred to have grown by the simultaneous action of (a) dissolution of carbonate, and (b) precipitation of silica in thin films of water at the boundaries of the carbonate being dissolved (Jones and Segnit, 1971; Laschet, 1984; Tada and Iijima, 1983; Williams and Crear, 1985).

Phosphate rock

Sedimentary phosphate deposits usually consist of a carbonate fluorapatite [$\text{Ca}_5(\text{PO}_4)_3(\text{F}, \text{CO}_3)$]; a variety of apatite known as francolite. When the apatite-like phase cannot be identified, the name collophane is commonly applied. Such phosphates, or phosphorites (the two terms are synonymous) are here referred to as phosphate rock.

Phosphate rock occurs on the modern sea bottom and in ancient deposits. Ancient deposits of phosphate rock form extensive phosphogenic provinces (Bentor, 1980; Germann *et al.*, 1984; Kolodny, 1981; Riggs, 1986; Sheldon, 1987; Notholt *et al.*, 1989; Notholt and Jarvis, 1990;).

Sedimentary iron ores

Valuable iron-rich sedimentary rocks, true ores in the fullest sense of the term, have influenced modern history. England achieved greatness through exploitation of her sedimentary iron ores, while at the same time mining her rich coal deposits. During the nineteenth- and early part of the twentieth

centuries Germany and France were at each other's throats over possession of the vital Lorraine deposits, the famous oolitic minette ores of Jurassic age. Discovery of the vast Lake Superior iron ore deposits in 1844 ushered in the industrial age for the United States. In Europe and in North America, where sedimentary iron ores and coal met, large industrial centers arose, particularly in England, France, Germany, and the United States.

The term sedimentary iron ores designates those consisting predominantly of iron minerals, notably oxides, hydroxides, carbonates, silicates, and sulfides. The oxides are hematite and magnetite; the hydroxide mineral is goethite (including limonite); the carbonate mineral is siderite; the silicate minerals are chamosite, greenalite, and glauconite; and the sulfide minerals are pyrite and pyrrhotite.

Sedimentary iron ores are classified into three broad groups: (1) *bog-iron deposits*, (2) *ironstones*, and (3) *iron formations*. The basis of the classification combines mineral composition, occurrence, and geologic age. In addition, sedimentary iron ores may be named according to their dominant iron mineral; e.g., siderite rock, hematite rock, or magnetite rock (James, 1954; Maynard, 1983; Guilbert and Park, 1986; Young and Taylor, 1989; Van Houton, 1990).

Evaporites

Evaporites form by precipitation from brines whose salinity values have been greatly increased by evaporation. Evaporation may take place in closed or in open systems in numerous environmental settings.

Although almost forty different precipitate-type minerals have been recorded from evaporite deposits, only about twenty are present in more than trace amounts. Of these, only two kinds are common, sulfates and halides, both of which form extensive deposits of sedimentary rock. Two kinds of sulfate minerals are common in sedimentary rocks: gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and anhydrite (CaSO_4).

Among the halides, halite rock (rock salt) is the most common. It forms successions up to 1,000 meters (m) thick (Schreiber and Friedman, 1976; Warren, 1989; Tucker and Wright, 1990).

Carbonaceous sediments and rocks

Carbonaceous sediments and rocks, primarily coal, have been classified in two ways: by rank (content of carbon and caloric value) and by petrographic characteristics. In order of increasing rank, the classes of coal are (1) lignite; (2) subbituminous coal; (3) bituminous coal; and (4) anthracite. The progression of carbonaceous material through the continuous series of lignite (or its precursor, peat) through bituminous coal to anthracite is known as coalification.

Coal has been recorded in strata ranging in age from Precambrian to Holocene. However, only after the Late Silurian Period, when land plants had become established, was it possible for plant material to accumulate on a scale to form large deposits of coal. In the history of the earth, two particularly rich coal-forming periods are known, the Carboniferous (principally Pennsylvanian) and Early Tertiary Periods. Most coals form from accumulated plant debris in sea-marginal swamps or in closed fluvial basins (Sackett *et al.*, 1974; Hunt, 1979).

Extrabasinal or allochthonous deposits

Extrabasinal or allochthonous rocks consist mainly of one group. These are the terrigenous rocks.

A fundamental basis for classification is particle size. On the basis of increasing particle size, we recognize *three main kinds of terrigenous rocks*: (1) shales, (2) sandstones, and (3) conglomerates and sedimentary breccias. According to the Grabau system of classification, we use the terms lutite for shale, arenite for sandstone, and rudite for conglomerates. Some geologists recognize a fourth kind of terrigenous rock, siltstone. For it the term siltite has been introduced.

Shales

Fine-textured terrigenous rocks compose about two thirds of the sedimentary rock record, yet because their particles are so small, they are incompletely understood. Various bases for naming these rocks have been proposed, including (1) particle size, (2) proportion of clay minerals, and (3) fissility, *the property of splitting easily into thin layers parallel to the bedding*.

Probably the most-satisfactory definition of shale is according to particle size. In terms of size, the name shale is the lithified equivalent of mud. Mud is a sediment consisting of clay- and silt-size particles. Likewise, shales are *terrigenous rocks composed of clay- and silt-size particles*.

The proportion of clay minerals in shales varies widely. In most shales, quartz may compose between one quarter and one half of the total; in some shales, quartz together with feldspar generally contain greater proportions of quartz and feldspar, whereas fine shales contain less of these and a greater proportion of clay minerals. Fine-textured terrigenous sedimentary rocks having abundant quartz (and commonly also feldspar) particles of silt size and that as a result, closely resemble sandstones.

On surface exposures, where weathering has taken place, it is easy to distinguish fissile from nonfissile fine-textured rocks. The terms mudrock, mudstone, claystone, and argillite have been employed for shales lacking fissility; argillites are more-indurated shales than mudstones and claystones. In the Dunham classification of carbonates, the term mudstone refers to fine-textured limestone (in which case the rock should be called lime mudstone to avoid confusion with fine-textured siliciclastic rocks).

A dark, thinly laminated carbonaceous shale, exceptionally rich in organic matter (5 percent or more of total organic carbon) and sulfides (FeS_2), is known as black shale. It forms by partial anaerobic decay of organic matter in a reducing setting in which water circulation is restricted and deposition is slow (Chamley, 1989; Dunbar and Rodgers, 1957; Füchtbauer and Leggewie, 1984; Heling, 1988; Pettijohn, 1975; Potter *et al.*, 1980; Weaver, 1989).

Sandstones

Sandstones are terrigenous sedimentary rocks in which sand-size particles predominate. As with limestones, sandstones can be classified on the basis of (1) particles, (2) matrix, and (3) cement. Particles are mostly derived from the lands, hence are terrigenous, but pyroclastic and even clastic-carbonate particles may be abundant. The essential particles of sandstones are (1) quartz, (2) feldspar, and (3) rock fragments. Many other kinds of particles occur in sands and sandstones,

End-member sand-size particles	Idealized end-member rock names	
	< 15% matrix	> 15% matrix
Quartz	Quartz sandstone	Argillaceous Quartz sandstone
Feldspar	Feldspar sandstone	Argillaceous feldspar sandstone
Rock fragments	Rock-fragment sandstone	Argillaceous rock-fragment sandstone

Figure C34 Classifying and naming sandstones.

but those other are not common and are not considered essential in naming and classifying sandstones. The matrix is the mud: physically deposited material that consists mostly of clay minerals and quartz. Cement is the chemically precipitated filling of original void spaces. Some sandstones lack any matrix; only mineral cement occupies the spaces among the framework particles. The argillaceous matrix of sandstones implies (1) availability of mud, and (2) a low-energy regime in the depositional environment.

Depending on the presence or absence of argillaceous matter, we recognize two end-member groups of sandstones: (1) argillaceous sandstones (sandstones containing about 15 percent or more of clay-size material), and (2) ordinary sandstones, which contain less than about 15 percent clay-size material. The value of 15 percent is arbitrary; in a qualitative study, the obvious presence of a fair amount of clay suffices to classify a sample as argillaceous.

Based on the proportions of quartz, feldspar, and rock fragments, we can divide each of these two first-order groups (argillaceous sandstones and ordinary sandstones) into three second-order groups. Thus, as indicated in Figure C34, we can recognize six sandstone end members: (1) quartz sandstone, (2) feldspar sandstone, (3) rock-fragment sandstone, (4) argillaceous quartz sandstone, (5) argillaceous feldspar sandstone, and (6) argillaceous rock-fragment sandstone.

The sand-size debris of most sandstones includes chiefly quartz, but with the quartz may be variable amounts of feldspar or rock fragments or feldspar and rock fragments. These mixtures are named by incorporating the names of all kinds of sand-size debris present, listed in increasing order of abundance. Thus if a sandstone contains 70 percent quartz, 20 percent feldspar, and 10 percent rock fragments, we would name it a rock fragment-feldspar-quartz sandstone.

The kinds of feldspars or rock fragments reflect (1) the parent terrain or provenance from which the particles in a sample of sandstone have been derived, and (2) their preservation during weathering, transportation, and diagenesis.

The pioneer sedimentary petrographer Paul D. Krynine (1902–1964; see *Sedimentologists*) provided the modern impetus in naming and classifying sandstones. Krynine's (1948) original article is a classic in geology; it combines astute observation in the field and of samples with a deep insight and appreciation for the fundamental principles of geology. In his classification of sandstones, Krynine introduced triangular diagrams for plotting his three fundamental end members: orthoquartzite, graywacke, and arkose (Figure C35).

The earliest description of graywacke dates from 1789, and the term arkose was introduced in 1823. According to Krynine, a graywacke is *a sandstone composed of angular quartz (and chert) particles and abundant metamorphic rock*

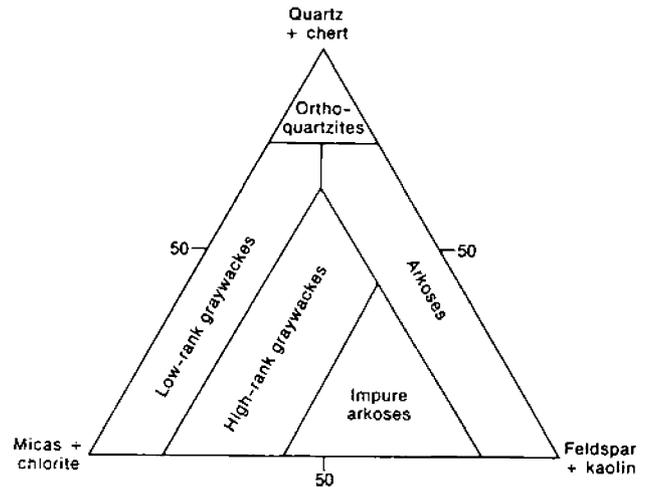

Figure C35 Triangular diagram; Krynine's classification of sandstones. (after P.D. Krynine, 1948, Figure C35, p.137).

fragments, with little or no cement and feldspar, and containing more than 12 percent to 17 percent micas and chlorite (either in the clay matrix or as metamorphic rock fragments). Krynine felt that the mica and chlorite between the particles were a mechanically deposited matrix and represented poor sorting; we now know that this can no longer be assumed.

When deeply buried and subjected to appropriate geothermal gradients and migrating solutions, framework particles may be dissolved and new clay minerals, such as chlorite and illite, may form. This diagenetic neoformation of clay-mineral cements within sandstones may generate a rock composition fitting the term graywacke. Yet Krynine and many others use this term to refer to a rock having a mechanically deposited matrix and poor sorting. To avoid the term graywacke, some authors substituted the term wacke. In his classification, Krynine used the term arkose for *a sandstone with more than 30 percent feldspar*.

A rock defined by Krynine as a graywacke would be named *argillaceous rock fragment-quartz sandstone* if it contained no feldspar, and an *argillaceous rock fragment-feldspar-quartz sandstone* if it contained feldspar in greater abundance than rock fragments, or an *argillaceous feldspar-rock fragment-quartz sandstone* if the rock fragments were more abundant than the feldspar. The arkose of Krynine would be named a *feldspar-quartz sandstone* if the quartz is more abundant than the feldspar, but a *quartz-feldspar sandstone* if feldspar abundance exceeds quartz abundance (Folk, 1956; McBride, 1962; Klein, 1963; Sanders, 1978; Füchtbauer *et al.*, 1988).

Conglomerates and sedimentary breccias

Coarse terrigenous rocks are formed by the lithification of gravel. The degree of rounding of the particles defines two categories. Conglomerate is defined as a coarse terrigenous sedimentary rock formed by the lithification of rounded gravel. Sedimentary breccia is a coarse terrigenous sedimentary rock formed by the lithification of angular gravel-size or larger particles. In conglomerates and sedimentary breccias more than 30 percent of the large particles exceed 2 mm in diameter. The particles may consist of pebbles, cobbles, boulders, or mixtures of these sizes.

Conglomerates and sedimentary breccias may be named and classified by (1) the proportion of gravel size particles, (2) the kind of matrix, and (3) the kinds of gravel-size particles.

According to the proportion of gravel-size particles and the kinds of matrix, (1) a sample containing 80 percent pebbles, cobbles, and/or boulders is termed a conglomerate proper, and (2) one having between 30 percent and 80 percent of such coarse particles is (a) a sandy or arenaceous conglomerate or (b) a shaly or argillaceous conglomerate. The matrix between the coarse particles in a conglomerate may also be calcareous or sideritic.

Based on the variety of pebbles, cobbles, and/or boulders composing them, we can classify conglomerates into two kinds: (1) conglomerates consisting only of pebbles, cobbles, and/or boulders of a single kind of rock (such as one or various varieties of chert and quartzite or of other rock), or oligomictic conglomerates; and (2) conglomerates containing pebbles, cobbles, and/or boulders of many kinds of rock, known as polymictic conglomerates.

The term diamictite has been proposed for a nonsorted non-calcareous, terrigenous sedimentary rock composed of sand-size and/or larger particles dispersed through a fine-textured matrix. Many, if not most, diamictites are conglomerates. Diamictites originate by landslides, earth flows, mudflows, solifluction, ice rafting, subaqueous slumping and sliding, and/or by glaciers. A nonlithified diamictite is a diamicton (Flint *et al.*, 1960; Pettijohn, 1975; Friedman and Sanders, 1978; Füchtbauer *et al.*, 1988).

Pyroclastic rocks

Pyroclastic rocks are lithified tephra. Their particles originate as explosive igneous material but are deposited as sediments.

Volcanoes and their products, both on land and in the sea, are the major source of particles for pyroclastic rocks, especially in areas of tectonic activity and in island arcs. Particles originating by explosive ejection from volcanic vents spread out over great areas. On the continents, pyroclastic rocks far exceed the volume of extrusive igneous rocks.

Tephra are chemically and texturally distinctive, so ancient tephra may be used for correlation. Mapping of particle size and thickness of tephra deposits assists in locating the parent volcano.

Figure C36 shows how sizes of tephra particles can be used to classify pyroclastic rocks.

Pyroclastic rocks composed mostly of blocks are volcanic breccia; pyroclastic rocks composed mostly of lapilli are lapilli tuffs; and pyroclastic rocks composed of ash are tuffs in the strict sense of the word.

The three end members of pyroclastic rocks are (1) volcanic rock fragments, (2) crystals, and (3) glass. If by size a rock is a

Limiting Particle Diameter mm	Standard Size Classes of Sediments φ units	Size Classes of Tephra Particles	Size Classes of Pyroclastic Rocks

tuff and rock fragments exceed glass, this tuff may be described as a glass, rock-fragment tuff. End members are listed in order of increasing abundance. By this approach one can recognize crystal-, rock-fragment-, and glass tuffs. Adjectival modifiers may be added.

Because of the chemical reactivity and instability of their constituents, pyroclastic rocks are highly susceptible to diagenetic alteration. Glass alters to clay minerals, especially to smectite, zeolites, chalcedony, opal, quartz, or to a microcrystalline material, which in a thin slice under the petrographic microscope resembles chert. An alteration product of tephra is bentonite, a plastic clay or shale composed for the most part of the clay mineral montmorillonite (a variety of smectite) that formed by the alteration of tephra.

One kind of tuff that carries a special name is ignimbrite or welded tuff, a nonsorted pyroclastic rock deposited from a nuée ardente while the particles were still in a plastic condition. Ignimbrites may occupy large areas and attain considerable thicknesses (Fisher, 1961, 1966; Lajoie, 1979; Schmincke, 1988; USDOE, 1988).

CLASTIC (NEPTUNIAN) DYKES AND SILLS

Clastic dykes are tabular bodies of clastic material, mostly fine sand, cutting across sedimentary formations or, more rarely, volcanic and granitic rocks (Allen, 1984; Peterson, 1968). They rank among the earliest described deformational sedimentary structures. Already in 1791, Werner published his theory of vein genesis based on the observation of marl veins in the middle Trias of central Germany. Since then, innumerable reports of sedimentary dykes throughout the world have accumulated (see Diller (1890), Williams (1927), Strauch (1966), Allen (1984), and Maltman (1994) for successive reviews). Clastic sills are also encountered, with the frequent difficulty of distinguishing them from normal beds (Archer, 1984). Features described as clastic dykes range from filled centimetric crevices to several-m-wide, several-km-long structures. A main genetic distinction is to be made between true clastic dykes and sills, forcefully injected from below, and passive fissure-fills, sometimes called neptunian dykes.

Intrusive clastic dykes are discordant—and sills concordant—planar to irregular and often branching sheet-like bodies which commonly occur in swarms. Their walls are generally smooth though locally disturbed and sometimes slickensided or erosionally grooved (Allen, 1984). The filling material is generally fine sand or clay and includes pieces of the host sediments. It is mostly structureless but in some cases a wall-parallel orientation of the sediment grains or even a wall-parallel layering is observed. Clastic dykes are often associated with other soft-sediment deformation structures or otherwise mobilized material (slumps). When the intrusion breaks through to the contemporaneous sediment surface, sand volcanoes or extruded sand sheets (often difficult to distinguish from clastic sills) can be formed. Unless they can be traced down to the source layer, and in spite of suggestive upward branching, wall-parallel grain fabric and irregular or striated walls, the intrusive origin of the dykes is not easily demonstrated.

Clastic dykes are formed as the result of forceful injection, commonly from below and more rarely sideways or even from above, after unconsolidated sediments have been liquidized (see *Liquefaction and Fluidization*). Therefore, such soft-sediment deformation features are penecontemporaneous with deposition or at least occur before complete lithification. Liquefaction is achieved through either thixotropic behavior of some cohesive materials (e.g., certain clays) or liquefaction of cohesionless saturated sands, whose primary strength results from grain interlocking and friction at particle contacts. Liquefaction is caused by the pore fluid pressure increase to the level of the lithostatic stress (thus making the effective stress equal to zero) in a system more or less closed by overlying less permeable, cohesive materials (Lowe, 1975). The consequence is a dramatic loss of strength of the sand whose particles are dispersed in the pore fluid. This will eventually result in closer grain packing and forcing up of pore water, leading to

fluidization when escaping excess pore water drags sediment. Fluidization occurs in an open system after overpressure has caused hydraulic fracturing in the impermeable overlying strata. In the case of true clastic dykes, fissuring and filling therefore occur simultaneously. In horizontal strata, the formation of dykes or sills respectively depends on the horizontal or vertical orientation of the σ_3 principal stress in the fracturing layers. Increase of pore fluid pressure and liquefaction may occur in different ways, either static, dynamic (impulsive) or cyclic. Main triggers for static liquefaction are artesian groundwater movements and escape of pore water from underlying compacting sediment. Rapid sediment deposition, slope failure, breaking waves and flood surges may be responsible for impulsive liquefaction. Finally, seismic shaking, pressure variations associated with waves or with flow separation will cause cyclic stresses and liquefaction (Owen, 1987). Unfortunately, since clastic dykes depend primarily on overpressuring which may occur in so many different environments, they are generally no clear diagnostic feature of the trigger agent, and the latter has rather to be deduced from the sedimentological context (Owen, 1987). Indeed, clastic dykes occur in a wide variety of environments, ranging from deep-water turbidite associations (Truswell, 1972) to shallow-water marine and nonmarine sediments to subaerial mass-flow deposits (Collinson *et al.*, 1989). They are also known from seismic (Obermeier, 1996) and glacial (Amârk, 1986) environments.

Though in many cases difficult to distinguish from injected sedimentary dykes, neptunian dykes fed from above sometimes exhibit characteristic features. Often, they will show a clear downward tapering, while their filling may more frequently include coarse material and is in some cases horizontally layered. Genetically, the fissuring and filling stages are not necessarily simultaneous and the cracks may widen progressively over years, then allowing for vertical layering of the fill. Many different causes can produce open cracks. Earthquake-related ground cracks are common feature, while other tectonic cracks like enlarged joints and tension gashes can also trap sediments and develop in neptunian dykes. Subaqueous slumps and subaerial landslides as well are another frequent cause of ground cracking. Karstification of carbonate rocks leads to extensive fissuring which again can and often do catch sediments from above. Finally, desiccation and syneresis cracks are also mentioned as features possibly evolving into neptunian dykes. Especially when they are synsedimentary subaqueous features, filling of the fissures may be slow with horizontal stratification (Strauch, 1966). However, subaerial progressive filling has also been shown to result in vertical layering and fining upward of the material brought in the fissure by rainwash and clay infiltration (Demoulin, 1996). Owing to weathering and collapse of the fissure walls, slow fissure filling frequently displays a brecciated structure. In other cases, rapid filling can occur, provided overlying sediment is available. It can occasionally involve injection from above, and yields a mostly structureless or faintly vertically laminated infill. Neptunian dykes have been described from as varying environments as those of true clastic dykes. Moreover, complex structures coupling forceful injection from below and collapse of surface sediments within the cracks can also form, namely as the result of seismic shaking (Thorson *et al.*, 1986). Note however that although passive fissure-fills of different origin have sometimes been mistakenly interpreted as periglacial ice-wedge casts, the latter are generally not referred to as neptunian dykes.

As synsedimentary features, clastic and many neptunian dykes can experience later compaction-induced deformation and folding. Displacement across the dykes or even across their infill as well as slickensided walls have in some cases been interpreted as the imprint of subsequent tectonic use of the weakened cracked zones. They should anyway be carefully distinguished from cataclastic shear zones which sometimes mimic them.

CLATHRATES

Clathrate hydrates

Clathrate hydrates (or gas hydrates) are solid ice-like crystalline compounds of hydrogen bonded water molecules that form a rigid lattice of cages that host small guest gas molecules. They are stable only when the cages contain gas molecules. They are stable at moderate to high pressures and low temperatures (Sloan, 1998). The stability depends on the composition of the gas molecules and of the pore fluid (Englezos and Bishnoi, 1988). Methane and other clathrates most likely formed in the solar nebula and thus played a role in the accretion of planets and satellites and probably comets (Lunine and Stevenson, 1985). On Earth, methane hydrate is the principal clathrate hydrate.

Methane hydrate has a body centered cubic structure I, which is one of the three hydrate structures known to occur in the natural environment. Structure I forms with gas molecules smaller than propane, hence with CH₄, CO₂, H₂S. Structure II forms with molecules greater than ethane but smaller than propane. The two most important clathrate hydrate structures I and II consist of different combinations of three types of cages; each has two cage sizes. A third hexagonal structure H was described from the Gulf of Mexico having three types of cages.

The predominant natural gas hydrate on Earth, methane hydrate, has a density of 0.93 g/cm³. Clathrate hydrates have large storage capacity for gas molecules; for example, the ratio of gas to water molecules in structure I methane hydrates is 1CH₄:5.75 H₂O, when decomposed, the volumetric ratio is 164 CH₄:0.8 H₂O (Kvenvolden, 1993). When hydrates form they exclude ions and fractionate O and H isotopes; they become enriched in ¹⁸O and D isotopes, like sea ice.

Most of the modern ocean seafloor is within the temperature and pressure stability field for methane hydrate. Methane concentration constraints restrict its occurrence to two main environments: (1) in the oceans to the uppermost few hundred meters of sediments on submerged continental margins slope and rise sediments, where water depths exceed ~500 m, and (2) in polar regions associated with permafrost. A conservative estimate of the oceanic gas hydrate reservoir is enormous: ~10¹⁹ g of methane C is stored in them (Kvenvolden, 1988). This C reservoir is larger than the C in all other known fossil fuel deposits. The permafrost reservoir is considerably smaller than the oceanic one by about two orders of magnitude (~4 × 10¹⁷ g).

The methane in hydrates originates either from bacterial anaerobic degradation of organic matter or from thermal breakdown of organic matter at elevated temperatures (>80 to 90° C). The conventional bacterial methane is characterized by δ¹³C values that range from about –55‰ to 85‰ (PDB) and C₁/(C₂ + C₃) > 200, whereas conventional thermogenic methane typically has δ¹³C values of –20‰ to –50‰, and C₁/(C₂ + C₃) < 100. The source of methane in the hydrates is from either *in situ* production of bacterial methane or upward transport of methane-rich fluids into the hydrate stability zone. The latter source may have a bacterial, thermogenic, or mixed origin (Hyndman and Davis, 1992). *In situ* production and/or transport of methane by fluids into the hydrate stability zone is the limiting factor for methane hydrate formation in most regions of the modern ocean. Geochemical studies, especially

of C isotope values of the methane, indicate that in methane hydrates, the methane is largely bacterial in origin, but in some regions, such as the Gulf of Mexico or Caspian Sea, it is thermogenic.

Only a fraction of the marine sediment organic C is available for methane production bacterially or thermogenically. Reasonable estimates of the efficiency for methane generation from organic matter vary from 2–3 percent to 20 percent. Accordingly, the maximum methane hydrate that can be generated *in situ* in continental margin slope and rise sediments, assuming an average porosity of 50 percent and 1 percent organic C content is 4–6 percent of the void space. The higher concentrations of 20–35 percent in convergent margins based on geochemical indicators, such as pore fluid Cl concentrations, or on geophysical interpretations, indicate that transport of methane into the stability field is widespread. Because advection of methane-rich fluids is more pervasive and aggressive in convergent than in rifted and sheared margins, Kastner (2001) suggested that convergent margins host 60–65 percent of the enormous oceanic methane hydrate reservoir.

Much of our knowledge about methane hydrate occurrence, distribution, and geochemistry in marine sediments is from recovered samples and geochemical data obtained through the Deep Sea Drilling Project (DSDP) and Ocean Drilling Project (ODP). All the successful recoveries were from about 100–400 mbsf, primarily from samples in the two-phase region of the stability field. The direct observations and inferences obtained from geophysical and pore fluid geochemical data indicate that methane hydrates are distributed inhomogeneously in ocean sediments, irregularly disseminated in turbidite sediments and in silty mudstones with increasing abundance near and in the sediment at the base of the three-phase equilibrium field of methane hydrate. A Bottom Simulating Reflector (BSR) of reverse polarity that parallels the seafloor often characterizes this boundary (Shipley *et al.*, 1979). In clay-rich sediments methane hydrate occurs in microfractures, or in thin platelets parallel to fissility or scaly fabric; it cements coarser sediment horizons of higher permeability, such as sandy silts or ash layers; and concentrates in fractures, fault zones, or along lithologic boundaries where the occurrence is modular to massive. Gas hydrates thus affect the sediment physical properties, particularly the permeability, seismic velocity, thermal conductivity, and electric resistivity. Sedimentological processes such as compaction or cementation by silicates or carbonates are inhibited where gas hydrate fills void space.

Because of continuous sedimentation, methane hydrate in the sediment at the BSR dissociates. The methane released is recycled, it migrates upward into the stability field, thus stimulates the formation of the methane hydrate near the base of the 3-phase stability field, and produces the generally larger accumulations near the BSR. This overall vertical distribution is amplified in convergent margins where upward transport of methane-rich fluids is widespread. The recently observed moderate to large accumulations of methane hydrate near the sea-floor at the Cascadia margin, Eel River basin in northern California, Gulf of Mexico, Okhotsk Sea, Black and Caspian Seas thus require active focused transport of methane-rich fluids or methane gas to the sea-floor.

Recent interest in natural clathrate hydrates has resulted from recognition that global warming may destabilize some of the vast quantities of methane hydrate in shallow marine slope sediments (and permafrost). The potential environmental consequences of rapid release of large quantities of methane

for both ocean and atmosphere are important questions surrounding the very large amounts of gas hydrates in the shallow geosphere. In the ocean, intense microbial oxidation of methane would reduce the amount released into the atmosphere, but this would result in extensive local oxygen consumption and CO₂ production, therefore in some reduction of the capacity of the ocean to incorporate fossil fuel CO₂. Because methane gas is an important contributor to the atmospheric radiation balance as it is a significantly more effective greenhouse gas than CO₂, any additional flux of methane into the atmosphere beyond the present annual growth rate of ~0.8 percent per year would accelerate global warming.

Significant environmental stresses or geologic perturbations, such as global warming, rapid deglaciation or glaciation, earthquakes, or tectonic uplift, may cause clathrate hydrate dissociation. If at the BSR it may trigger geologic hazards such as giant landslides that could cause tsunamis and perhaps rapidly release large quantities of methane to the ocean and atmosphere with complex climatic feedbacks. New evidence exists for massive methane releases from gas hydrate and their possible association with global warming in the geologic past, for example in the late Paleocene, ~55.6 Ma (Dickens *et al.*, 1997); this event was accompanied by a thermal maximum.

It also has been suggested that clathrate hydrates may have played a role in past climate change. For example, during deglaciation, an increase in atmospheric methane from hydrate dissociation may have accelerated the retreat of continental ice sheets (Nisbet, 1990); or during glaciation, the decomposition of gas hydrate resulting from lowering sea level may have moderated the extent of glaciation (Paull *et al.*, 1991).

A clathrate structure of silica

Melanophlogite is a rare cubic, low-density (2.06 g/cm³) polymorph of SiO₂ having a clathrate structure. The guest material in the cavities consists of small organic molecules containing S that are essential structural elements stabilizing the Melanophlogite structure. Melanophlogite occurs as authigenic single crystals and interlocking intergrowths on S crystals in Sicilian sulfur deposits (Skinner and Appleman, 1963; Kamb, 1965).

CLAY MINERALOGY

Definitions of clay and clay mineral

The term “clay” is common to many disciplines and frequently used in two quite different ways. On the one hand, it is a term for the finest division of many particle size schemes; on the other hand it is a term applied to many naturally occurring materials that may otherwise be classified as soil, sediment or rock. Not surprisingly then, there is no universally accepted definition of the word “clay”, although in context its meaning is generally understood. Most recently Guggenheim and Martin (1995) offered the following definition of clay as a material: “The term clay refers to a naturally occurring material composed primarily of fine-grained minerals, which is generally plastic at appropriate water contents and will harden when dried or fired. Although clay usually contains phyllosilicates, it may contain other materials that impart plasticity and harden when dried or fired. Associated phases in clay may include materials that do not impart plasticity and organic matter”. In its other context, i.e., particle size, clay is variously defined depending on discipline or country. The fraction less than 2 micrometers (equivalent spherical diameter) is a common definition, but the boundary with silt can be as high as 6 microns in some schemes. When dealing with natural materials, such as sediments, there is a conceptual link between both uses of the word clay, since clay materials inevitably contain a large proportion of particles that are clay size. Additionally, the clay size fraction, even if only a minor fraction of any given soil, sediment or rock, will in most cases be composed predominantly of minerals that are known as “clay minerals”. Again, just like clay, there is no universally accepted definition of the term “clay mineral”. Guggenheim and Martin (1995) define it as follows: ‘The term “clay mineral” refers to phyllosilicate minerals and to minerals which impart plasticity to clay and which harden upon drying or firing’. Most “clay minerals” are phyllosilicates (synonym: layer silicates) and a correspondingly narrower use of the term is common place, but it is important to realize that minerals that are not phyllosilicates are also included in the definition of clay mineral if they contribute to the properties associated with clay. This encompasses many oxides of iron and aluminum, that like the phyllosilicate clay minerals are similarly predisposed toward a natural occurrence in the clay size fraction;

additionally minerals like allophane and imogolite are included. In contrast, minerals such as quartz and feldspars, although frequently found in clay size fractions, would never be considered “clay minerals”. A further difficulty with a more precise definition of “clay mineral” arises in part because there are no meaningful boundaries to continuous properties such as particle size. Hence many hydrous layer silicates that occur as clay minerals for example, micas and chlorites have larger relatives whose size flouts any such description. For other types, for example, kaolinite and smectite, it is rare indeed to find specimens that have outgrown the description “clay mineral” probably because their crystal structures place severe constraints on the size to which they can grow. Clay minerals thus occur as fine-grained particles with consequent high surface to volume ratios, further augmented by the platy shapes of many, such that surface properties are accentuated. The historical development of the modern concept of “clay minerals” is described in more detail by Grim (1968); there have long been points of contention in relation to definitions and some will no doubt remain (Moore, 1996; Guggenheim and Martin, 1996).

Structure and classification of clay minerals

The crystal structures of phyllosilicate clay minerals have been elucidated mainly from the study of larger analogous specimens (Brindley and Brown, 1980). They are hydrous layer silicates consisting of planes of atoms arranged in layers, their crystal habits and morphologies reflecting this arrangement, so that most are platy and have perfect cleavage. There are two basic modular components of phyllosilicate clay minerals; sheets of tetrahedrally coordinated atoms and sheets of octahedrally coordinated atoms, known as tetrahedral and octahedral sheets (Figure C37).

Tetrahedra are formed of a cation, usually silicon, surrounded by four oxygens. By sharing three of these oxygens between adjacent tetrahedra they may be linked together to form a continuous tetrahedral sheet, in which the unshared oxygens all point in the same direction. Thus one side of a tetrahedral sheet consists of an hexagonal mesh of shared oxygens, whilst the other side is formed by the remaining so-called “apical” oxygens.

An octahedral sheet is formed from two planes of close packed oxygens and/or hydroxyls. In the center of such a sheet, and adjacent to every anion, there are three octahedral sites which may be occupied by cations such as aluminum, iron and magnesium, each cation being surrounded by six anions. There are two kinds of common octahedral sheets distinguished by different cation to anion ratios as required for electrical neutrality. If divalent cations fill all three sites the octahedral sheet is known as trioctahedral. Trivalent cations need only occupy two out of every three sites to maintain neutrality and the sheet is then called dioctahedral. Octahedral sites are linked together by sharing of edges. The vacancies in the dioctahedral sheet lead to a more distorted structure than the completely occupied trioctahedral sheet.

By joining tetrahedral and octahedral sheets together, two basic clay mineral units known as layers can be formed. The unit formed by linking one tetrahedral sheet and one octahedral sheet together is called a 1:1 layer, sometimes also designated T-O. The linkage is achieved by replacing two out of every three anions of an octahedral sheet by the apical oxygens of a tetrahedral sheet, so that at the ‘junction plane’ the apical oxygens are shared jointly by tetrahedral and

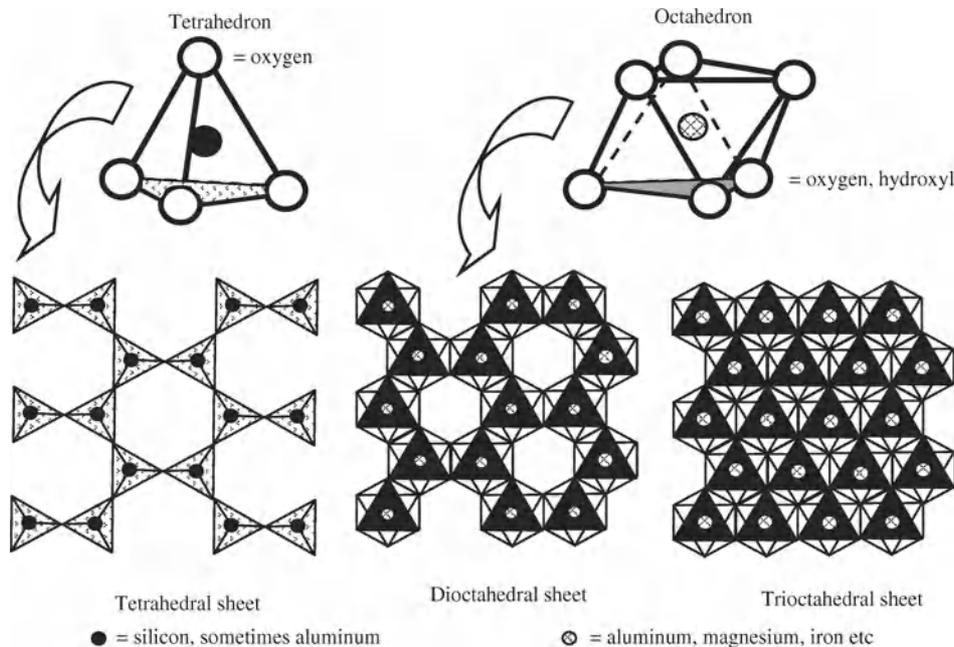

Figure C37 Schematic diagram of tetrahedron, octahedron, and fragments of tetrahedral, dioctahedral and trioctahedral sheets.

octahedral sheets. The remaining unshared anion of the octahedral sheet in this junction plane is an hydroxyl that lies in projection at the center of the hexagonal ring of apical oxygens. A tetrahedral sheet can be similarly linked to the other side of an octahedral sheet and the unit formed is known as a 2:1 or T-O-T layer. In reality, the dimensions of tetrahedral and octahedral sheets are different and a variety of structural adjustments, such as tetrahedral rotation, and atomic substitutions are necessary to enable the sheets to fit together. Furthermore, substitutions of cations by others of lower valence such as aluminum for silicon in tetrahedral sheets, and magnesium or ferrous iron for aluminum in octahedral sheets are common place. Any substitutions in 1:1 layers are usually fully compensated by others, such that there is no net layer charge. Substitutions in 2:1 layers, however, frequently give rise to layers that carry a net negative charge. This charge may be neutralized by cations, hydrated cations, or by octahedrally coordinated hydroxyl groups or sheets, which occupy a position between the layers known as the interlayer. Additionally, because of the similarity of many clay mineral structures it is common to find minerals that consist of two or more layer types, so-called interstratified or mixed-layer clay minerals (Šrodoń, 1999). The different layers in mixed-layer clay minerals can be visualized as stacked in a sequence normal to the plane of the layers, and the stacking sequence may be random or more or less organized into a regular ordered pattern of layer types. Most mixed-layer clay minerals involve two kinds of layers, such as mixed-layer illite-smectite, or chlorite-smectite, more rarely interstratifications of three kinds of layers are reported. Some mixed-layer clays in which the layers are organized into a regular sequence are given specific mineral names (Brindley and Brown, 1980); rectorite and corrensite are examples.

The classification of the phyllosilicate clay minerals (Figure C38) is based collectively, on the features of layer

type (1:1 or 2:1), the dioctahedral or trioctahedral character of the octahedral sheets, the magnitude of any net negative layer charge resulting from atomic substitutions, and the nature of the interlayer material. The most important members of the 1:1 kaolin-serpentine group, are kaolinite, dickite, halloysite, and berthierine. Of the 2:1 clay minerals, pyrophyllite and talc represent the uncharged dioctahedral and trioctahedral species, respectively. The distinction between smectites and vermiculites is arbitrarily placed at a layer charge of 0.6 per formula unit. Cations required to compensate these net negative layer charges may be hydrated such that both smectites and vermiculites exhibit intracrystalline swelling. Such cations may also be exchanged with others. This property when measured is known as the cation exchange capacity, abbreviated CEC, although exchangable cations may also reside at other sites, so that most clay minerals exhibit some CEC. The amount of swelling can be related to the kind and number of interlayer cations, humidity or the nature of the solution in which the clay occurs and to the magnitude of the layer charge. In micas and illites the net negative charge is stronger and the cations that compensate it are unhydrated and more strongly held such that they are not exchangable. In chlorites the 2:1 layer charge is compensated by an interlayer hydroxide sheet. The clay minerals sepiolite and palygorskite are classified with the other 2:1 minerals but they differ from them because the 2:1 layers are not laterally continuous. Instead, tetrahedra are inverted periodically dividing the structure into ribbons of three hexagonal chains width in sepiolite and two in palygorskite so that only the tetrahedral basal oxygens form continuous planes throughout the structure. Tetrahedra in the structure with apical oxygens facing up and down are linked by octahedral sheets to form a 2:1 layer structure that is limited in extent to the direction perpendicular to the ribbons.

Layer type	Group	Subgroup	Species
1:1	Layer charge (q)		
	q ~ 0	Kaolin-serpentine	Kaolin Serpentine
	q ~ 0	Pyrophyllite-talc (q ~ 0)	Pyrophyllite Talc
		Smectite (q ~ 0.2-0.6)	Di. smectite Tri. smectite

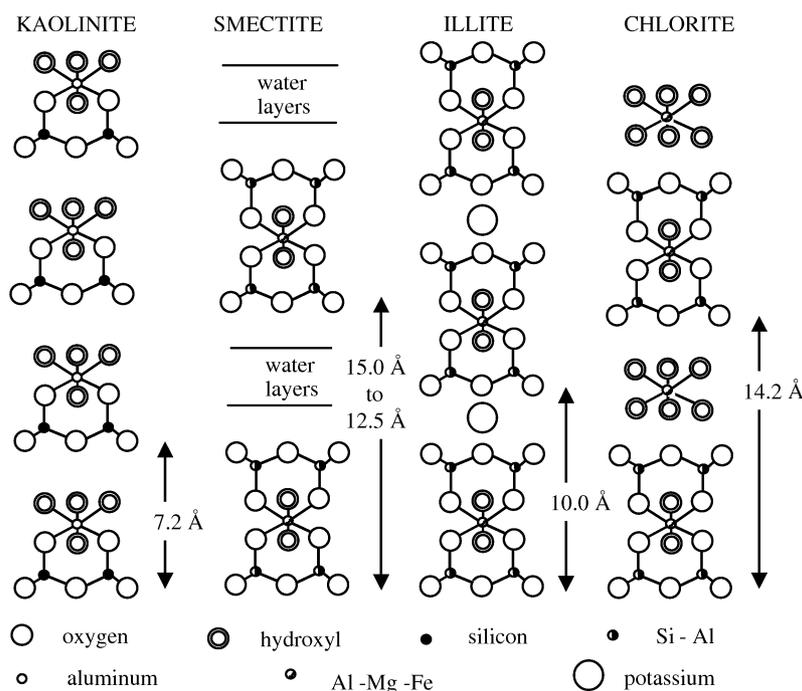

Figure C39 Diagrammatic representation of some phyllosilicate clay minerals and characteristic 'basal spacings' representing the distance between repeating layers.

Identification of clay minerals

The precise identification of clay minerals often requires analytical data from several techniques. X-ray powder diffraction (XRPD) is one of the most important (Brindley and Brown, 1980; Moore and Reynolds, 1997), but it is often essential to obtain supplementary data from chemical, spectroscopic, thermal or other techniques (Wilson, 1987). The importance of XRPD lies in the ability to measure the so-called basal spacings, and changes in these spacings after diagnostic treatments; these measurements can be easily

related to the layer structure and hence to the type of clay minerals present. A diagrammatic representation of some clay minerals and the corresponding layer spacings is shown in Figure C39.

Origins, occurrence and distribution of clay minerals

Clay minerals are the characteristic minerals of the Earth's near surface hydrous environments including those of weathering, sedimentation, diagenesis, and hydrothermal

alteration. Within all of these environments clay minerals may have one of three different origins; they may be neoformed, transformed, or inherited (Millot, 1970; Eberl, 1984). Neof ormation describes the direct formation by crystallization of a clay mineral from solution or by ageing of amorphous gels. Neof ormation is limited by the constraints of time and temperature, such that longer times and higher temperatures promote neof ormation. The sluggishness of neof ormation and the apparent stability of clay minerals at low temperatures means that clay minerals formed in one environment are often recycled into another. This is an origin known as inheritance. Most clay minerals found in modern sedimentary environments represent the redistributed products of weathering and as such they are inherited (Chamley, 1989; Weaver, 1989). The origin known as transformed lies between these two poles since it describes the formation of clay minerals where some structural elements of a precursor mineral (usually another clay mineral) are retained but new ones are added.

As far as sediments and sedimentary rock are concerned, the importance of weathering is as a primary and often the ultimate source for many clay minerals. Weathering and the formation of various kinds of clay minerals in soils is controlled by many variables operating at various scales including, climate, drainage, topography, parent rock type, and time. At a global scale, a broadly latitudinal climatically controlled pattern of clay mineral distribution is recognized in zonal soils. Thus in polar, tundra, temperate and desert climatic zones the processes of inheritance and transformation are dominant and the clay minerals assemblages are, very generally speaking, characterized by assemblages containing illite and chlorite inherited from parent materials and mixed-layer clay minerals and vermiculite formed by transformation from illite and chlorite. In tropical climates neof ormation processes are much more evident: kaolin is formed where soil solutions are thoroughly depleted of bases cations, usually as a result of constant leaching, and smectite is formed where conditions allow base cations to accumulate.

The broadly latitudinal pattern of clay mineral distribution in zonal soils is mirrored in the recent sediments of the ocean basins and attests to the largely detrital origin of clay minerals in the modern marine environment (Chamley, 1989; Weaver, 1989). However, neof ormation of clay minerals in certain sedimentary environments is commonplace and in most cases the clay minerals involved are rich in iron or magnesium and poor in aluminum. In the marine environment examples include the iron-rich clay minerals glauconite, berthierine, odinite, and nontronite. Magnesium-rich clay minerals, such as sepiolite and palygorskite, and some species of trioctahedral smectites, tend to be most commonly encountered in perimarine evaporitic settings or in alkaline lakes.

Clay minerals are found in most sediments and sedimentary rocks, but they are most abundant in mudrocks and shales, where they typically account for about 50 percent of the mineral components. When sediments are buried by yet more sediment then diagenetic processes begin to act and their action is commonly recorded by the changes they induce in the clay minerals and clay mineral assemblages present. Probably the best known and most widespread is the smectite-to-illite reaction, whereby originally deposited smectitic clays are progressively transformed to illite via mixed-layer illite-smectite, although there is much debate about the nature of the reaction(s) involved. The article by Środoń (1999) provides

a recent review, and summarizes those aspects that are still contentious.

CLIMATIC CONTROL OF SEDIMENTATION

Introduction

Sedimentation is influenced by three extrinsic variables, tectonics, sea level, and climate, with climate potentially dependent upon the other two variables. Global climate has undergone substantial changes on a variety of temporal and geographic scales throughout earth history. Interpreting climates of the past (paleoclimate) is an important aspect of

understanding earth history (Crowley and North, 1991; Parrish, 1998).

Global climate

Climate may be defined as the condition of the atmosphere at a specific location near the earth's surface averaged over several years or tens of years. The climatic conditions that most affect sedimentation are mean annual temperature, mean annual precipitation, seasonal variations in temperature and precipitation, the rate of evaporation compared to precipitation, and the direction, velocity, and seasonal variation of winds and ocean currents.

The first-order variables affecting global climate are the angle at which solar radiation strikes the earth's surface and the Coriolis effect. The Coriolis effect results from the earth's rotation and deflects currents to the right in the northern hemisphere and to the left in the southern hemisphere. These variables produce climatic zones that are roughly parallel to latitude (Figure C40). Solar radiation striking the equator at nearly right angles effectively heats the atmosphere, causing the air to rise and move toward the poles (Hadley cell). The air descends at about 30°N and 30°S and flows back toward the equator, where it is deflected by the Coriolis effect, producing the easterly trade winds. The equatorial climatic zone where the trade winds meet, called the intertropical convergence zone, is characterized by low atmospheric pressure and high precipitation associated with convective cooling of the rising air mass. In contrast, the descending part of the Hadley cell results in high atmospheric pressure and dry conditions (subtropical high). Solar heating is at a minimum near the poles, because the sun's rays strike the earth at a very low angle. Cold air at the poles flows toward the equator and is deflected by the Coriolis effect to become the polar easterlies. At about 60°N and 60°S the polar air begins to rise and flow back toward the poles, completing the polar cell and producing a zone of low pressure (subpolar low) characterized by abundant precipitation. Air moving poleward from the subtropical high creates upper-level, westerly winds at mid-latitudes. Collision of warm tropical and cold polar air along the polar front results in eastward-moving, low-pressure troughs that are responsible for much of the precipitation in the mid-latitudes. A narrow zone of upper-level, high-velocity, east-flowing wind (jet stream) is also created along the polar front and influences movement of the low-pressure troughs.

The simple global pattern of climatic zones shown in Figure C40 is disrupted by other variables (Figure C41). The tilt of the earth on its axis of rotation results in seasonal shifts of the climatic zones by five to ten degrees of latitude. Different heat capacities of land and sea tend to intensify the subpolar low and subtropical high over the oceans, especially during winter. Disruption of zonal circulation may also result from the development of a high pressure cell in winter and low pressure cell in summer over a large land mass at mid to high latitudes, such as occurs in the Asian monsoons. Other effects more localized in time and space include increased precipitation on the windward side of mountain ranges (orographic effect), variations in reflectance of solar radiation among different surfaces (albedo), variations in the amount of solar radiation that strikes the earth due to cloud cover or volcanic ash or eolian dust in the atmosphere, and the redistribution of heat by ocean currents.

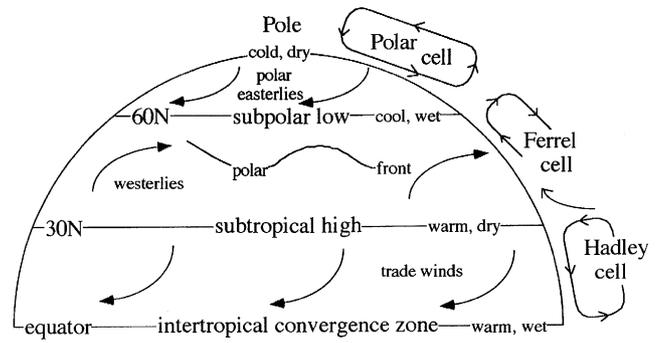

Figure C40 Climatic zones of the northern hemisphere. Arrows indicate wind directions. Climatic zones in the southern hemisphere are a mirror image of those in the northern hemisphere.

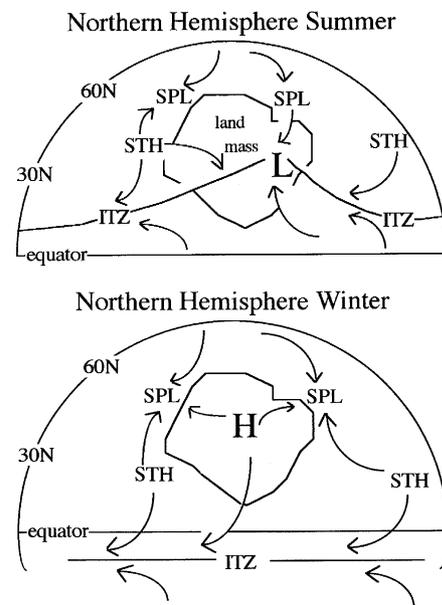

Figure C41 Example of the disruption of the general climatic zones of Figure C40. ITZ = intertropical convergence zone; STH = subtropical high; SPL = subpolar low; arrows indicate wind directions. The ITZ, STH, and SPL shift north during northern hemisphere summer and south during southern hemisphere summer, and the STH and SPL are intensified over the oceans. During summer, a large low pressure cell develops over the large land mass, deflecting the ITZ into it. In winter, a high pressure cell develops over the cold land mass.

Effects of climate on sedimentation

Climate plays a major role in determining sediment yield, which is the amount of siliclastic sediment produced by weathering and transported out of a drainage basin to a sedimentary basin. Empirical data suggest that sediment yield in modern drainage basins, when normalized to temperature, is primarily related to annual precipitation and the competing effects of surface runoff and vegetative stabilization of soil (Figure C42; Langbein and Schumm, 1958; Leeder *et al.*, 1998). Under arid conditions, sediment yield is low, because weathering rates are low and there is little surface runoff.

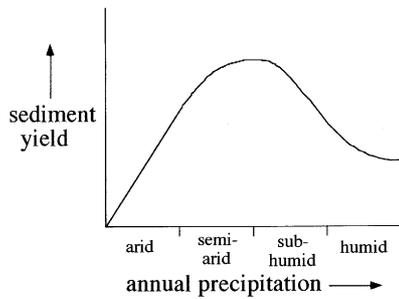

Figure C42 Schematic bivariate plot showing the relationship between sediment yield and annual precipitation.

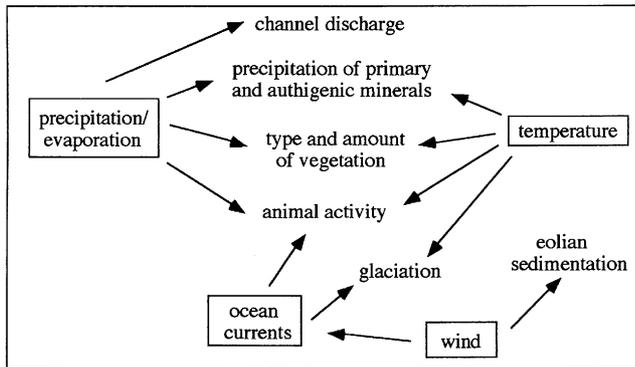

Figure C43 Climatic influence on some of the processes and variables that affect depositional environments.

Sediment yield reaches a maximum in semiarid and sub-humid climates, because there is sufficient precipitation for weathering and surface runoff but vegetative cover remains low to moderate. Included in the semiarid and sub-humid climatic groups are climates characterized by strongly seasonal precipitation, which may have large annual values of precipitation but relatively sparse vegetative cover due to a protracted dry season. Under humid conditions, lush vegetation tends to hold the soil in place, reducing sediment yield. Variations in sediment yield may affect deposition or incision of alluvial fans and rivers (Bull, 1991), the type of river and its bars and bedforms (Schumm, 1977), and whether shorelines prograde into the sea or undergo retreat in the face of rising sea level. In regions of extremely low sediment yield, carbonate and/or evaporite sedimentation may occur along the shoreline and in the shallow oceans.

In addition to sediment yield, climate also affects most depositional environments in terms of depositional processes, the type of sediment deposited, and syndepositional modification of the sediment. Some of the most important relationships between climatic variables and sedimentation are shown in Figure C43.

Interpretation of paleoclimate

Interpretation of the climates that existed in the geologic past is fundamental to the study of earth history and provides a template for interpreting future climatic change. There are two basic approaches to paleoclimate interpretation, modeling

and paleoclimatic indicators. Whenever possible these two approaches should be used in concert to provide the most reliable interpretation.

Paleoclimate modeling involves applying the physics of modern climate to paleogeography, and includes energy balance (e.g., North and Crowley, 1985; Schmidt and Mysak, 1996) and general circulation models (e.g., Rees *et al.*, 1999; Poulsen *et al.*, 1999). A third type of modeling is concerned with global geochemical cycles, such as variations through time in the concentration of atmospheric carbon dioxide (Berner, 1994). Numerical models provide testable hypotheses regarding global paleoclimate and are especially useful in predicting the effects of specific variables on paleoclimate.

Paleoclimatic indicators are types of rock or features within rocks that only develop under specific climatic conditions. Perhaps the best terrestrial paleoclimatic indicators are plant fossils, because plant species and their relative abundance on earth are sensitive to precipitation, temperature, and evaporation rate (e.g., Wolfe, 1979, 1993; DiMichele *et al.*, 2001). Vertebrate fossils may also be used as paleoclimatic indicators, particularly the distribution of large ectothermic animals (Markwick, 1994). Paleosols are effective terrestrial paleoclimatic indicators, especially the mature, well-drained types (Mack and James, 1994). Particularly diagnostic of paleoclimate are calcic, gypsic, and natric paleosols, which indicate relatively dry paleoclimate (Watson, 1990), extremely chemically weathered paleosols (oxisols, laterites, bauxites), which indicate humid paleoclimate (Bardossy and Aleva, 1990), cryoturbated paleosols indicative of permafrost (Retallack, 1999), and vertic paleosols that contain features produced by shrinking and swelling of expandable clays and that are best developed in regions with seasonal precipitation (Gustavson, 1991). The formation of peat, which may later convert to coal, is favored in regions with humid climate, but may also be related to locally high water table regardless of climate. Other terrestrial paleoclimatic indicators include widespread eolian deposits, which provide evidence about wind directions and are best but not exclusively developed in regions of dry climate (Peterson, 1988), tillites deposited by glaciers (Eyles *et al.*, 1983), and the composition, sedimentary structures, and depositional cycles of lacustrine sediment (Hardie *et al.*, 1978; Olsen, 1990).

Some marine sedimentary rocks also provide important evidence about paleoclimate. Many marine organisms are sensitive to water temperature, salinity, and ocean currents and the distribution of their fossils provides information about global paleoclimate (Huber, 1992). Moreover, the ratio of ^{18}O to ^{16}O in calcite or aragonite shells of some benthic and planktonic organisms has been used to estimate the temperature of the seawater from which the shells precipitated (Savin, 1977; Wilson and Opdyke, 1996). The oxygen isotopic ratio of marine shells is also influenced by preferential storage of the lighter isotope (^{16}O) in continental glaciers and its subsequent release during melting, providing a high-resolution record of glacial onset and fluctuations (Shackleton, 1988). Marine bedded chert, phosphorite, and organic-rich sediment tend to be associated with zones of oceanic upwelling, which are related to global wind patterns (Parrish, 1995). Finally, marine gypsum/anhydrite and halite precipitate in areas where high evaporation rates create hypersaline water.

Using modern climate as a guide is a useful approach to understanding ancient climate and is the foundation of paleoclimatic modeling and use of paleoclimatic indicators.

Some climatic variables or climate-related processes may have been quite different in the geologic past, however, affecting the boundary conditions of models and the applicability of certain paleoclimatic indicators. Several examples illustrate the problem: (1) lower solar luminosity in the Archean compared to today; (2) greater ratio of sea to land in the Archean compared to today; (3) higher global sea level in the Cambrian and Cretaceous, which may have ameliorated terrestrial climate and affected ocean circulation; (4) prior to the appearance of vascular land plants in the Devonian, sediment yield was not affected by vegetation; and (5) the global distribution of extinct plants and animals may not have been the same as that of their closest surviving relatives.

Temporal scales of climate change

Climatic cycles refer to repetitive changes in earth's climate related to global processes and may occur on the scale of a few years to tens of millions of years. At the largest timescale, the earth may have experienced as many as nine changes from warm to cool conditions over the past 700 million years (Frakes *et al.*, 1992). These climatic intervals are commonly referred to as "icehouse" and "greenhouse" periods, because most of the cool intervals have evidence for continental glaciation and because the cycles appear to be strongly influenced by changes in the atmospheric concentration of carbon dioxide, a greenhouse gas.

At much smaller temporal scales are Milankovitch cycles, which result from orbital perturbations that significantly affect the distribution of solar energy on the earth, especially at high latitudes. One of the perturbations involves changes in the shape of the earth's orbit around the sun, which occurs at periods of 100 kyears and 400 kyears (thousand years). In addition, a complete cycle of change in the angle of tilt of the earth's axis of rotation takes place every 41 kyears, and the precession effect, which is primarily related to the earth's wobble as it spins, produces cycles of 19 kyears and 23 kyears. The waxing and waning of Pleistocene glaciers have been correlated with Milankovitch cycles (Hays *et al.*, 1976), as have other sedimentologic patterns in the stratigraphic record (Olsen and Kent, 1996).

Not all climatic changes in the geologic past were necessarily driven by global cycles, however. Climate changes may occur on a continent as it drifts across latitudinal climate zones, and local climate change may result from the rise and fall of mountains or from changes in ocean and wind currents. Given the multitude of variables that affect climate, it is unwise to assume that all climatic changes in earth history will occur at the same time scale and for the same reason.

Summary

1. Climate is the average condition of the atmosphere near the earth's surface and includes temperature, precipitation, evaporation, winds, and ocean currents. Climatic zones on the earth are generally distributed parallel to latitude, although local conditions may disrupt this pattern.
2. Climate affects the amount of siliciclastic sediment made available to sedimentary basins, as well as sediment composition, depositional processes, and syndepositional modification by organisms and precipitation of authigenic minerals.

3. The interpretation of ancient climate (paleoclimate) is based on numerical modeling and paleoclimatic indicators in the rocks, such as plant fossils, evaporite minerals, and paleosols. Uniformitarian considerations are necessary when interpreting paleoclimate, especially for the Precambrian.
4. Cyclic changes in climate may occur on the scale of years to tens of millions of years, although not all the climate changes in the geologic past resulted from global cycles.

COAL BALLS

Definition

Coal balls are permineralized peat, mainly found in Upper Carboniferous coal seams of Europe and North America but also in some Chinese Permian coals. Coal balls are predominantly calcium carbonate which has precipitated in the cell lumina and spaces between the plants within a peat formed in a mire (Scott and Rex, 1985).

Formation

Peat accumulates in wetland environments (mires such as swamps and bogs) where the accumulation of organic matter is faster than its decay. Studies on modern peat-forming environments indicate that the two main sources of water are from throughflow (rheotrophic) and rainfall (ombrotrophic) (Moore, 1987). In general the breakdown of plant material (cellulose and lignin) predominantly through the action of bacteria causes a decrease in pH. However, during the Carboniferous in Tropical Euramerica, in particular, mineral charged waters flowing through rheotrophic peats precipitated calcium carbonate, usually in the form of calcite. The calcite precipitated not only within cell lumina and spaces with the plants but also between plant parts and fragments (Scott and Rex, 1985) (Figure C44). This gave rise to a limestone 'nodule' within the peat which entombed the plants but did not replace them (Winston, 1986). These nodules are known as coal balls (Figures C45, C46). Discovered first in England in the 1850s these coal balls ranged in size from a few centimeters to tens of centimeters across. They appeared to be stratigraphically restricted to the base of the British Coal Measures.

However, subsequently coal balls were found in continental Europe from Spain in the South to the Ukraine in the east. By far the most diverse occurrences of coal balls have been discovered in North America (mainly in the USA, but also some finds in Nova Scotia, Canada). In the USA coal balls may replace entire coal seams in part and coal ball masses may be several meters in diameter (DiMichele and Phillips, 1994; Phillips, 1980; Greb *et al.*, 1999).

When cut coal balls reveal excellent anatomical preservation of the plants which formed the peat (Figure C47). The original organic cell wall material (albeit slightly chemically altered) is preserved (Collinson *et al.*, 1994). The calcite is precipitated as fibrous calcite which grows on organic walls into voids (Figure C44). There may be subsequent alterations, as in the case of some Belgium coal balls, to dolomite. In many cases, the coal seam containing coal balls is overlain by marine rocks. In England, roof nodules within marine shales contained anatomically preserved plants. This led to the suggestion by Stopes and Watson (1908) that the source of the carbonate was marine. Research in North America by Mamay and Yochelson (1962) showed that some coal balls had a marine core thus strengthening the idea of a marine source for the carbonate. Isotopic studies, however, suggest that not all of the carbonate is marine and that there is likely to be a complex origin for the carbonate, some of which appears to be derived from meteoric fresh water (Scott *et al.*, 1996; DeMaris, 2000). At least five models of formation for coal balls have been proposed, each with supporting data.

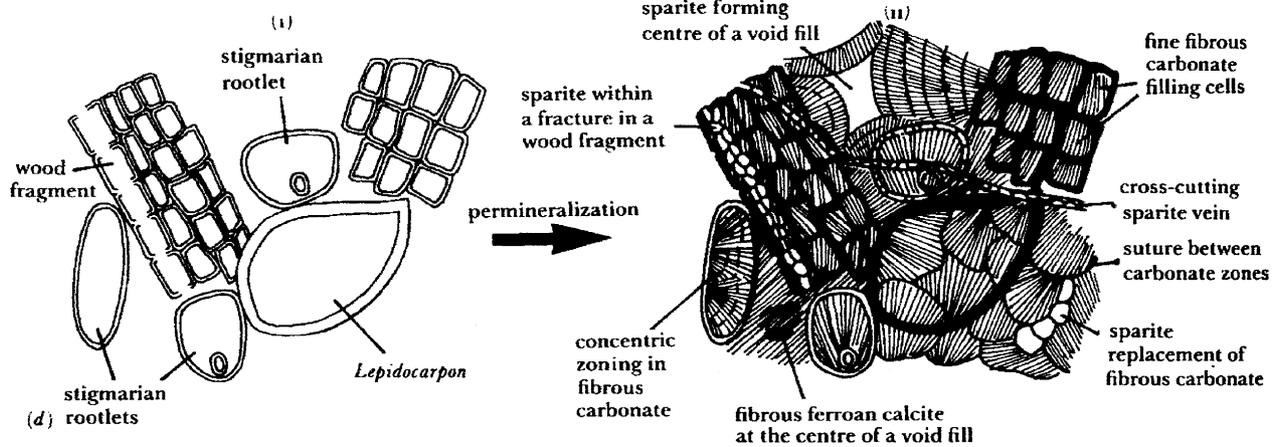

Figure C44 Petrography of a Carboniferous coal ball (from Scott and Rex, 1985).

Figure C45 Coal ball, *in situ*, Springfield Coal, Pennsylvania, Indiana, USA.

Figure C46 Section cut through coal ball shown in Figure C45.

Whilst most coal balls are found in Upper Carboniferous coal seams from tropical Euramerica some coal balls have been described from the Permian of China (Tian 1985). We do not understand why carbonate coal balls are restricted to Late Paleozoic coal seams.

Content

A wide variety of plant species and plant parts may be preserved in coal balls (DiMichelle and Phillips, 1994). Permineralization may happen at any time during the formation of the peat from immediately the plant material has been incorporated into the peat to when there has been some considerable decay within the peat (Scott *et al.*, 1996). The speed of permineralization in some cases may be illustrated by the preservation of ephemeral structures such as pollen drops. In many cases, however, plants may have started to rot before permineralization so that strips of bark or cortex of larger trunks may be preserved (DiMichele and Phillips, 1994). A feature of coal balls is that the original organic cells walls are preserved. Because they are entombed within limestone they are not compacted, as normal peat would be, by burial. This ensures anatomical preservation of the plants. The organic cell walls are subject to temperature rise during burial and the organic material undergoes several changes whilst still retaining features of their original cell wall chemistry.

The detailed plant anatomy has allowed the identity and the life history of the preserved plants to be elucidated. Serial peels allow the reconstruction of the morphology of the plants. The reconstruction of a number of coal ball plants from small scramblers to large trees (Phillips and DiMichele, 1992; Bateman *et al.*, 1992) has been made possible from the connection of plant organs, recurrent association and specific anatomical or morphological features of the plants. As coal balls represent peat which may have acted as a substrate for other plants, rhizomes, roots and rootlets are common, often growing through other plants and plant organs (DiMichele and Phillips, 1994).

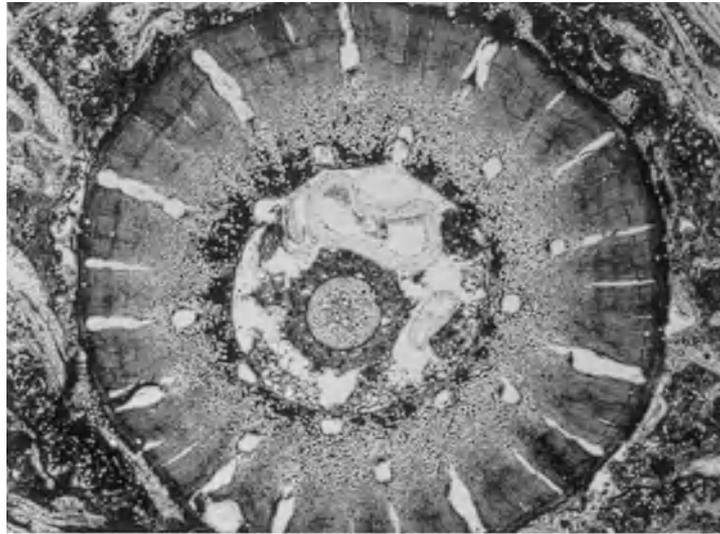

Figure C47 Thin section of Carboniferous coal ball showing anatomical preservation of *Lepidodendron*, Lancashire, England ($\times 2$).

In Namurian and Westphalian coal balls of Europe and North America arborescent lycopsids are the dominant plant (Galtier, 1997). However ferns, sphenopsods and pteridosperms may also be locally abundant. In some coal balls of the North American mid-continent basin some coal balls are dominated by Cordaites, a close relative of conifers. Some Chinese coal balls of Permian age are also dominated by Cordaites. In Stephanian coals of USA, coal balls are dominated by tree ferns (Phillips, 1980).

Spores and pollen may be extracted from fertile structures allowing comparison of the vegetation in coal balls with that from coals where spores and pollen are the only way of identifying the coal-forming vegetation (Balme, 1995).

Significance

Detailed anatomical and studies of reproductive biology have allowed the life habits and ecology of the plants to be understood and in addition allowed phylogenetic reconstruction of several important plant groups (Bateman *et al.*, 1992).

Stratigraphic studies of coal ball plants and spores have indicated major vegetation changes of coal-ball floras through the Upper Carboniferous. Extinctions of plants have been linked to distinctive climatic changes, in particular decreasing rainfall which affected the more wet-loving plants (DiMichele and Phillips, 1994). Coal balls also provide evidence of plant-arthropod interaction (Scott and Taylor, 1983). Recent studies have indicated an extensive arthropod decomposer community as recorded by coprolitic debris (Labendeira, 1998).

COASTAL SEDIMENTARY FACIES

Introduction

This section describes some of the more common clastic sedimentary facies associated with open coasts. For a review of carbonate coastal facies, the reader is referred to Demicco and Hardy (1994). The discussion here also does not address facies of high-latitude coasts or low-latitude coasts dominated by mangrove swamps (see Hill *et al.*, 1995, and Cobb and Cecil, 1993, respectively). Many of the facies described here originate in both marine and lacustrine settings, although tidally influenced facies are restricted to the marine environment.

For more detailed information on coastal sedimentary facies, the reader is referred to the excellent summaries provided by Reineck and Singh (1973), Walker and James (1992), Galloway and Hobday (1996), and Reading (1996). In addition, the following complementary sections are available in this volume: Barrier Islands, Beach, Deltas and Estuaries, Hummocky and Swaley Cross-Stratification, Off-Shore Sands, Salt Marsh, Storm Deposits, Swash and Backwash, and Tidal Delta and Inlet.

Coastal sedimentary processes

A complex array of processes influence coastal sedimentary facies. Of these, the most important are waves, tides, and biogenic processes. Sediment input is also critical to the facies character (in its influence on grain size) and to the nature of the preserved deposits (the effects of sedimentation rate).

Waves may exist as "seas", driven by local winds, or as "swell", generated by distant storms. Swell tends to have longer period and to influence the seabed to greater depths than do local sea waves. "High-energy" coasts are likely to be dominated by swell. "Low-energy" coasts receive smaller everyday waves, but can experience very large waves during storms.

Waves move sediment by two mechanisms. The passage of waves induces a back and forth orbital motion at the bottom. In water that is deep relative to the size of the wave, this motion is symmetrical in velocity and duration of flow. In shallower water, the motion becomes asymmetric, with short relatively strong landward flow under the crest of a wave and a more prolonged weaker seaward flow under the trough

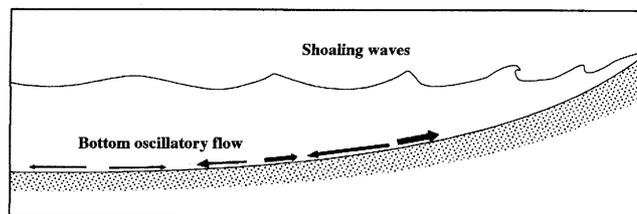

Figure C48 Nature of bottom oscillatory currents under shoaling waves. Length of arrow indicates duration of flow. Thickness of arrow indicates flow velocity.

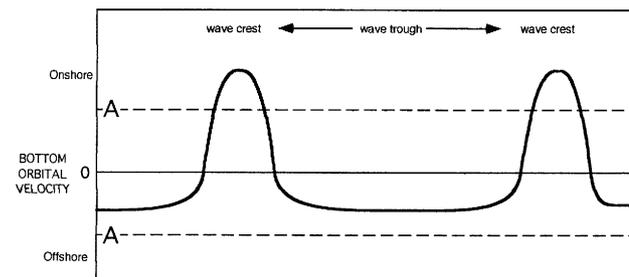

Figure C49 Schematic showing direction and velocity of bottom oscillatory currents at a point on the nearshore profile under shoaling waves. Line "A" represents a threshold velocity that is exceeded by landward flow as wave crests pass, but not by seaward flow as troughs pass (see Komar, 1976).

(Figure C48). The orbital velocity asymmetry is important for promoting the onshore transport of coarser material (Figure C49) and bed load in general. For the conditions under which this asymmetric flow occurs, see the "Stokes wave" field in Komar (1976, Figure C50–17).

Waves also, as they encounter the shoreline, generate sustained flow in the form of shore-parallel longshore currents and seaward-directed rip currents (Figure C50). These currents, which form nearshore circulation cells, not only transport sediment but also shape the nearshore morphology into bars and troughs.

The intensity and nature of wave-generated processes can differ significantly as conditions change from fair-weather to storm. Storms, which on most coasts obtain for only a small percentage of time, mobilize the seabed at greater depths and intensify nearshore circulation. Rip currents are stronger and extend into deeper water. In addition, wind-driven currents can augment the offshore flow (Swift *et al.*, 1985). As a consequence, relatively large volumes of sediment are transported alongshore and offshore in a short period of time. Much of this material, however, can be reworked in the long intervals between storms and returned to its pre-storm setting.

Tides influence sedimentary facies in two ways (see *Sediment Movement by Tides*). The rhythmic rise and fall of the sea changes water depth and locally exposes extensive intertidal flats. It also generates tidal currents that flow alternately landward (flood tides) and seaward (ebb tides). Tides in an open coast setting mostly only raise and lower the water level, exposing the seabed to different wave-energy regimes. Tidal currents here are likely to be important only near inlets, or, in epeiric seas, further offshore.

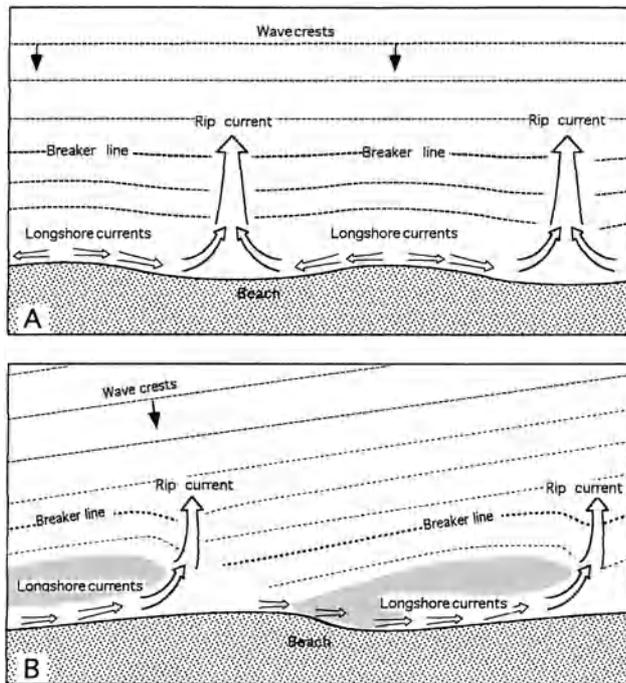

Figure C50 Nearshore circulation cells where wave incidence is parallel to coast (A) or oblique (B). Circulation consists of unidirectional rip and longshore currents generated by the hydraulic head caused by set-up/setdown of the sea surface in and near the breaker zone.

Biogenic processes are important in the development of coastal facies. Biogenic effects include bioturbation, the generation of distinctive traces, contribution of shell detritus, the fixing of suspended fine sediment by filter feeding and vegetative baffling, and the binding and bioerosion of the substrate. These processes depend on many factors, but faunal activities are particularly sensitive to variations in salinity. Faunal traces in brackish environments tend to be simpler, less diverse, and more likely to be dominated by a single ichnogenus (Pemberton and Wightman, 1992) than those made in oceanic salinities.

The response of sediment to fluid motions depends in large part on its textural nature, which is determined partly by local dynamic processes and partly by what is available to the system. Grain size is also a major influence on the rate and style of bioturbation, which combined with the frequency and intensity of physical processes determine the degree of preservation of physical structures. On most open coasts the sediment lies somewhere in the spectrum of very fine-grained sand to gravel, although coastline adjacent to or influenced a large delta may be dominated by mud.

The shoreface

A fundamental aspect of most open clastic coasts is the *shoreface* (Figure C51), a relatively steeply-inclined (1:200) ramp that extends offshore to a nearly flat (1:2000) inner shelf or basin floor (Johnson, 1919). This feature is probably

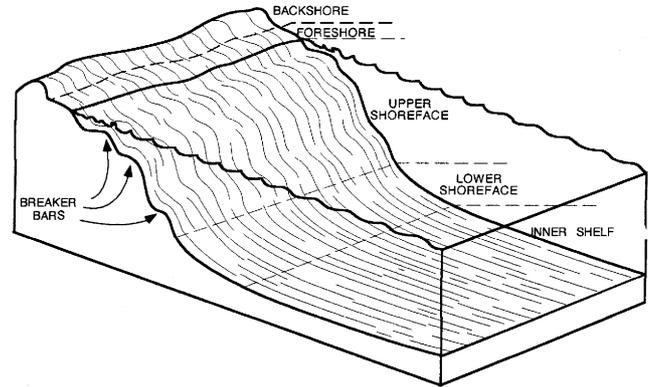

Figure C51 Typical morphologic zonation of a wave-dominated open coast. Many shorefaces have 1 to 3 breaker bars.

maintained by a combination of sediment transport to shoreward under shoaling waves (as described above) and transport to seaward by rip currents or geostrophic flow during storms (Niedoroda and Swift, 1981).

As noted by Niedoroda *et al.* (1985), the boundaries between the shoreface and its adjacent coastal environments can be difficult to define, and as a result, subsequent work on the shoreface has led to conflicting variations on the original definitions. Many workers and texts follow Johnson's (1919) lead in placing the landward boundary of the shoreface at the low-tide line, but others, however, place the boundary just seaward of the surf zone, and a few place it at the top of the swash zone.

The seaward boundary of the shoreface is even more problematic, because it involves a subtle change in slope. On many modern coasts, the inner shelf is characterized by a gently inclined, nearly planar surface, whereas the adjacent shoreface is not only more steeply inclined, but the angle of slope increases to landward. Many workers place the base of the shoreface at this increase in slope, but a few do not. Some extend the shoreface to a location where the seabed texture changes (typically from sand to mud). Others place the base of the shoreface at the mean fair-weather wave base, with or without morphologic connotation.

Most workers refer to the area seaward from the shoreface as "shelf" or "offshore". Howard and Reineck (1981) identify a "transition zone" separating the shoreface and the offshore in which the sediment is siltier and/or more bioturbated than that of the shoreface.

The depth to which a shoreface extends obviously depends on its definition, but the break in slope used by most workers can occur in water depths ranging from a few meters to 25–30 m. The depth of the slope break is in part a function of wave energy, but much of the variation results from the seafloor profile in a transgressive or erosional setting. In progradational settings, where sufficient sediment exists to provide for an equilibrium profile with the shoaling waves, the break in slope occurs in relatively shallow depths. Even where wave energy is high (as on the Pacific Northwest coast of the United States), progradational shorefaces do not extend to depths much greater than 10 m.

In the study of ancient coastal sediment, shoreface deposits are identified on the basis of a variety of criteria. General agreement exists that the preservation of shoreface successions

requires shoreline progradation, and that, accordingly, the deposits display an upward-shallowing facies trend and upward textural coarsening. Otherwise there is little consistency of usage. Some workers attribute the entire sandy component of a progradational succession to the shoreface. Others restrict the shoreface to thick-bedded sandstone as opposed to interbedded sand and shale. Some associate shoreface deposits with specific physical structures, such as trough cross-bedding and swaley cross-stratification. Others use the degree of bioturbation to separate the shoreface from underlying shelf facies. Some workers propose evidence of deposition above fair-weather wave base as a criterion of shoreface deposits.

An assumption that shoreface deposits are sandy and shelf deposits muddy is unsupported. In some areas the base of the shoreface marks the transition between sand and mud, but in many places sand continues well out onto the inner shelf. On much of the Pacific coast of California, Oregon, and Washington, for example, fine to very-fine sand extends to water depths of 60 m or more. In contrast, the shoreface of the Suriname coast of South America is underlain by mud and the adjacent shelf by sand (Rine and Ginsburg, 1985). The proportions of sand, silt and mud, depend on the sediment available and the wave-energy regime (Galloway and Hobday, 1996) and are not specifically related to the shoreface morphology.

An assumption that fair-weather wave base defines the base of the shoreface is similarly unfounded. Again, although this can be the case in some settings, it is demonstrably not in many others. Wave base is commonly regarded as a water depth equal to half the wave-length. Long-period waves (≤ 8 s) characterize many coasts during fair weather and such waves have deep-water wave lengths of 100 m or more. Ten-second waves, which prevail during summer fair-weather conditions on the western coast of the US, have a wave base of nearly 80 m, well beyond any shoreface.

The thickness of inferred individual ancient shoreface successions also is highly variable. Some workers place them in the range of several tens of meters, whereas others place the thickness at only a few meters. Given the water depth to which modern prograding shorefaces extend, most individual ancient shoreface successions will be less than 10–15 m thick, unless influenced by conditions of exceptional accommodation.

Shoreface subdivisions

Galloway and Hobday (1996) describe the active surf zone as “upper shoreface”, a zone of breaker bars as “middle shoreface”, and the area from the outermost bar to the break in slope as “lower shoreface”. Many interpreters of ancient coastal deposits use texture, physical structures or trace fossils to divide the shoreface into upper, middle and lower parts, and a few subdivide these further into “proximal” and “distal” portions. These divisions may be valid lithologic entities, but they also may be unrelated to the morphologic shoreface.

Sedimentary facies of the shoreface and adjacent environments

The *upper shoreface* is equivalent to the nearshore zone, where wave-generated currents predominate (see Clifton *et al.*, 1971). Upper shoreface facies are generally the coarsest part of the coastal system and commonly are characterized by high-angle

trough cross-bedding that is directed parallel to the shoreline (in response to longshore currents) or offshore (in response to rip currents). Modern medium- to coarse-grained nearshore zones are dominated during fair-weather by medium-scale lunate megaripples (dunes) that face and migrate in an onshore direction (Figure C52). Cross-bedding produced by these structures seems rarely preserved, however, in ancient upper shoreface deposits, which seem dominated by storm effects. If gravel is present, it typically is well-sorted into discrete beds and layers, and gravel and shells commonly form erosional lags within the deposit. Small, shore-normal gravel-filled gutter casts (*q.v.*) exist at the base of some gravel beds. Fine-grained sandy shorefaces are likely to lack larger bedforms and to be dominated by planar beds and rippled surfaces (Figure C53), unless breaker bars provide a mechanism for focusing longshore or offshore flow (Figure C54) or wave energy is so low that bioturbation predominates in the troughs (Figure C55).

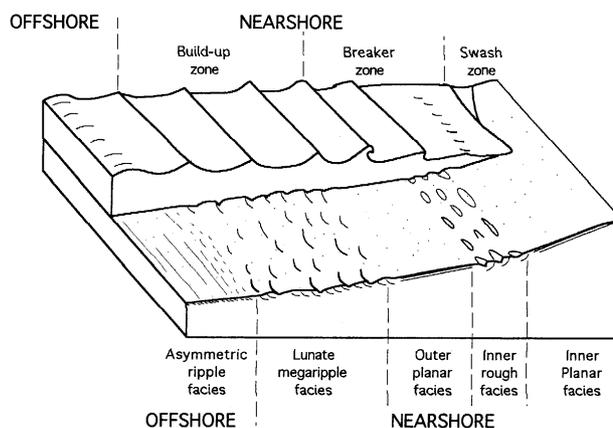

Figure C52 Sedimentary structural facies in the unbarred nearshore (upper shoreface) in coarse sandy sediment on the high-energy coast of southern Oregon under fair-weather conditions.

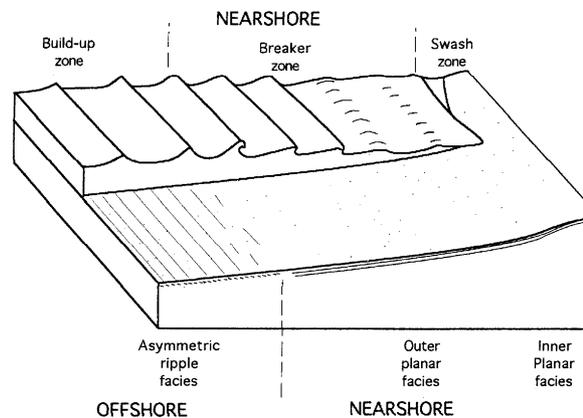

Figure C53 Sedimentary structural facies in the unbarred nearshore (upper shoreface) in fine sandy sediment on a high-energy coast under fair-weather conditions. Flatter beach/nearshore profile expands the surf zone relative to coarser shorelines. No medium-large scale bedforms. Surf and swash zones underlain by planar parallel lamination.

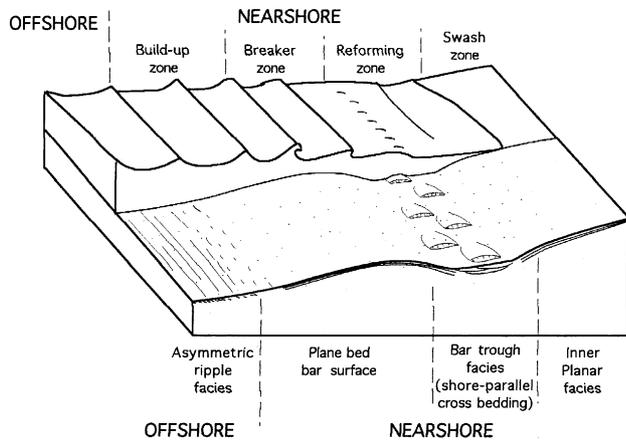

Figure C54 Sedimentary structural facies in a barred high-to-moderate-energy fine-grained nearshore under fair-weather conditions. Longshore flow in the trough of the shore-parallel bar is strong enough to create small dunes that migrate alongshore in the trough.

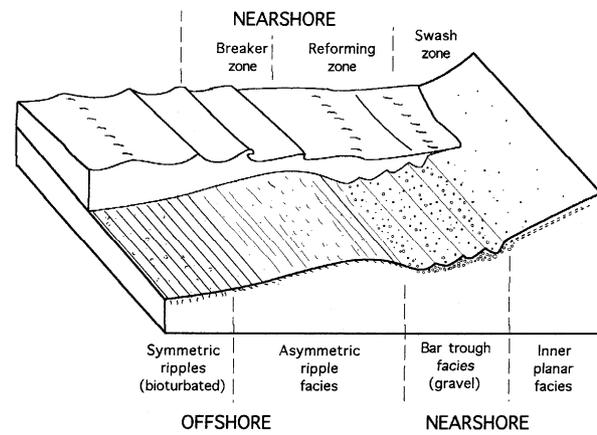

Figure C56 Sedimentary structural facies in a barred low energy coarse-grained nearshore under fair-weather conditions. Coarse sediment is concentrated in the trough of the shore-parallel bar.

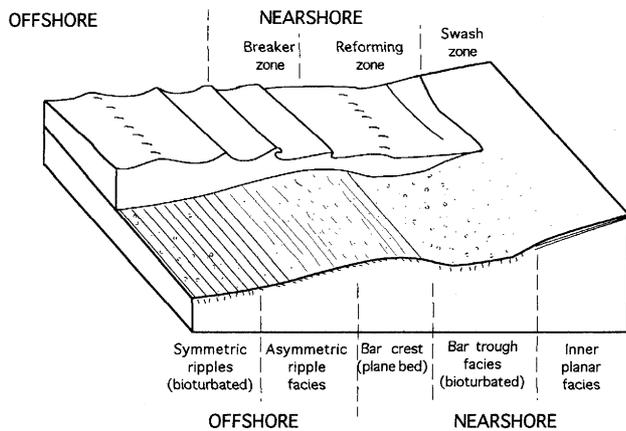

Figure C55 Sedimentary structural facies in a barred low-energy fine-grained nearshore under fair-weather conditions (example, Padre Island, Texas, after Hill and Hunter, 1976). Sediment in the longshore trough and seaward from the bar is intensely bioturbated.

Coarse sediment, if present, typically is concentrated in troughs behind breaker bars (Figure C56).

Burrowing in upper shoreface deposits is dominated by the *Skolithos* ichnofacies, characterized by mostly vertical cylindrical and U-shaped burrows, the dwelling structures of suspension feeders or passive carnivores (Pemberton *et al.*, 1992). The trace *Macaronichnus* is common in fine sand of high-energy coastal deposits and feeding pits of rays or other vertebrates may occur. The thickness of upper shoreface deposits generally ranges from 1 to 8 m, depending on the intensity of wave energy.

Many interpreters of the stratigraphic record postulate a *middle shoreface* facies in their deposits based on the presence of bar-trough facies or other evidence, but this identification is questionable. On many coasts the innermost breaker bar is part of the active surf zone, and during storms, the largest

waves commonly break on the outermost breaker bar. As a consequence, preserved bar-trough facies may be indistinguishable from that of the inner surf zone.

A *lower shoreface* facies is identifiable in most pebbly shoreface deposits. This facies, 1–3 m thick, consists of small pebbles of relatively uniform size in a matrix of well-sorted fine-to very fine-grained sand. The pebbles occur as scattered clasts, in small clusters, or as thin discontinuous stringers 1–2 pebbles thick. The associated sand may be laminated or structureless and is indistinguishable from inner shelf sand. The facies results from a combination of offshore transport from the upper shoreface during storms and onshore transport of most of this material by the shoaling waves in the aftermath of a storm. Winnowed by the waves, the coarser material moves landward more slowly and some is trapped in burrows, swales, or other depressions on the seafloor. In the absence of pebbles, the upper shoreface facies may be the only recognizable shoreface component.

On transgressive coasts, *shoreface-attached ridges* extend obliquely into the sea. These ridges, composed of fine to coarse sand, are tens of km long, several km wide, and 5–15 m high. Their origin has been attributed to longshore migration of tidal inlets during transgression, leaving behind a ridge formed by one side of the tidal delta. (McBride and Moslow, 1991). Cores through shoreface-attached ridges show that they consist of an upward-coarsening accumulation of storm-event beds (Rine *et al.*, 1991). Some shoreface-attached ridges show evidence of both storm and tidal influences in their internal structures (Antia *et al.*, 1994).

The *beach foreshore* facies lies within an intertidal zone subject to the swash and backwash of the waves. Foreshore sands are typically very well-sorted and characterized by planar lamination. Foreshore deposits are generally 1–2 m thick, and if the grain size permits, show an upward-fining. Individual lamina may show inverse grading. Placers of heavy minerals define the upper part of some foreshore deposits. Small vertical burrows and the trace *Macaronichnus* typify the ichnologic signature of the foreshore.

Nonmarine coastal facies of the open coast include eolian dunes, characterized by large-scale landward dipping foresets

and backshore facies of wind/tidal flats. The character of the *backshore* facies depends on the specific setting and the amount of vegetative growth. Backshore sand is commonly fine and well sorted; layers of pebbles and coarser sand are introduced during floods, and layers of muddy and/or peaty sediment can develop under wetter conditions. Structures such as climbing adhesion ripples or vertebrate footprints document subaerial exposure. Roots are common, and substantial coals may directly overlie the foreshore facies in some ancient deposits.

Mudflats dominate some open coasts proximal to, or down-current from, the mouths of large mud-bearing streams. In settings such as the coast of Surinam, inshore fluid mud maintains its presence by frictionally reducing the energy of incoming waves. Episodically, mud deposition ceases, either during storms or because the mud moves along the coast in discrete waves (Rine and Ginsburg, 1985), and sandy beaches develop. A return to muddy deposition isolates the sandy sediment in shore-parallel ridges or *cheniers*. *Cheniers* on the coast of Surinam are about 2 m high and contain a combination of steeply and gently landward dipping cross-beds or, where fine-grained, gently landward and seaward-dipping cross-beds (Augustinius, 1989). *Cheniers* adjacent to the Mississippi River contain shell aggregates concentrated by storm waves. Mud in the associated flats may be laminated to structureless; mud flats covered by salt marshes will contain root or rhizome structures.

Sedimentary facies of inlet areas

Tidal inlets, fluid interfaces between bays and the open sea, are common on many contemporary open coasts. Inlets may range from simple channels a few meters deep and tens of meters wide to complexes of channels and shoals more than 10 km or more across wide at the mouths of large embayments. Individual channels in this setting may be tens of meters deep and hundreds of meters wide. Inlet sediment is mostly sand, and occurs in a setting where tidal flow is likely to be at its highest. As a consequence, inlet channels are typically floored by 2- and 3-dimensional dunes. Individual channels may be dominated by either ebb or flood tide. Lag deposits of shells and or pebbles (where the adjacent shoreface is gravelly) are generally present, and may contain species representative of both open coast and bay. Trough and tabular cross-bedding and abundant burrows characterizes the resulting deposit.

Small inlets tend to migrate laterally along the coast, particularly where wave-driven longshore sediment transport is significant. Larger inlets may be more stationary, but interior inlet channels may migrate rapidly. In Willapa Bay, Washington, for example, a primary inlet channel, 25 m deep and 600–700 m wide, has moved laterally more than a kilometer in the past 50 years. Inlet facies in such a setting are likely to consist of a lower part composed of cross-bedded sand produced in the primary channel overlain by the deposits of smaller tidal channels and wave- and tide-influenced shoals. Channel migration can produce clinofolds, the thickness of which depends on the depth of the channel. The lateral extent of inlet deposits depends on the degree of inlet migration. Extensive migration will generate laterally extensive inlet facies within a coastal succession.

Lobate bodies of sand, *flood tidal-deltas*, form sandy ramps on the bayward side of many inlets. Where the tidal inlet migrates, flood tidal deltas may compose laterally extensive

sand bodies along the seaward side of a lagoon enclosed by a barrier island. Initially these deltas form as a set of lobes building into the bay, covered by straight to sinuous 2-dimensional landward-facing dunes (Hine, 1975). As they mature, tidal flow is concentrated into channels, ultimately producing a ramp dissected by flood-dominated tidal channels. The resulting deposit is dominated by landward-directed trough and tabular cross-bedding and contains internal erosional surfaces capped by shell lags.

Ebb tidal deltas form on the seaward side of inlets, where they are subject to the influence of both waves and tides. Off large embayments, these deltas may be quite large, exceeding 10 km in width and extending 5 km or more into the adjacent sea. Off smaller inlets on a transgressive coast, the deltas may form the nucleus of shoreface-attached ridges. Flood- and ebb-dominated tidal channels cross the shoal constituting the delta: typically the ebb flow is concentrated in the deeper channels. Upward-fining storm beds with erosional bases are common, particularly in the shallower parts of an ebb tidal delta.

Preservation of coastal sedimentary facies and resulting facies successions

Thick accumulations of coastal facies typically reflect a record of fluctuating sea level superimposed on a setting of overall tectonic subsidence. The shoreline response to sea-level change depends on the rate of sedimentation. In general, the influx of sediment at the shoreline promotes progradation, whereby the additional sediment forces the shoreline to shift basin-ward. Most prograding open coasts today are characterized by a series of each ridges, each marking an earlier position of the shoreline. The resulting accumulation conforms to Walther's Law, which holds that a vertical arrangement of facies conforms to their lateral distribution at the time of deposition. Progradational successions show an upward-shallowing, produced as shallower water facies encroach over their deeper water counterparts (Figure C57). On most open coasts, the result typically generates an upward-coarsening interval. Figures C58–C62 show examples of progradational successions that reflect differing combinations of grain size and wave energy.

Although progradation is the most common circumstance of preservation of coastal sedimentary facies, not all facies are preserved. Those associated with features that stand in relief above other, more landward, features are likely to be destroyed as progradation progresses. Although breaker bars, for example, are common on many upper shorefaces, their potential for preservation is limited. During progradation, the seaward migration of the bar troughs that lie to landward will erase much, if not all, of the bar.

Where relative sea level falls during progradation a "forced regression" ensues (Figure C63). Wave erosion associated with the readjustment to a new, lower base level can create a "regressive surface of marine erosion". The amount of sediment removed by this erosion depends on the rate and degree of base level fall and prevailing wave energy. Commonly the surface marks an abrupt change from shelf to shoreface deposits.

Progradation may occur during relative sea-level rise, if the rate of sedimentation is sufficiently high. But commonly a rise in base level results in deposition within the feeding river

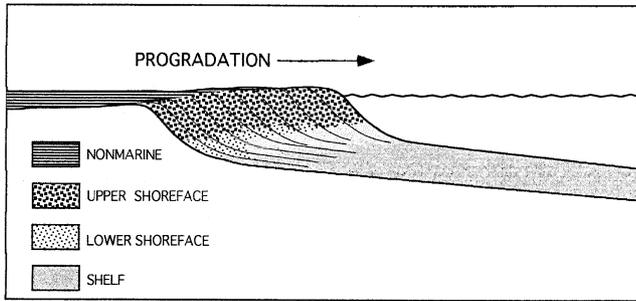

Figure C57 Characteristic mode of accumulation of shoreline deposits through progradation whereby shallow water facies build laterally over deeper water counterparts, generating an upward-shallowing succession or parasequence.

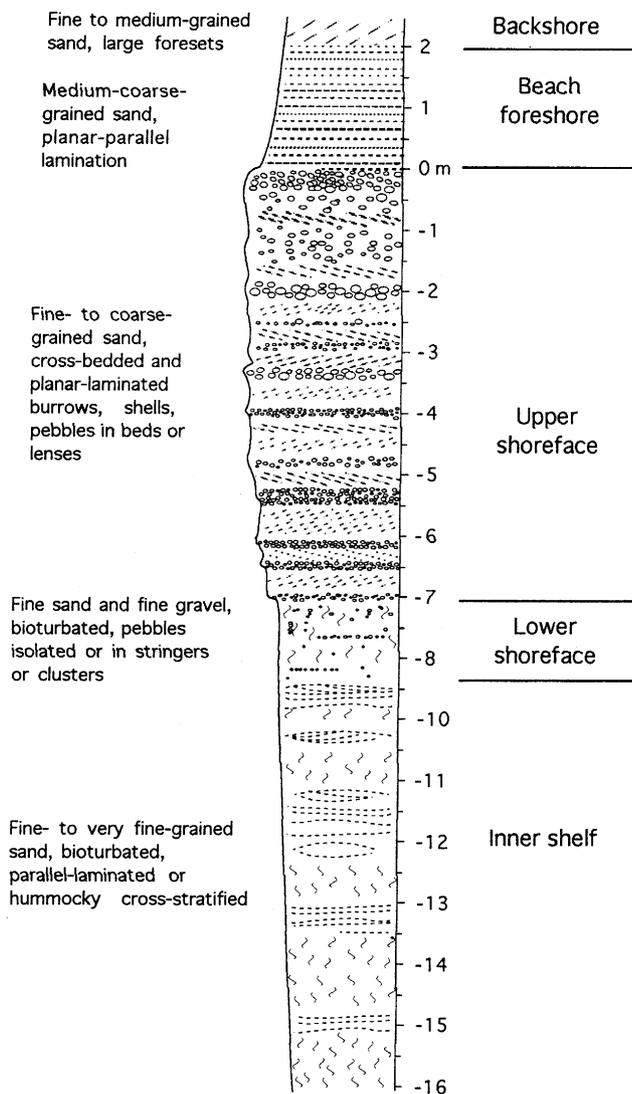

Figure C58 Shoreface succession on a prograding pebbly, high-energy coast (Pleistocene, Central California).

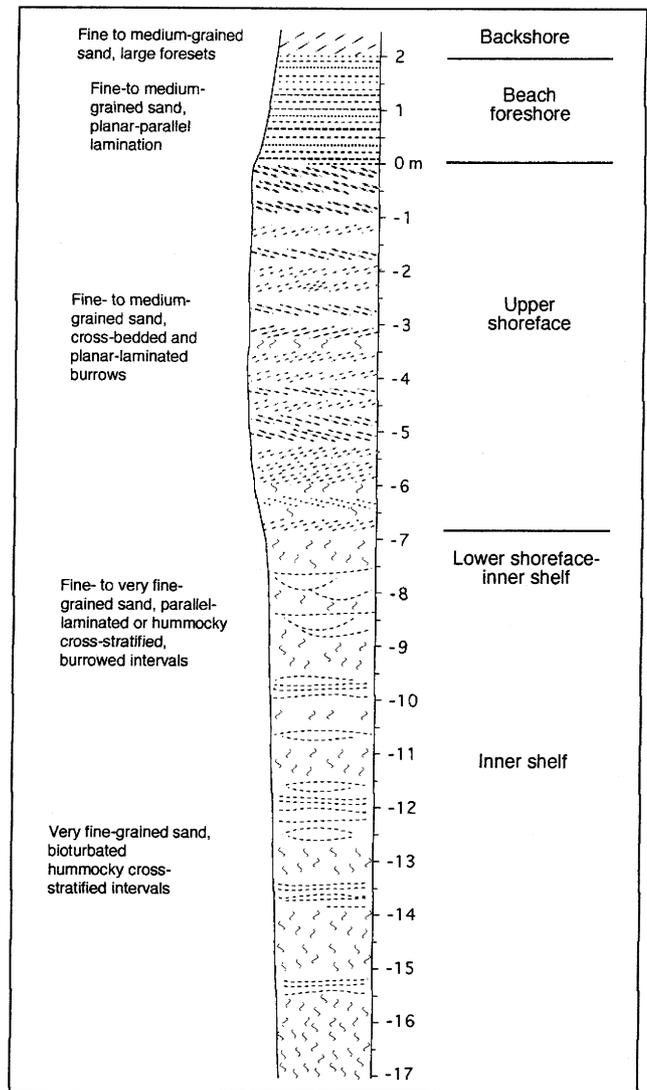

Figure C60 Typical shoreface succession on a prograding finer-grained, non-pebbly, unbarred, high-energy coast (hypothetical).

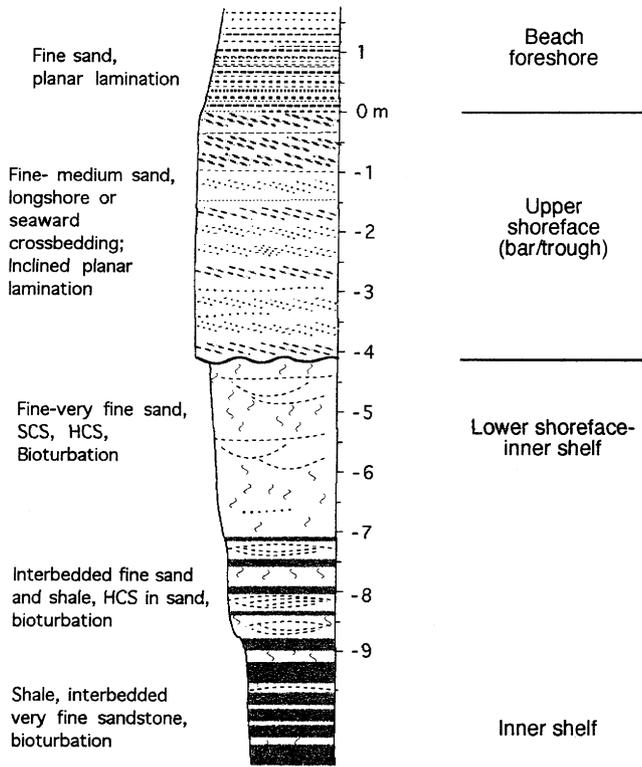

Figure C61 Shoreface succession on a prograding fine-grained, non-pebbly, moderate-low energy coast (Cretaceous, Book Cliffs, Utah).

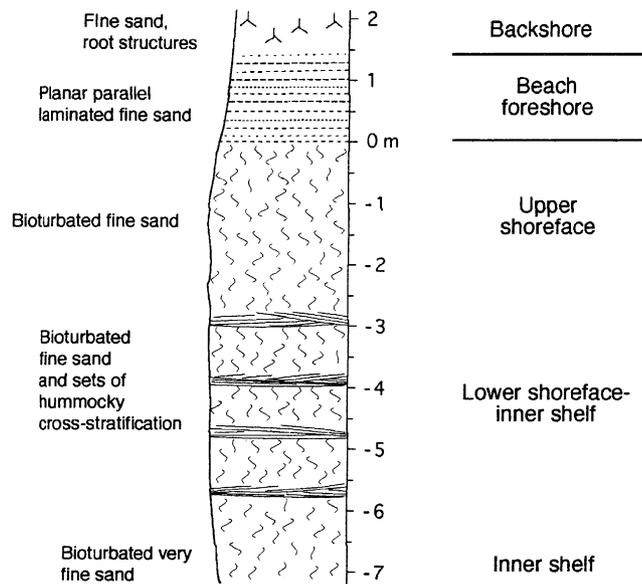

Figure C62 Shoreface succession on a prograding very fine-grained, low-energy coast (Eocene, West Texas).

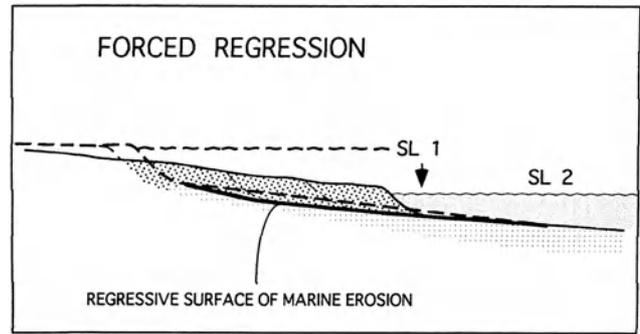

Figure C63 Progradation accompanied by a fall in sea level (forced regression) occurs over a regressive surface of marine erosion, cut as wave base is lowered.

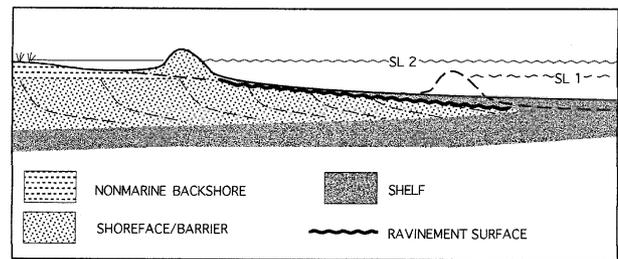

Figure C64 Transgressive erosion caused by the lateral translation of the shoreface (see Brunn, 1962). None of the transgressive coastal facies are preserved, and the transgression is recorded by an erosional (“ravinement”) surface overlain by deeper water (typically shelf) deposition.

systems. With less sediment contributed to the coast, marine transgression occurs, whereby the shoreline shifts landward. Where the sand supply is limited, landward transport by shoaling waves and coastal winds concentrates it in a shoreface-foredune ridge system. In most wave-dominated settings, enough sand exists that a small rise in relative sea level is met by an upbuilding of the shoreline to a topographically higher position. If the sediment input is sufficiently reduced, a basin develops behind the topographically high beach ridge and a barrier island is created. Most present-day coasts fronted by barrier islands are in a state of transgression.

Barrier islands formed during transgression have a limited potential for preservation. The landward translation of a shoreface erases the deposits that lie landward from its base, leaving an erosional (*ravinement*) surface overlain by shelf facies (Figure C64). Commonly this surface is the only preserved expression of a transgression.

Under conditions of rapid accommodation and sufficient sedimentation, however, lagoonal and inlet facies are preserved (Figure C65). These may occur in inverted succession whereby the landward-most facies (lagoonal marshes and back-bay muds) are overlain by sandier deposits associated with the approach of the transgressing barrier and capped by tidal inlet facies just below the ravinement surface (Figure C66). The thickness and organization of these

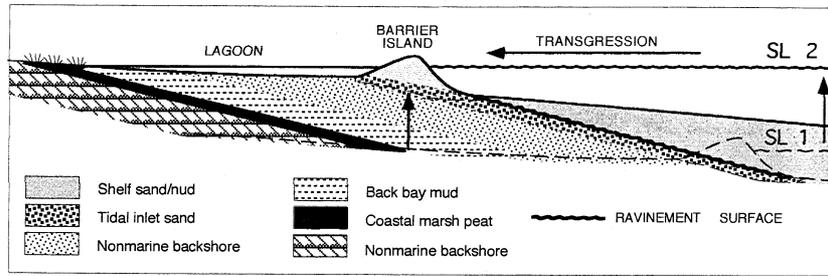

Figure C65 Transgressive succession produced in settings with rapid accommodation and adequate sedimentation. A lagoonal succession develops as the lagoonal facies are buried by the landward-migrating barrier. It is capped by a “ravinement” surface overlain by shelf facies.

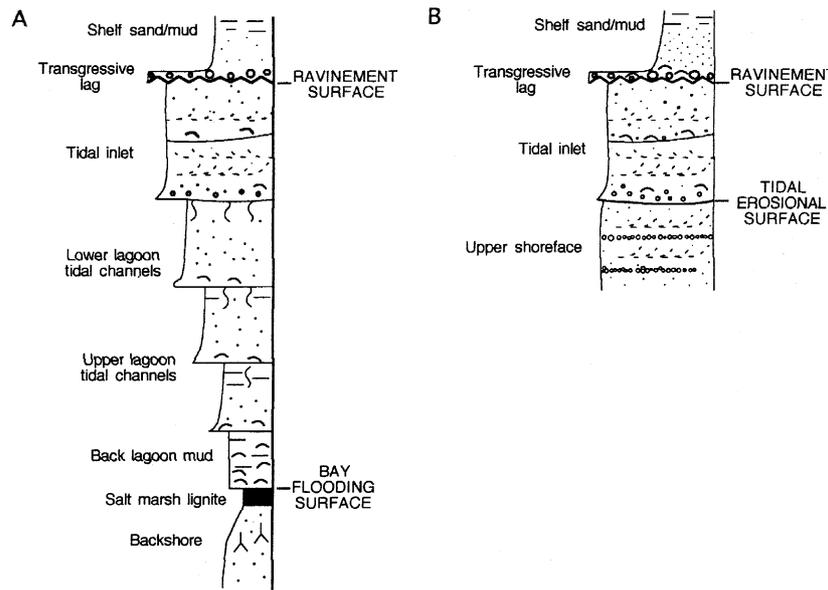

Figure C66 Vertical successions produced by preservation of transgressing lagoons. A. High rate of accommodation. B. Modest rate of accommodation.

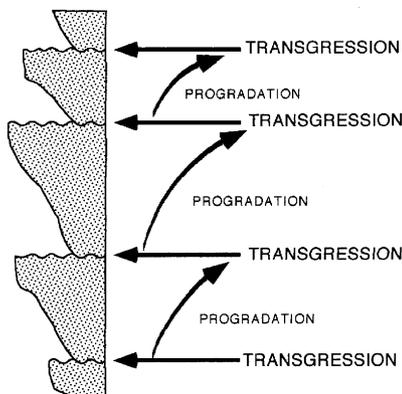

Figure C67 Typical pattern of stacked shoreline successions. Shallowing-upward progradational parasequences are separated by transgressive surfaces of erosion (ravinement surfaces). Falls in sea level prior to transgressions can produce erosional sequence boundaries and incised-valley fill deposits at the top of the parasequences.

transgressive lagoonal deposits differs depending on the balance between accommodation and sedimentation. Although most are but a few meters thick, some can exceed 20 m. Most display a basal “bay-flooding surface” and a capping ravinement surface, although vigorous tidal currents and low rates of accommodation may in some places lead to the erosion of the lower part of the succession (Figure C66).

Most successions of coastal deposits consist of stacked sets of progradational deposits separated by erosional (ravinement) surfaces (Figure C67). The degree of preservation of individual progradational intervals depends on the amount of accommodation provided during the interval between progradation and transgression (Figure C68).

H. Edward Clifton

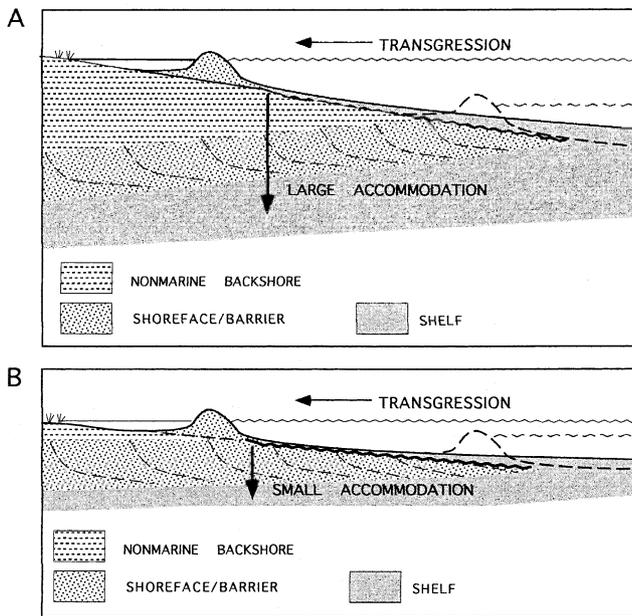

Figure C68 Preservation of progradational sequences as a function of accommodation in an area of alternating regression and transgression. Where the amount of accommodation is large (subsidence is rapid relative to the rate of sea-level change), complete parasequences, including nonmarine facies at their tops are preserved. Where the amount of accommodation is small, erosion associated with the marine transgression is likely to remove a significant part of the parasequence deposited as part of the previous regression. Such “beheaded” successions could prove difficult to interpret. The location relative to the point of maximum regression is also a factor. Near the turnaround to transgression, much of regressive shoreline deposit is likely to be lost.

COLLOIDAL PROPERTIES OF SEDIMENTS

Sediment is a mass of organic or inorganic solid fragmented material that comes from the weathering of rock and is carried by, suspended in, or dropped by air, water, or ice, and that forms layers on the earth's surface as gravel, sand, silts, or mud. In sediments, the clay-sized and the fine silt-sized particles are classified as colloids, which are made up of particles having dimensions of 10–10,000Å. The term “colloids” indicates microparticles or macromolecules that are

small enough to move primarily by Brownian motion, rather than by gravitational settling, and are large enough to provide a microscopic "environment" into or onto which molecules of interest can escape the aqueous solution. (The theoretical gravitational settling velocity of colloid particles is less than 0.01 cm s^{-1} .) Colloids found in soil and sediment are aggregates of highly disperse or loosely cohering organic, mineral and organo-mineral particles, which are capable of acting as sorbents and as ion exchangers.

Colloids are ubiquitous, they are found everywhere in concentrations of above 10^7 to 10^8 particles per liter of water. Colloidal dispersions bridge the gap between the true dissolved solutes and true bulk phases. The different varieties of colloidal materials found in natural system are: (i) soil colloids (aluminosilicates; humus and colloidal humic acids; iron hydrous oxides; polymeric coating of soil particles by humus, by hydrous Fe(III) oxides and hydroxy-Al(III) compounds); (ii) river-borne particles (weathering products and soil colloids, along with colloidal Fe(III) oxides stabilized by humic and fulvic acids; phytoplankton, biological debris, and colloidal humic acid); and (iii) sulfide and polysulfide colloids in anoxic sediments.

The fine size of the colloidal particles is responsible for their very high surface area/volume ratio. Chemical and physical reactions are promoted in colloidal suspension due to the large area of solid-liquid interface characteristic of systems containing many small particles. The high surface area of the colloids also means that there are many broken bonds, and both positively and negatively charged ions and molecules will be present on the solid surface. According to Gouy-Chapman model, the excess ions are non-uniformly distributed in the vicinity of the colloid surface, their concentration is the largest at the surface, and decreasing non-linearly till they reach bulk concentration (Stumm, 1992). The net charge on the solid colloidal particles will be the sum of all these surface charges together with the contributions from the adsorbed ions. The charge will depend on the chemical and crystallographic structure of the solid and on the pH of the solution surrounding the solid (Yariv and Cross, 1979). For each type of colloidal solid, there is a pH value at which the surface concentrations of H^+ and OH^- are equal and there is no net charge on the particle, called the point of zero charge (PZC); in the absence of ions other than H^+ and OH^- , the PZC will be at a pH referred to as the isoelectric point (IEP). At pH values above the IEP, the colloidal particles will carry a net negative charge, and the particles will have a net positive charge at pH values below the IEP.

Colloidal sediments can be grouped into two distinct classes as lyophilic (i.e., liquid loving) and lyophobic (liquid-hating). Lyophilic colloids display strong affinity between the dispersed particles and the liquid. The liquid is strongly adsorbed to the surface of the particle, so the interfacial tension between the particle and the liquid is very similar to that between the liquid molecules, leading to an intrinsically stable system. In case of lyophobic colloids, the liquid does not show much affinity for the particles. If attractive forces exist between the particles, there will be a strong tendency for them to stick together when they come in contact, rendering the system generally unstable, and resulting in flocculation (q.v.). A system containing colloidal particles is said to be stable if during the period of observation it is slow in changing its state of dispersion. Colloidal stability can be affected by the presence of electrolytes, adsorbates that affect the surface charge of the

colloids, polymers that affect particle interaction by forming bridges between them or sterically stabilizing them. Colloidal flocculation, induced by a rise in electrolyte concentration, is an important sedimentation process, and has significant implications regarding dispersion of potential pollutants that may be bound to the charged particle surface.

Interactions of different interfacial forces, such as electrostatic repulsion, van der Waals attraction, hydration phenomenon, hydrodynamic interactions on particle collision, and forces due to adsorbed substances dictate colloidal stability, and these factors can be categorized into two groups as (i) the frequency of collisions between particles and (ii) the probability of particles adhering if they collide. Particles in suspension collide with each other as a consequence of at least three mechanisms of particle transport: (1) particles move because of their thermal energy (Brownian motion); (2) if colloids are sufficiently large or the fluid shear rate is high, the relative motion from velocity gradients exceeds that caused by Brownian effects; (3) in settling, particles of different gravitational settling velocities may collide and agglomerate (Ryan and Elimelech, 1996).

Colloids are stable when they are electrically charged. The stability is usually explained by Derjaguin-Landau-Verwey-Overbeek (DLVO) theory. The attractive forces and repulsive forces between two particles are calculated as a function of particle-particle separation distance. The curves of potential energy versus particle-particle separation distance typically show an energy barrier that must be overcome by colliding particles to adhere. The primary attractive forces are dispersion forces, and the primary repulsive forces are long-range electrical forces and short-range Born repulsion. The double-layer potential energy is affected by the changes in solution chemistry, though the attractive van der Waals forces are independent of it. Short-range repulsive forces (up to a few nanometers separation distance) may also be affected by changes in solution chemistry (Ryan and Elimelech, 1996).

Figure C69 shows the plot of normalized potential energy as a function of separation distance between a colloid and collector. A typical total potential energy curve is characterized by a deep well at a very small separation distance, which is the primary minimum ($\phi_{\text{min}1}$), a repulsive energy barrier, which is the primary maximum (ϕ_{max}), and a shallow well at a larger separation distance ($\phi_{\text{min}2}$).

The attractive energy is primarily the result of London-van der Waals dispersion forces and is related to the polarizability of the particles and the distance of separation between the particles. For colloidal particles, the attractive energy declines with the separation according to

$$\phi^{\text{vdW}} = -A_H/d^n \quad (\text{Eq. 1})$$

where A_H is the Hamaker constant, which depends on the difference in polarizability between dispersed particles and the dispersing medium, d is the separation, and n is an exponent, the value of which is $1 < n < 3$, depending on the geometry of the system (flat-flat, flat-sphere, sphere-sphere, etc.). If a colloidal particle and the dispersing solvent are of similar polarizability, then the tendency for the particles to seek out one another and to separate from the solvent is small and there is little tendency for the particles to adhere. The electrical repulsion energy is due to the repulsion of like-charged surfaces. There are three components of surface charge

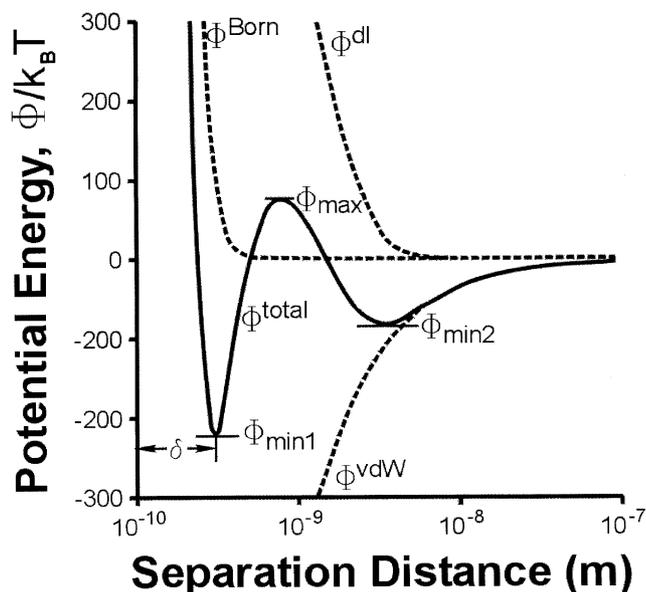

Figure C69 The resultant curve for the total potential energy, ϕ^{total} (solid curve), is the sum of the van der Waals potential energy, ϕ^{vdW} , the double layer potential energy, ϕ^{dl} , which is due to the repulsion between the particles of similar charge, and the Born potential energy, ϕ^{Born} , the short range repulsion energy. k_B is the Boltzmann's constant, and T is the absolute temperature.

resulting from specific chemical interactions or specific adsorption: (1) constant charge surfaces (e.g., clays); (2) constant potential surfaces (e.g., AgI); and (3) constant chemical affinity surfaces (e.g., oxides).

Another component of surface charge is counter charge that is held electrostatically to balance the specific-adsorption charge. The counter charge is usually treated through an electric double layer based on the Gouy–Chapman–Stern theory. According to this theory, the repulsive energy drops off exponentially with distance from the surface according to

$$\phi^{\text{dl}} \propto \exp(-\kappa d) \quad (\text{Eq. 2})$$

where κ is the reciprocal thickness of double layer, which is proportional to the square root of the ionic strength, I , for a $z:z$ electrolyte, $\kappa \propto I^{1/2}$.

Another repulsive interaction that has not been widely documented is steric repulsion. This repulsion occurs when particles that are coated with large polymers collide and the polymeric coatings overlap. Factors affecting the extent of the steric repulsion are the similarity of the coating to the solvent and to the particle, and the expansion or contraction of the polymer according to the properties of the solvent.

Finally, it can be said that colloids represent the most valuable soil fraction, as colloids can retain mineral nutrients (including trace elements) in the mobile state, and retain moisture and support formation of soil structure favorable to aeration. It is the colloidal component that dominates the leachable chemistry component of the sediments.

COLORS OF SEDIMENTARY ROCKS

The colors of sedimentary rocks can have complex origins and in cases are secondary. However, colors are commonly primary and reflect important aspects of depositional environments including redox conditions and rates of deposition of organic matter. These parameters in turn affect fauna and thus a strong correlation exists between color and biofacies patterns, including macrofaunal distributions and burrowing type and depth (Leszczynski, 1993), particularly in deposits of oxygen-stratified basins (Myrow and Landing, 1992). Color may be useful for the interpretation of variations in such factors as relative sea level, oceanic circulation, sedimentation rate and primary productivity.

Colors are generally controlled by accessory minerals and compounds of iron and organic carbon (see reviews by Pettijohn, 1975; Potter *et al.*, 1980; and Myrow, 1990). Compounds of other transition metals (e.g., Ti, Mn, Co, Cu, and Zn) also impart a pigment in some cases. For the most part the colors of sediment and sedimentary rock fall within two spectra: green-gray to red and olive-gray to black (Figure C70). The first color spectrum is controlled by the oxidation state of iron, specifically the $\text{Fe}^{+3}/\text{Fe}^{+2}$ ratio in various minerals, and not the total iron content (Tomlinson, 1916; McBride, 1974). In particular, the color is a function of the mole fraction representing the proportion of iron in the +2 state ($\text{Fe}^{+2}/\text{Fe}^{+2} + \text{Fe}^{+3}$) per gram of rock. In relatively unoxidized strata, green colors result from the presence of iron-bearing phyllosilicates such as chlorite, illite, and in cases, glauconite. Kaolinite and smectite provide for white to light neutral colors. Red coloration is due to the presence of hematite, whereas less common yellows and browns generally result from limonite and goethite, respectively. Red hematitic staining is generally an early diagenetic phenomenon resulting from: (1) dehydration reactions in which limonite stains on detrital particles are altered to hematite; (2) dissolution of iron silicates and precipitation of the released iron; and (3) direct oxidation of magnetite and ilmenite grains (Hubert and Reed, 1978). Very low levels of hematite can impart a deep red coloration to a rock. The conversion from red to green colors occurs by reduction of the iron, which is either carried away in solution or reprecipitated as iron-rich clay minerals such as chlorite (Thompson, 1970). The strength of red or green color is a function of grain size, with fine-grained rocks having higher iron content and thus more intense color. This

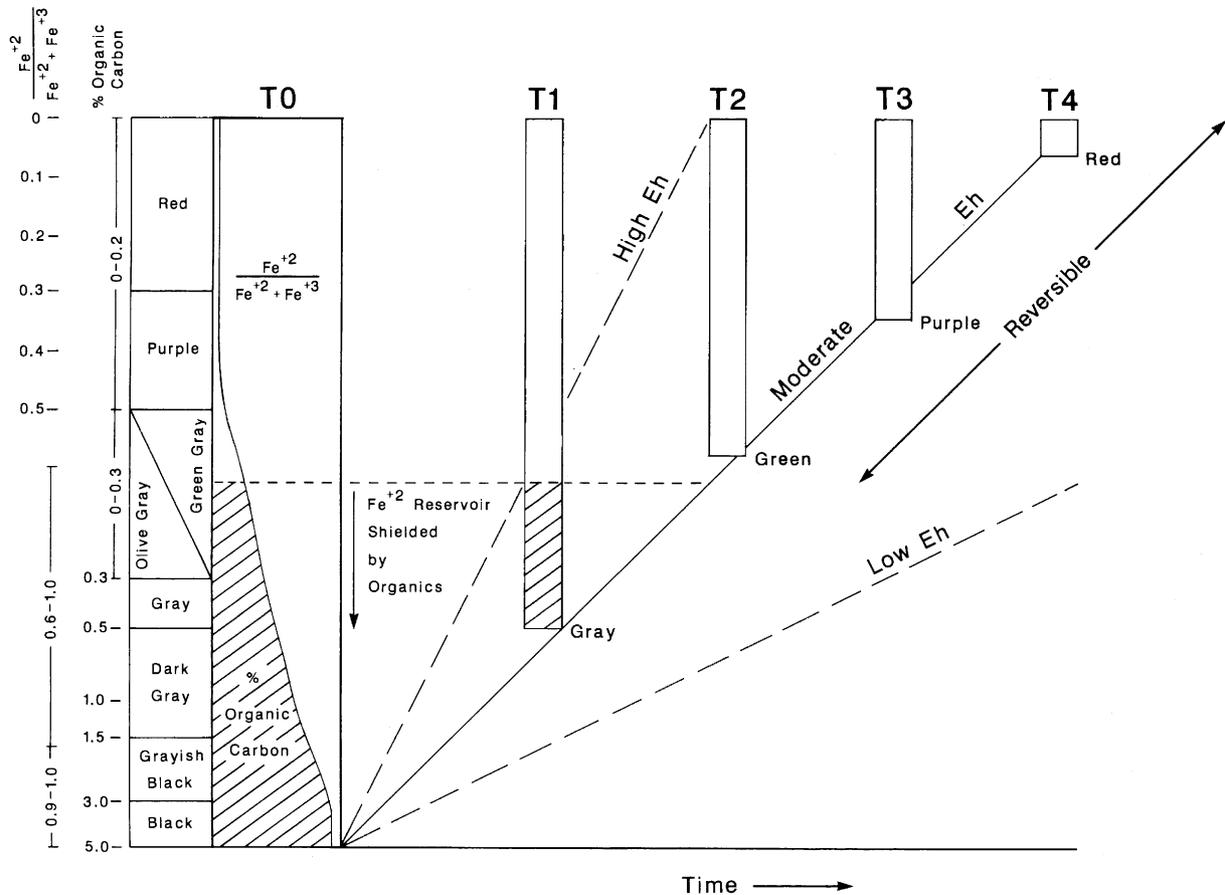

Figure C70 Graph relating color of rock, organic content and oxidation state of iron to time. "Time" refers to the length of time that pore fluids interact with sediment prior to lithification. Dark colors, olive-gray to black, are controlled by organic content. Green-gray to red colors, controlled by the oxidation state of iron, are reversible. The color history of sediment is dependent upon the Eh conditions. Three representative paths (high, moderate and low Eh) are shown for sediment with initially high organic content. Figure from Myrow (1990).

relationship is due to the presence of amorphous or poorly crystalline iron oxides attached to clays (McPherson, 1980). Changes in the oxidation state of iron, and hence the color, result from interactions with altering fluids at any time in the postdepositional history of a unit, and are thus controlled in part by permeability. Oxidation or reduction spots are due to incomplete diagenetic alteration of a layer.

The green-gray to black color spectrum in rocks is a function of total organic carbon (TOC), with darker colors corresponding to higher carbon content. This relationship is empirically confirmed in studies of modern sediment (e.g., Sheu and Presley, 1986). Main controls on organic carbon content include accumulation rate of organic matter, sediment accumulation rate, rate of decay of organics, and oxygen levels (Potter *et al.*, 1980). Diagenetic loss of carbon, which leads to lighter colors, is an irreversible process. The carbon reservoir acts to shield the iron-bearing minerals from oxidation until most of the carbon is oxidized, at which point the green to red color spectrum is found. Oxidative loss of carbon, and red coloration, occurs when bottom water and/or pore-fluids are highly oxygenated. Green colors result from deposition of sediment with low organic content and weakly

reducing to oxidizing conditions. Gray to black colors are associated with high TOC and dysaerobic to anaerobic bottom waters.

Gray colors also occur as a result of the presence of disseminated pyrite. During burial diagenesis metastable minerals such as mackinawite (FeS) and greigite (FeS_4) are transformed into submicron sized framboids of pyrite (Berner, 1971). Thermal maturity may also be an important factor in some rock. For instance, Lyons (1988) demonstrated that the black color of some limestone is due to carbonization of very small quantities of organic matter (<0.06 percent TOC). Darker colors may also be imparted by Mn oxides or Fe-Mn oxides such as pyrolusite. Shale with siderite is gray to bluish on fresh surfaces but altered to brown tones by weathering (Pettijohn, 1975).

COMPACTION (CONSOLIDATION) OF SEDIMENTS

Compaction may be defined as the process by which the sediment volume is reduced and the sediment density increased. Sediments change their physical properties after deposition due to the stress from the overburden (gravitational compaction) and as a result of biological or chemical reactions involving dissolution and precipitation of minerals. In some sediments compaction of amorphous materials like organic material (kerogen) and biogenic silica (Opal A) also play an important role. All natural processes modifying sediments after deposition are in geological literature referred to as diagenesis (*q.v.*) and this term also includes compaction processes. Soil engineers use the term compaction to describe densifications on the laboratory and in the field by vibrations of mechanical equipment to reduce the pore volume and consolidation for the expulsion and flow of water in soils. Geologist tends to use the term consolidation to describe a strengthening of the rocks, often by precipitation of cements (lithification).

Compaction of sediments and rocks (soil and rock mechanics) has been developed as a quantitative engineering subject since Terzaghi (1925) from the need to predict the

response of sediments due to changes in stress caused by different types of constructions. Laboratory tests determining the mechanical properties of different types of sediments (soils) have formed the basis for such quantitative prediction (Lambe and Whitman, 1979). Such tests measure the friction coefficients between grains and the mechanical strength of grains. Later Terzaghi's principles were applied to petroleum engineering and structural geology (Hubbert and Rubey, 1959). The terminology used in the engineering literature is rather different from that used by most geologists and that may cause confusion.

Sedimentologists and petroleum geologists have taken an increasing interest in sediment compaction. This is stimulated by the need to predict the porosity of reservoir rocks as a function of burial history in sedimentary basins (Wilson, 1994). The densities of the different lithologies are required to compute subsidence and backstripping in basin modeling (Giles, 1997; Sclater and Christie, 1980). There is also a need to understand the distribution of rock strength, seismic velocities and attributes in sedimentary basins.

Until recently, sediment compaction has been mostly treated as mechanical compaction as a function of effective stress. Compaction processes involving chemical dissolution and precipitation of grains (chemical compaction) are principally different since chemical processes then control the rate of compaction and the strength of the rocks.

It is much more difficult to study chemical compaction in the laboratory, particularly in silicate rocks (i.e., sandstones) due to the slow kinetic reaction rates involved in the compaction processes at low temperatures.

Clastic sediments are granular materials and the grains may be rock fragments, minerals or amorphous materials. The fluids between the grains may be water, oil or gasses or a mixture of these fluids.

Porosity (ϕ) is the volume fraction of the fluids in the sediment. The volume fraction of the solids then becomes $1-\phi$. The ratio between the volume of the pore space (void) filled with fluids and the solid grains and matrix (mainly clay minerals) is also referred to as the void ratio (v_r):

$$v_r = \phi / (1 - \phi) \quad (\text{Eq. 1})$$

Stresses in sedimentary basins

The effective stress of the overburden is an average of the stress transmitted through the solid phases through a network of load-bearing grains. The stress at grain contacts may be very high because of small contact areas and focused on some grains, which may then bend or fracture. With increasing compaction the rearrangements or breakage of grains will increase both the contact area and the number of grain contacts. Precipitation of cement in the grain surfaces increases the area of contact further so that the stress per contact is reduced enough to prevent further grain crushing or mechanical compaction all together.

The total overburden stress (σ_v) at a certain depth in sedimentary basins is equal to the weight of the overlying rock and fluids per unit area and is often referred to as the lithostatic stress.

At a certain depth (Z_s) below the seafloor in a sedimentary basin the total vertical stress is:

$$\sigma_v = Z_s \cdot \rho_b + Z_w \cdot \rho_w \quad (\text{Eq. 2})$$

Here the average bulk density of the sedimentary rocks over a depth range Z_w is ρ_b . The water depth above the seafloor is Z_w and the density of water (ρ_w).

The bulk density (ρ_b) of the rocks varies as a function of the porosity (ϕ), the density of the fluid (ρ_f) in the pore space, and the density of the solid phase (ρ_m), which are mainly minerals:

$$\rho_b = \rho_f \phi + \rho_m (1 - \phi) \quad (\text{Eq. 3})$$

Usually the density of the mineral matrix in sandstones and shales is close to 2.65–2.70 g/cm³ because this is the density of the most common minerals. If there are significant contents of denser minerals such as siderite or pyrite the bulk density will be higher. Smectite and mixed layer minerals have variable but generally lower densities. The fluid density also varies with the composition of water and petroleum. The weight per unit area of the rock column including fluids is called the lithostatic pressure (stress).

The total overburden stress (load) (σ_v) can be obtained by integrating the sediment density (ρ) over the entire overburden sequence (Z) or by estimating an average density (ρ_s). This stress is partly carried by the grain framework (solid phase) which is called the effective stress (σ_e) and by the stress (pressure) carried by the fluid phase which is pore pressure (P_p)

$$\sigma_v = \sigma_e + P_p \quad (\text{Eq. 4})$$

The effective stress is thus

$$\sigma_e = \sigma_v - P_p \quad (\text{Eq. 5})$$

This was first formulated by Terzaghi in 1925 and it formed the basis for modern soil and rock mechanics.

If the average sediment density (ρ_s) in the upper 3 km in a sedimentary basin is 2.0 g/cm³, the total stress at 3 km depth is 60 MPa. At hydrostatic conditions (no overpressure) the pore pressure (P_p) is equal to the average density of the pore fluid multiplied by the height (Z) of a water column in the sediments and any water column above (water depth). Saline water may have a density of 1.033 g/cm³ and the pore pressure at 3 km depth is then 31 MPa and the effective stress (σ_e) is then 29 MPa at 3 km depth. For very fine-grained sediments and rocks with low porosity and poorly connected pores, the fluid phase will carry a smaller fraction of the overburden load following poro-elastic theory. A constant α (Biot constant) was therefore introduced in the Terzaghi's law:

$$\sigma_e = \sigma - \alpha P_p \quad (\text{Eq. 6})$$

For porous and compressible sediments α may be taken to be 1, but for stiff sedimentary rocks α may have significantly lower values meaning that more of the total load is carried by the solid phase.

Geomechanical properties

The reduction in porosity with burial depth may be described as an exponential function following Athy (1930):

$$\phi = \phi_0 e^{-cZ} \quad (\text{Eq. 7})$$

Here the porosity (ϕ) is an exponential function of an initial porosity ϕ_0 , a compressibility parameter c and the burial depth

(Z). This may be a useful approximate expression for compaction trends in sedimentary basins and it is useful in mathematical modeling. However there is nothing in the mechanical and chemical compaction processes that should cause the porosity to be a negative exponential function of depth or the effective stress. Sedimentary basins consist of sedimentary layers with different compressibility, and the compaction curves showing observed porosity loss with depth may be very complex.

In the laboratory we can measure the induced deformation (strain) in a sample of sediment or rock for a given effective stress and construct stress–strain curves. Experimental data show degree of time dependent compaction (creep) at constant stress. In sedimentary basins the rates of increase in effective stress due to loading are very slow compared to the experimental loading rates in the laboratory and it is somewhat uncertain how significant mechanical creep is in a sedimentary basin.

If one assumes that the grain structure may be considered linearly elastic and isotropic for very small deformations, one may define the following deformational characteristics: Young's modulus (E) is the ratio between increase in normal effective stress ($\Delta\sigma$) and the resulting strain ($\Delta\epsilon_z$) in the stress direction (z), when there is no change in the orthogonal normal stresses.

$$E = \Delta\sigma_z / \Delta\epsilon_z \quad (\text{Eq. 8})$$

The bulk modulus (K) is the ratio between the increase in equal all-round stress ($\Delta\sigma$) and the resulting volumetric compression, $\Delta\epsilon_{vol} = \Delta V/V$:

$$K = \Delta\sigma / \Delta\epsilon_{vol} \quad (\text{Eq. 9})$$

The bulk compressibility (c) is the inverse of the bulk modulus K and is a parameter describing the rate of compaction as a function of stress. In sedimentary basins with only minor tectonic stress, the vertical stress (σ_v) is normally the principle stress as in uniaxial compression tests. The compressibility of a sedimentary layer may be expressed as the shortening (ΔL) over a bed thickness L and the strain (ϵ) is then ($\Delta L/L$).

The ratio between the lateral expansion (lateral strain ϵ_l) and vertical shortening (axial strain ϵ_a) is expressed as the Poissons ratio (ν):

$$\nu = (\epsilon_l / \epsilon_a) \quad (\text{Eq. 10})$$

If the lateral expansion in both directions is equal to half the shortening, there is no change in volume. This corresponds to $\nu = 0.5$.

For uniaxial compaction (one dimensional compaction) which may be assumed for wide sedimentary basins, the lateral strain is zero and a lateral effective stress will be built up. For linearly elastic and isotropic grain structure, the lateral effective stress increase is:

$$\Delta\sigma_{he} = \Delta\sigma_{ve} \cdot \nu / (1 - \nu)$$

The compaction processes determine rock properties such as rock strength and the mechanical responses to changes in stress during drilling and production of petroleum.

Compaction processes in sedimentary rocks also determine well log responses and the velocity of seismic signals and their attributes.

Types of compaction

Modeling of sediment compaction requires that we understand the processes involved. A clear distinction must be made between purely mechanical compaction and chemical compaction:

- (1) Mechanical compaction
 - (a) Rearrangement (sliding and reorientation) of grains.
 - (b) Bending and ductile deformation of grains.
 - (c) Breakage of grains (grain crushing).
- (2) Chemical compaction
 - (a) Dissolution at contacts between grains or along stylolites (pressure solution) and a corresponding precipitation on minerals (cement) in the pore space.
 - (b) Dissolution of thermodynamically unstable grains that are load-bearing.

Mechanical compaction

The vertical stress is normally the maximum stress (major principle stress) in sedimentary basins that are not subjected to strong tectonic compression, extension or uplift. During progressive burial at hydrostatic pore pressures (drained conditions), the sedimentary rocks always experience increasing effective stress, and such sediments are referred to as normally consolidated. Sediments that previously have experienced higher effective stresses than at present are referred to as over-consolidated.

The term under-consolidation is sometimes used to characterize poorly compacted sediments, particularly mud with high pore pressure. This term should however be avoided since the degree of consolidation always refers to the maximum effective stress sediments have experienced, and they can therefore not be under-consolidated. The term under-compaction may also cause confusion.

The degree of compaction (porosity loss) varies greatly with the lithology at the same effective stress (Figure C71). During uplift and erosion or a build up of over-pressure (higher than hydrostatic pore pressures) the effective stress may be reduced so that the sediments become over-consolidated and brittle. Sediments are likely to respond in a ductile manner also in

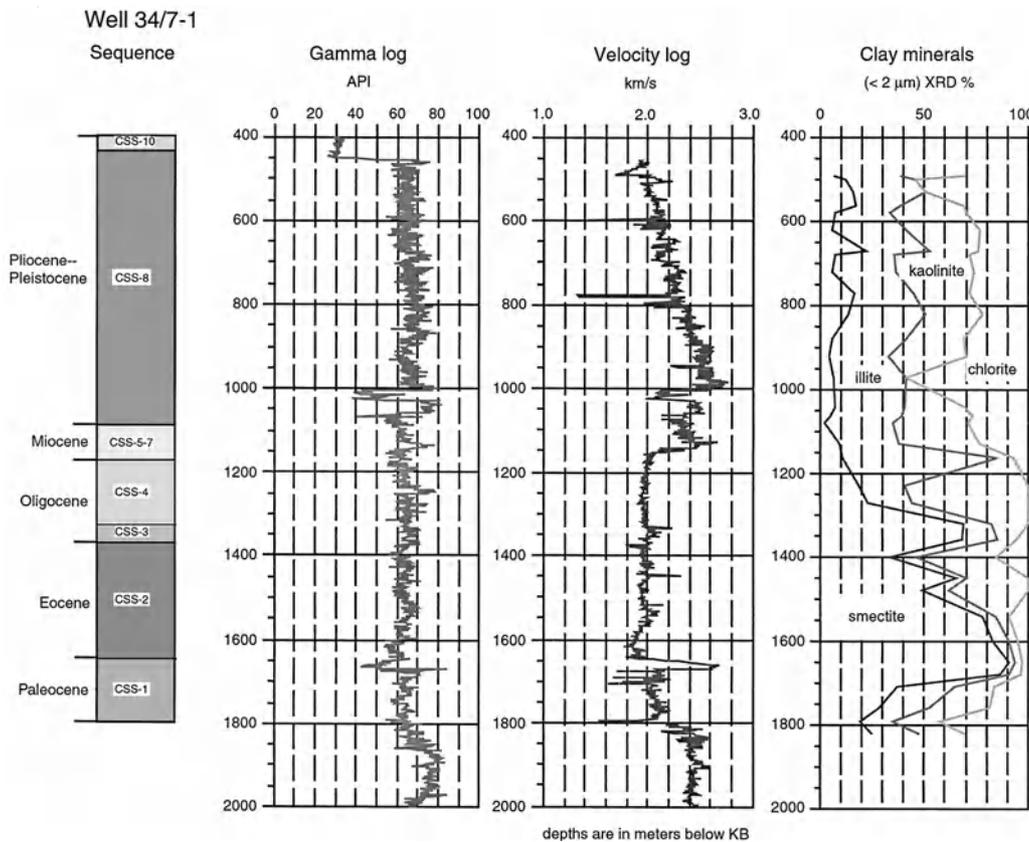

Figure C71 The velocity from well logs (or seismic data) may be a good indicator of the degree of compaction. The velocity in a well penetrating tertiary sediments from the Northern North Sea show that Pliocene and Pleistocene muds show a normal compaction trend (higher velocities) with depth. Smectite rich Eocene and Oligocene muds have very much lower velocities and is less compacted despite greater burial depth. This may be partly due to overpressure but is mostly due to the poor compressibility of smectitic clays. Modified from Thyberg *et al.* (2000).

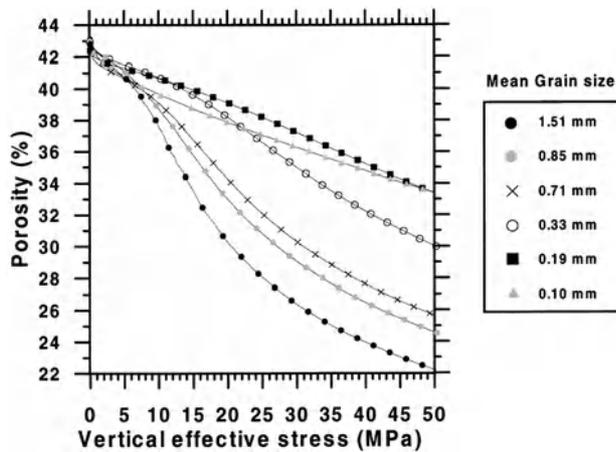

Figure C72 Experimental uniaxial compaction of well sorted quartz rich and showing that coarse sands have a much higher porosity loss than fine grained sand. From Chuhan *et al.* (2002).

response to tectonic stress if the strain rates are very low so that the rocks can deform by chemical compaction (Bjørlykke and Høeg, 1997).

Experimental compaction of sand

Compaction of sand depends on the composition and primary sorting of grains. Sands with lithic fragments show more compaction at low to moderate stresses than well-sorted sand (Pittman and Larese, 1991).

Experimental uniaxial compression at high stress (50 MPa) on well-sorted mono-quartz rich sands shows that stress–strain curves are non-linear over the entire stress range. Initial compaction is due to grain sliding rotation and re-orientation. A stable grain framework is then established and further compaction requires grain breakage. Recent experimental work (Chuhan *et al.*, 2002) show that coarse, well-sorted sands have a higher porosity loss than fine-grained sand subjected to the same stress (Figure C72). Coarse sands also show evidence of more frequent grain fracturing than fine sands in sandstone reservoirs, probably because the stress per contact increases with increasing grain size (Figure C73). Fracturing reduces the grain size and gradually distributes the load onto more grain contacts. At higher stresses porosity/stress curves for different sands approach similar slopes indicating similar compressibility. The porosity at higher stresses is therefore mostly a result of the differences in compaction up to 20–25 MPa or 2.0–2.5 km burial depth.

The grain crushing can thus be considered a part of an adjusting (self-organizing) process where the sediment is adapting itself to higher stress. Grain crushing is particularly intense in sandstones where chlorite or micro-quartz coatings retard the precipitation of quartz overgrowth (Fisher *et al.*, 1999). This is also true in cold basins (<20°C/km) where the onset of quartz cementation may start at 5–6 km. Fracturing of grains may destroy grain coatings, thus opening fresh surfaces for quartz cementation (Figure C73(B)).

Compaction of mudstones

Mudstones compact mechanically as function of the effective stress and the compressibility of the mud (Aplin *et al.*, 1999).

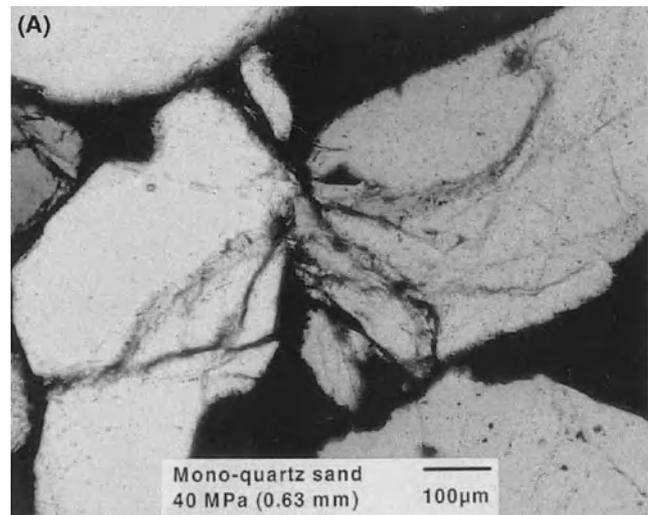

Figure C73 Fracturing of sand grains: (A) Experimental fracturing of sand at 40 MPa stress. This is equivalent to the effective stress below 3.5–4 km of overburden; (B) Natural fracturing of sand grains in Jurassic reservoir rocks at 4,800 m depth, Lavrans Field, Haltenbanken, offshore Norway. The fractures were produced by mechanical compaction prior to quartz cementation, and subsequently healed by authigenic quartz, which is darker on the cathodoluminescence microphotograph. The present burial depth (4,800 m) is probably the maximum, and the reservoir pressure is hydrostatic. Chlorite coating the grains delayed quartz cementation until fractures produced a suitable substratum.

Laboratory tests show that pure clay minerals may retain a relatively high porosity even at high stresses. Smectite which is the most fine grained clay retains porosities of about 45 percent at stresses equivalent to about 5 km of overburden (Rieke and Chillingarian, 1974) while illite and kaolinite which form larger crystals compact more readily.

Smectitic clays consist of very small particles, down to 10 Å thick, and have very large specific surface areas (Nadeau and Bain, 1986). This implies that the stress is distributed on a very large number of grain contacts so that the stress per grain and unit area is very low. This may explain the low compressibility of smectitic shales down to 2–3 km burial depth (Bjørlykke,

1998). Some of the water constituting the high porosity is actually bound water due to the large surface area of smectitic clays.

Fine-grained clay and mudstones tend to compact slowly when loaded in sedimentary basins as well as when loaded by constructions. The rate of compaction is a function of the gradual increase in effective stress as the pore fluid escapes with a corresponding reduction in pore pressure.

The composition of the pore water has very significant effects on the rate of compaction in fine-grained mudstones. The cation concentration (salinity) in the pore water plays an important role because the cations adsorbed on the mineral surfaces. Marine clays have a "house of card structure" from the flocculation process, and may become unstable (quick) and collapse if the saline pore water has been diluted by meteoric ground water (Rosenquist, 1958). Such clays can gain strength and stiffness by adding salt (NaCl or KCl). The compressibility of mud is thus a complex function of mineralogy, grain size and pore water composition.

Chemical compaction

Compaction processes involving dissolution and precipitation of minerals or other solids may be referred to as chemical compaction. We then have to consider the chemical processes involved and the thermodynamics and kinetics of the critical reactions. Chemical compaction is therefore different in principal from mechanical compaction. We distinguish between two types of dissolution:

- (a) Dissolution of grain or matrix because minerals or associations of minerals are chemically unstable, for example, aragonite, gypsum, and smectite. Kaolinite becomes unstable in the presence of K-feldspar.

Dissolution of amorphous materials like Opal A may cause compaction when replaced by Opal CT and quartz. Transformation of solids like kerogen into fluids (petroleum) changes the fluid/solid ratio (void ratio). This type of dissolution will only result in compaction if the dissolving grains are load-bearing. Dissolution of pore-filling kaolinite and smectite and precipitation of illite in sandstones (>120–140°C) will normally not cause compaction in sandstones. There will however be a porosity increase corresponding to the dehydration involved in mineral reactions. In mudstones, however, kaolinite crystals may be a load-bearing part of the grain framework and therefore cause a closer packing of grains as they dissolve.

- (b) Dissolution at grain contacts and precipitation of the same mineral in the pore space (pressure solution).

For reactions with very low kinetic reaction rates at low temperature like in most silicate reactions, temperature rather than stress at the grain contacts may be rate limiting for the reactions and thereby for the rate of compaction.

Chemical compaction of sandstones

The stress at the contact between sand grains is very high prior to precipitation of mineral cement because of the small contact area. This causes increased solubility of minerals like quartz, and there is thus a thermodynamic drive for dissolving at grain contact and precipitation on mineral surfaces of quartz that

are not under stress (Renard *et al.*, 2000). The increase in solubility has been estimated to be 1–3 percent for an increase in effective stress of 10 MPa (Jahren and Ramm, 2000). Due to very high activation energies precipitation of quartz is however very slow and at normal pH values (5–6) quartz does not precipitate in sedimentary basins at temperatures below 70–80°C (Bjørlykke and Egeberg, 1993).

Chemical compaction of quartz sandstones consists of four steps:

- (1) Dissolution of quartz at grain contacts or along stylolites;
- (2) Transport of silica in solution along a thin water film at the contact;
- (3) Diffusion of silica in the pore water;
- (4) Precipitation of quartz on grain surfaces.

In the case of highly soluble minerals with a low kinetic activation energy like halite steps 1–3 may be rate limiting (Renard *et al.*, 2001) and the system is then dissolution- or transport-controlled. In the case of dissolution at contacts between quartz grains the transport of silica along thin water film is very complex and is not a clear function of the stress (Renard *et al.*, 2001) and the rate of pressure solution can then be ignored. The rate of quartz cementation should also be a function of the degree of supersaturation with respect to quartz in the pore water, and therefore influenced by dissolution and transport of silica. There is considerable evidence that the precipitation of cement is rate limiting (Oelkers *et al.*, 1996) for short diffusion distances (a few cm). The kinetics of the precipitation process will therefore be controlled by temperature. The rate of quartz cementation at constant temperature is then a function of the surface area available for quartz cementation (Walderhaug, 1996; Bjørkum and Nadeau, 1998). Based on these assumptions, compaction and porosity loss of sandstones can be modeled as a function of subsidence rates, geothermal gradients, and grain textures determining the surface area available for quartz cementation. As a result of the larger surface area, finegrained sandstones will compact faster than coarse grained sandstones under the same temperature condition. This is in contrast to mechanical compaction where well-sorted coarse grained sand is most compressible. Compaction of sand at grain contact or along stylolites requires some stress even if the magnitude of stress is not rate limiting. Petrographic observations suggest that pressure solution of quartz does not require very high stress and that dissolution preferentially occurs along contacts between mica and quartz (Bjørkum, 1996).

Surface controlled quartz cementation occurs as a function of temperature and time and sandstones compact even when there is no burial or temperature increase (Figure C74) (Walderhaug *et al.*, 2001).

Relationships between compaction and porosity loss

During mechanical compaction the volume of the solid phase remains practically constant and the change in rock volume (shortening) is therefore a direct function of the porosity (fluid) loss. Chemical compaction implies that the volume of the solid phase may change due to dehydration of minerals and other mineral reaction. Generation of oil and gas from solid load-bearing kerogen is another phase change that has consequences for compaction because it causes changes in the fluid/solid ratio (void ratio) due to temperature rather than stress.

Changes in the volume of solids in a volume of rock may be due to net export (leaching) or import (precipitation) of solids by diffusion or fluid flow (advection). If all the pore space between grains is filled by mineral cement where the solids constituents are imported from outside, the porosity may be reduced to zero with little or no compaction. This can occur by diffusion on a local scale and is typical of concretion, which

can form at shallow depths and provide an indication of porosity at shallow burial. Dissolution of chemically unstable grains may increase the porosity when there is a net transport of solids from the rock volume. This may be the case when feldspar and carbonate minerals are dissolved during meteoric water flushing.

Flow of compaction-driven pore water normally has fluxes, which are very low and insufficient to transport and precipitate large volumes of cement. When we consider larger volumes of rocks (e.g., $>1,000\text{ m}^3$), the import and export of solids in solution can be ignored except in very special settings.

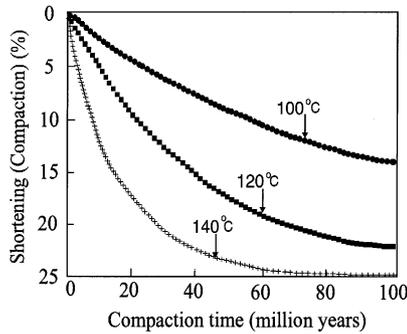

Figure C74 Modeling of compaction as a function of temperature and time even if there is no further subsidence. The rate of quartz cementation and thereby also the rate of compaction is a function of the activation energy E (J mol^{-1}) and the surface area A ($\text{mol cm}^{-2} \text{s}^{-1}$) available for quartz cementation. From Walderhaug *et al.* (2001).

Compaction of carbonate sand

Normal marine carbonate sediments consist of grains composed of fossils fragments, ooids, pellets or lithic fragments which may primarily be composed of aragonite, Mg-calcite or calcite. In terms of mechanical compaction they are in principal like siliceous sand and mud. Carbonate grains are mechanically weaker than quartz grains, but the difference as measured by experimental compaction of carbonate sand is not very great. Chemical compaction of carbonate sediments is however very different from that of siliceous sediments because of the faster reaction kinetics also at low temperatures. Chemical compaction may therefore start at shallow depths (low temperatures) shortly after deposition.

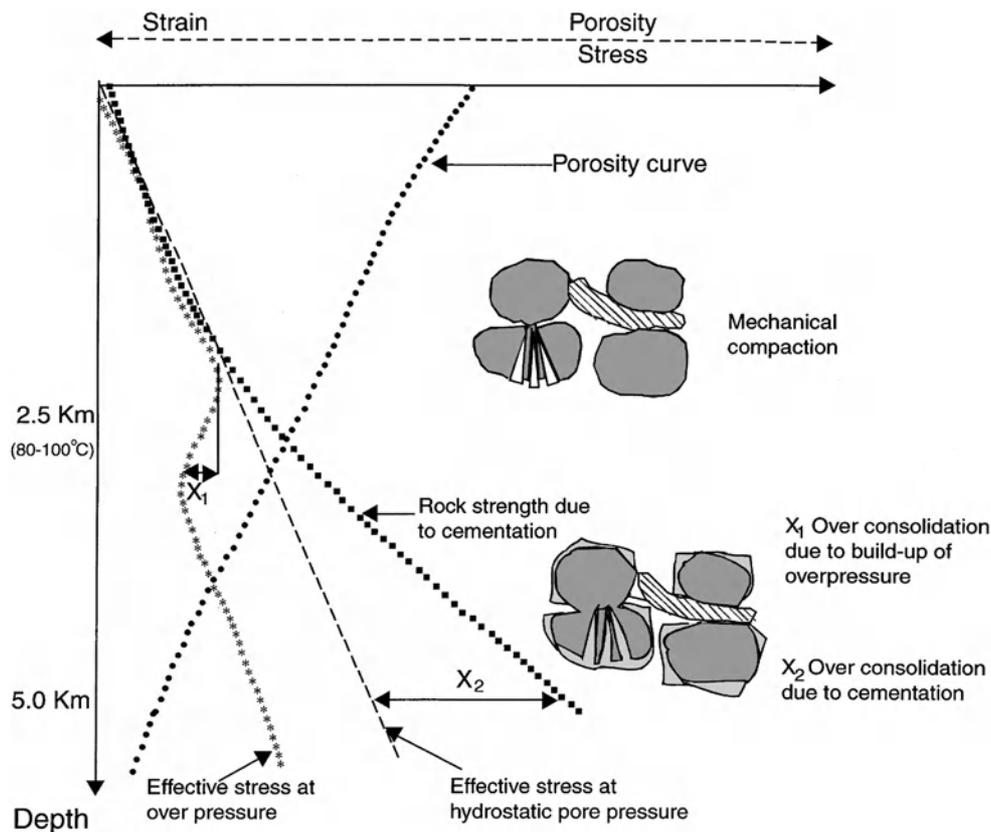

Figure C75 Schematic illustration of the effects of mechanical and chemical compaction. During progressive burial sediments may become over-consolidated by a build up of over-pressure (X_1), and by cementation (X_2). Further compaction then requires a stress exceeding the over-consolidation stress due to mechanical compaction, or the “pseudo over-consolidation” stress due to cementation.

Chemical compaction in carbonate sediments includes two different processes:

- (1) Dissolution of thermodynamically unstable mineral. Dissolution of load-bearing grains that is, of aragonite may be the cause compaction at shallow depth (low stresses). Dissolution of aragonite may be accompanied by precipitation of early calcite cement, which will stabilize grain structure and thus preserve porosity during burial.
- (2) Pressure solution. The driving force here is the increased solubility of minerals like calcite due to stress at grain contacts, and the temperature plays a minor role. The rate of precipitation may also depend on grains surface properties. Large calcite crystals, for example, from crinoids, may provide very suitable sites (low solubilities) for precipitation, while very small crystals and organic coatings may retard precipitation of cement, thus influencing the rate of compaction.

Chemical compaction and rock strength

Sediments become over-consolidated when the effective stress is reduced by uplift and erosion or overpressure and can then be loaded up to the previous maximum stress before any significant compaction occurs (Figure C75). Precipitation of cement in the pores between grains causes an increase in the strength of the grain framework and produces a pseudo over-consolidation effect, that is not due to high mechanical stresses. This “over-consolidation” may allow a rather high increase in overburden stress without any significant mechanical compaction. In the case of sandstones, quartz cement will normally become significant at 2.5 km to 3 km depth (80–100°C). Only 2–3 percent quartz cement may be enough to strengthen the grain framework and virtually stop further mechanical compaction. Fractures in quartz grains formed by mechanical compaction usually do not penetrate the quartz overgrowths, indicating that mechanical compaction stops after significant quartz cementation (Figure C75). Well-cemented sandstones have a high rock strength. Consequently, reducing fluid pressure during production of water or petroleum will normally not cause mechanical compaction and surface subsidence.

Summary

Mechanical compaction tests of sediments form the basis for predicting subsidence (settlement) due to the loading of constructions like buildings, pipelines or oil platforms. Compaction tests at high stresses can also simulate mechanical compaction in the upper 2–3 km (at temperatures <80–120°C) in clastic sedimentary basins, while chemical compaction is dominant in the deeper and hotter parts. In carbonate sediments compaction is more a function of stress and is less dependent on temperature.

Modeling of chemical compaction may now provide a basis for quantitative prediction of porosity in deep reservoir rocks. Compaction processes also control the rock mechanical and petrophysical properties, seismic velocities and attributes but this is still poorly understood.

CONVOLUTE LAMINATION

A term introduced by Kuenen (1953) for irregularly wavy laminae confined within a single sediment layer. The deformation dies out both downward, and upward, and may be confined to a part of a bed: it does not affect the geometry of the lower or upper boundaries of the bed. It is commonly found in turbidites, but is also present in other facies (Figure C76). The convolutions appear to develop gradually above some level within the bed, frequently distorting otherwise plane or ripple cross-lamination, and may show one or more surfaces of erosional truncation before dying out upward, generally at or just below the top of the bed. Thus they are generally interpreted as having developed during or

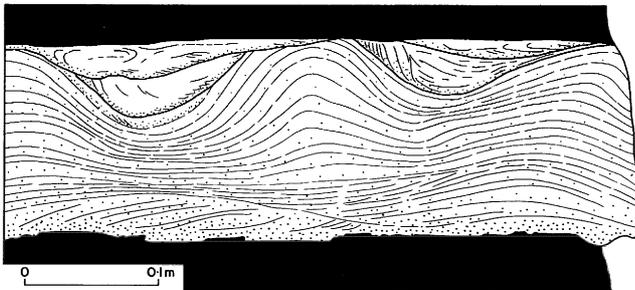

Figure C76 Syndepositional convolute lamination. Redrawn by Allen (1982, p.349, his Figure 9.4) from observations made on the Pliocene turbidites of the Ventura Basin, California. See Allen's book for original source.

immediately after deposition. Good figures are provided by Allen (1982) and Ricci Lucchi (1995).

The actual structure was described earlier by several authors using several different names (see Potter and Pettijohn, 1963, p. 152; Allen, 1982, p. 349), and its abundance was noted particularly by Rich (1950) who thought the structure had been formed postdepositionally by intra-stratal sliding, and had therefore developed on submarine slopes. Bouma (1962) thought that the structure developed in, or as a replacement of, the rippled (C) division of his ideal turbidite "sequence," but it is now clear that it may affect either the plane laminated (B) or rippled (C) divisions. The structure has much in common with Pillow Structure (*q.v.*), which has also been misinterpreted as a slope indicator.

Most convolute lamination is found in fine grained sand or coarse silts, and has been reported (rarely) from limestones as well as from siliciclastics. Allen (1982) distinguished three types: postdepositional, syndepositional, and metadepositional, depending on the geometry (the metadepositional variety shows erosional truncation at the top of the bed). The mechanism of formation is deposition that is rapid enough to produce pore pressure exceeding hydrostatic, and consequent loss of strength (partial liquefaction) of the sediment either during or immediately following deposition. Gravitational instability then produces "diapir-like" structures, and shear by the depositing flow commonly results in a predominant orientation and direction of overturning of the (generally very irregular) folds. Thus, some convolute lamination can be used as a paleocurrent indicator.

CORING METHODS, CORES

Cores are a very important source for the study of sediments. The oil and gas industry prefers to eliminate or strongly reduce coring by collecting a suite of well logs and thereby reducing well costs. Exploration and production people nevertheless need some cores for grain size, grain shape and surface

characteristics, mineralogy and diagenesis, and for the calibration of seismic and well log data. Most sedimentary geologists, working at universities, governments and the mining industry prefer to deal with cores. Because of the variety in interests and the many types and hardnesses of sediment, an extensive array of coring methods has been developed. They range from simple hand-operated samplers on land and shallow water, to large and expensive drilling operations.

The specific need and the available budget dictate the size and type of a selected coring device. It is also possible to categorize coring equipment by the desired length and diameter of needed core, the hardness of the sediment, and if the coring occurs onshore or offshore. The small hand-operated tools have the advantage that they are light and can be transported everywhere. The large variety of coring devices fills more than a book and therefore only a few major types will be discussed. Typically a core is a long, cylindrical object. Nevertheless the term "core" refers also to other shapes, such as box core, box sample, square long box core, and some others.

Sampling unconsolidated sediments on land or in wading depth is easy and inexpensive as long as a short sample is sufficient. Metal pipes, plastic or PVC tubes, or even metal cans with a hole in the bottom to let air or water out, have provided great results. For work off a small boat one can use metal, plastic or PVC tubes with extension rods (Bouma, 1969; Figures C77-A, C78-A). In most cases a core catcher is required. A second pair of hands facilitates the operation and prevents hitting the boat several times, which often results in core loss.

Small boxes, such as the Senckenberg box (Reineck, 1957) do well on land and at wading depth, even in sands. Petri dishes are being used successfully because the sample can be radiographed while still in the dish, or photographed, dried, impregnated, etc.

Moving into deeper water requires a ship, the size depending on water depth, and the size and weight of both the corer and the winch. The most common corers are gravity corers and piston corers. Both categories collect the core in a pipe. In most cases one uses a metal pipe and a plastic liner inside, sometimes both can be replaced by one PVC tube. A beveled coring nose, with a core catcher inside, is secured to the base of the pipe. The top of the pipe fits inside a slightly wider pipe, which has a hook (bail) at the top with stabilizing fins underneath and weights below the fins. A valve on top of the upper pipe closes directly after the corer terminates penetration.

Rather than letting the corer free-fall over the last 3–5 m, a tripping device is used that gives a pre-measured free-fall (Bouma, 1969). It consists of an arm connected to the main cable via a cable-clamping device (Figure C77-B1, B2). At the end of the arm is a cable (corer length + free-fall long) with a weight. As soon as the weight hits the sediment it unhooks the cable at the clamping device and free-fall starts. Due to friction between the core pipe and the sediment, one seldom collects a core over 2–3 m in length. The friction along the inside of the liner results in a core shortening, ranging from 10–40%.

The piston corer is very similar to the gravity corer, except that a piston is inserted at the base of the liner. The main cable is connected to the piston. A loop of cable (free-fall length) is rolled up between the fins (Figure C77-B1). The trigger cable has the length of the corer plus free-fall. If everything is

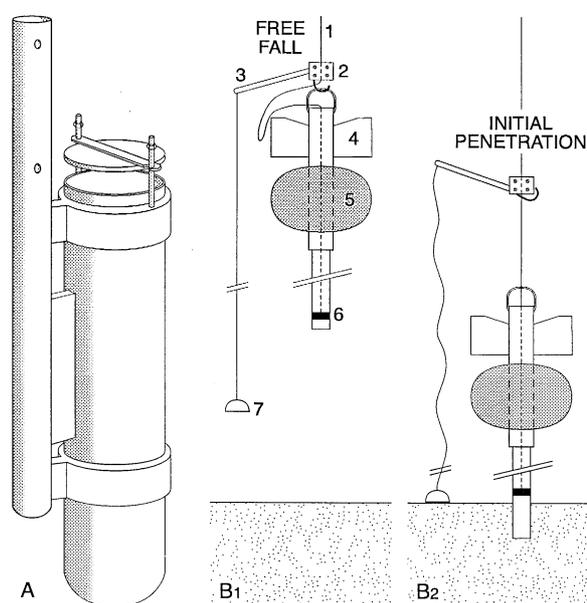

Figure C77 Two types of coring devices. (A) van Straaten tube used offshore in water up to 10 m deep. The valve can be swung to the side and the core pushed out, unless a liner is used. Three meter long extension rods make it possible to work from a small boat. (B) Piston corer operation. 1, main cable; 2, trigger device wire-clamp; 3, trigger arm; 4, stabilizing fans; 5, weights; 6, piston; 7, trigger weight. (B1) lowering, (B2) initial penetration; piston stays just above the bottom.

connected properly, the piston should stop as soon as it is near the water–sediment interface, while the core pipe slides over the piston, penetrating the sediment (Figure C77-B2). Because of the piston a slight vacuum is created underneath it which reduces the friction of sediment within the liner. This type of piston corer, weighing about one ton, and having a pipe length of 12–13 m, may collect a core up to 12 m long. Nine meters is more common. If the length setting was wrong, or the clamping device opens too early, the piston can suck in sediment, characterized by flow-in structures (Figure C78-B).

A Giant Piston Corer was developed at the Woods Hole Oceanographic Institution with the goal to collect 50 m long cores. The lighter Jumbo Piston Corer (2,300 kg) has been used successfully in the Gulf of Mexico. Recovered cores were up to 19.2 m in length, retrieved from 800–2,600 m water depth (Silva and Bryant, 2000). The extended length is necessary for geological and geotechnical studies to better understand the processes of slumping, sliding, debris flows and turbidity currents.

Anything longer than the devices mentioned above has to be done with rotary drilling from a special vessel such as operated by the Deep Sea Drilling Project, its successor the Ocean Drilling Project, or the drilling vessels working for the oil industry. Deep drilling onshore is simpler because the rig is stable rather than heaving and other motions. Coring at sea or land can produce cores 8 to 3 $\frac{1}{2}$ “(20.5 to 9 cm) in diameter with a common diameter of 4” (10 cm). The mining industry, and most other shallow drilling requirements, uses the slimhole version, producing cores that are 2 $\frac{1}{2}$ to 1 $\frac{1}{2}$ “(6.3 to 3.8 cm) in diameter with a common size of 1 $\frac{7}{8}$ ” (4.7 cm). Those rigs are

for land use and typically are mounted on a medium-sized truck.

Cochran (1959) and Bouma (1969) have described several varieties of coring devices. Amateurs with some experience can handle small devices. Professionals should handle the larger tools to avoid serious accidents and poor core recovery.

CROSS-STRATIFICATION

Introduction

Cross-strata are layers of sediment that are inclined relative to the base and top of the set in which the inclined layers are grouped. Each group is called a set of cross-strata or a

Figure C79 Example of eolian cross-stratification. Bed “A” (between heavy white lines) is a cross-stratified bed or set of cross-strata. Because the cross-strata (such as bed “B”, between thin white lines) are themselves cross-stratified (bed “C”, for example), this structure is called compound cross-stratification.

cross-stratified bed (Figure C79). Individual cross-strata can be classified (McKee and Weir, 1953) as cross-laminae (<1 cm thick) or cross-beds (>1 cm thick). In general, each set of cross-strata is deposited by a migrating bedform. Thin sets are deposited by small migrating bedforms such as ripples, small dunes, or small antidunes, and thick sets are deposited by larger dunes, antidunes, bars, or other large bedforms (Allen, 1962; Harms and Fahnestock, 1965). Cross-strata are a natural record of transported sediment and are therefore useful for understanding the behavior of modern bedforms and for interpreting environments in ancient deposits.

Because most cross-strata are deposited by migrating bedforms, study of cross-strata is inextricably entwined with studies of bedforms, sediment transport, and lee-side processes including granular flow. Advances in the understanding of cross-stratification include recognition of cross-laminae deposited by current ripples (Sorby, 1859), recognition of climbing eolian dune deposits (Barrell, 1917; Shotton, 1937), experimental studies of grainflows (Bagnold, 1941), discovery of large subaqueous dunes using sonar, recognition that subaqueous dunes deposit cross-strata (Allen, 1962, 1963a; Potter and Pettijohn, 1963; Harms and Fahnestock, 1965), recognition of stratification types in eolian dunes (Hunter, 1977), and the use of 3-D computer graphics to visualize the migration of complex bedforms (Rubin, 1987).

Origin of cross-stratified beds

Deposition of cross-stratified beds requires two conditions: migration of geomorphic surfaces that are inclined relative to the generalized depositional surface and deposition during migration. The inclined surfaces can either be individual landforms (such as delta-like bodies) or can occur within a train (bedforms); most sets of cross-strata are produced by trains of migrating bedforms.

Bedforms can only leave deposits where deposition occurs while the bedforms are migrating. This combination is defined as bedform climbing, because deposition causes the bedforms to move upward (climb) while they migrate. Where the rate of deposition is rapid enough (relative to the rate of migration), both the stoss and lee slopes of the migrating bedforms are preserved, resulting in complete preservation of the original bedforms (supercritical climb of Hunter, 1977). In other cases, the stoss sides of bedforms can undergo erosion while the lower lee sides are preferentially preserved (subcritical climb).

Origin of individual cross-strata

Sediment grains within cross-strata are deposited by a variety of processes: settling out from the water or air, avalanching (grainflow), or deposition by superimposed bedforms. On steep lee slopes, initial deposition is primarily by grains settling out of the flow. In both air and water, sediment can be sorted by grain size or density as it settles out on the lee slopes. On wind ripples, segregation by size can mask or obscure cross-lamination. Instead of producing visible cross-lamination, wind ripples typically deposit inversely graded laminae, because the grains on the lee sides of the wind ripples are sorted from coarse at the crest to fine at the trough (Hunter, 1977).

Cross-stratification deposited by grainflow is common on steep lee slopes of bedforms. Grainflow occurs because sediment that is transported across a bedform crest tends to be deposited at higher rate on the upper lee side than the lower lee side. Consequently, the lee slope can steepen until the slope exceeds the angle of repose, reaches the higher angle of initial yield, and causes the slope to fail by grainflow. In air, grainflow is discontinuous in time and space, producing grainflow deposits that are lenticular in horizontal cross-section. In contrast, subaqueous grainflow can occur more continuously in both time and space (Hunter and Kocurek, 1986). In both air and water, grainflow sorts grains by size, with the finest grains tending to sink to the base of the flow (Bagnold, 1941). On low-angle lee slopes, cross-strata are commonly deposited by superimposed bedforms.

Classifications of cross-stratification

McKee and Weir (1953) classified cross-stratification on the basis of descriptive features such as the shape of the set and shape of individual cross-strata. This is a useful approach, because some of these attributes are related to the kinds of bedforms that deposited the cross-strata (Allen, 1962). For example, sets of cross-strata with a planar base and uniform dip azimuth are deposited by two-dimensional bedforms (straight-crested bedforms without scour pits in their troughs), whereas trough-shaped (festoon) sets of cross-strata are deposited by more sinuous bedforms with scour pits in their troughs (Figure C80). Rubin (1987) also followed a geometric approach and classified cross-stratification based on properties that reflect whether the strata are constant along-strike (i.e., deposited by two-dimensional bedforms), constant down-dip (i.e., deposited by bedforms that maintained the same shape while migrating), and properties of the cross-stratification that indicate whether the original bedforms were transverse, oblique, or parallel to the resultant sediment-transport vector. Other classifications have been proposed for cross-stratification and bounding surfaces deposited by specific subaqueous or eolian bedforms.

Kinds of cross-stratification

Compound cross-stratification

Some cross-stratification is complicated by containing cross-strata that are internally cross-stratified (Figure C79), a structure defined as compound cross-stratification (Harms *et al.*, 1975), double cross-bedding, or furious cross-bedding (Reiche, 1938). Compound cross-stratification is formed where

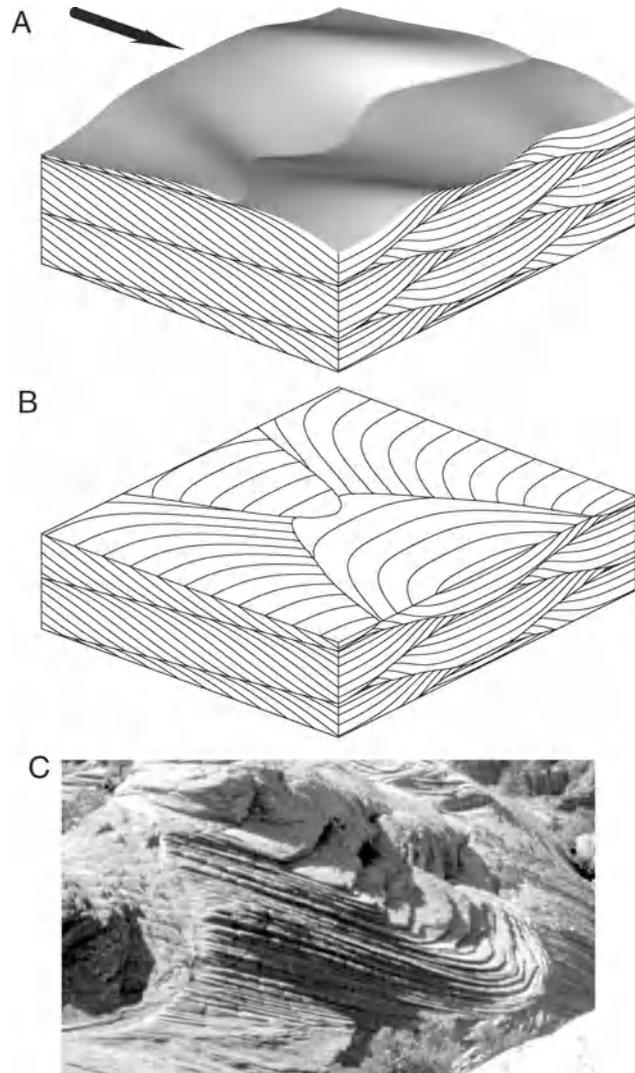

Figure C80 Trough cross-stratification. (A) Simulated bedform surface and stratification. Each trough-shaped set of strata is deposited by a migrating scour pit in the bedform trough. Arrow shows migration direction. (B) Horizontal section through structure in (A). (C) Eolian example of structure shown in (A) and (B). Dunes and scour pit migrated left-to-right out of the outcrop.

the lee side of a bedform undergoes changes in shape (often accompanied by erosion). Shape can change in response to changes in flow (such as ebb-flood reversals in tidal currents or annual changes in wind direction), or by migration of bedforms superimposed on a larger bedform as described by Allen (1963b, epsilon cross-stratification) or McCabe and Jones (1977). Some workers refer to bounding surfaces within sets of cross-strata as reactivation surfaces, but if “reactivation” is taken literally the term is more appropriate to surfaces produced by fluctuating-flow, because superimposed bedforms can produce bounding surfaces under steady conditions (no reactivation required).

Compound cross-strata deposited by bedform assemblages are particularly useful for determining the flow direction

relative to the bedform crest. For example, the best method of identifying an oblique bedform is to demonstrate that bedforms superimposed on the lee side of the main bedform systematically migrated along the crest of the main bedform in a preferred direction (Rubin and Hunter, 1983).

Cyclic cross-stratification

Some cross-stratification exhibits cyclic changes in grain size (such as mud drapes in tidal bundles), dip azimuth and inclination, stratification type (e.g., alternations of grainflow and grainfall), or spacing of bounding surfaces. In herringbone cross-stratification (attributed to reversing tidal flows) successive sets dip in opposing directions. Scalloped cross-bedding contains cyclically truncated trough-shaped subsets. Some cyclic cross-strata arise from flow cycles, and others arise from the passage of superimposed bedforms.

Deformed cross-stratification

Because cross-strata are deposited on slopes, they are particularly susceptible to slumping. Slumping can disturb individual beds or a sequence of beds near the free surface. Bedforms can also fail by the crestal region of a bedforms subsiding and sediment flowing into trough regions. This kind of failure may include the lower set boundary as well as sediment in the subsurface.

Relation of set thickness to bedform size

Where bedforms in a train are similar to each other and have a relatively uniform trough elevation, the thickness of the preserved sets depends on the bedform wavelength and the angle of climb (Rubin and Hunter, 1982). In such situations, the thickness of cross-stratified beds can be a very small fraction of the original bedform height. For example, eolian dunes in large deserts are commonly 100 m in height, whereas eolian cross-stratified beds in the rock record are typically a full order of magnitude smaller.

On the other extreme, where bedforms have irregular trough elevations, the thickness of cross-stratified beds depends on the particular sequence of troughs passing a point on the bed (Paola and Borgman, 1991). In this case, the thickness of cross-stratified beds can be a substantial proportion of the original bedform height.

Relation of dip direction to flow direction

Dip directions of cross-stratification are routinely used to infer paleocurrent directions. Although this approach probably gives reasonable results when sufficient measurements are made, the results can be biased in individual cases, particularly where bedforms are oblique to flow (Rubin and Hunter, 1987). Trough axes may be a more representative measure of the flow direction, but even trough axes can diverge from the actual transport direction. For example, in oblique bedforms, both the cross-strata dips and trough axis trends can diverge substantially from the transport direction. A more general rule can be demonstrated for compound cross-stratification deposited by bedform assemblages: the transport direction lies between the dip direction of the bounding surfaces scoured by the superimposed bedforms and the dip direction of foresets

deposited by superimposed bedforms (Rubin and Hunter, 1983; Rubin, 1987).

Techniques

Several new techniques are particularly useful for studying the geometry of cross-stratification. Ground-penetrating radar has proven successful at mapping internal stratification within eolian dunes, and borehole imagery can determine vertical profiles of dip directions. Three-dimensional graphics modeling is essential for reconstructing the morphology and behavior of bedforms that are too complicated to be visualized otherwise.

Future studies

Perhaps the greatest advance in understanding cross-stratification will come with the development of coupled flow and sediment-transport models that can accurately predict the morphology, migration, and evolution of bedforms, including interaction between successive bedforms in a train. Such a model would allow computational experiments to recreate specific bedding geometries from simulated flow sequences.

CYCLIC SEDIMENTATION

Introduction and background

Cyclic or rhythmic sedimentation is an old stratigraphic problem that has received considerable attention in the past (Suess, 1888; Grabau, 1913; Wanless and Shepard, 1936; Wheeler and Murray, 1957; Wells, 1960; Merriam, 1964; Vella, 1965; Duff *et al.*, 1967; Elam and Chuber, 1972; Schwarzacher, 1975), and remains today an unresolved controversial topic (Wilkinson, 1982; James, 1984; Algeo and Wilkinson, 1988; Einsele *et al.*, 1991; Goldhammer *et al.*, 1993; Drummond and Wilkinson, 1993a,b,c; de Boer and Smith, 1994; Read, 1995; Grammer *et al.*, 1996; Wilkinson *et al.*, 1996; Miall, 1997). Most, if not all, stratigraphic successions display repetitions of strata, at different scales, that reflect a succession of related depositional processes and environmental conditions that are repeated in the same order. The repetition of such events is termed cyclic or rhythmic sedimentation, and this leads to the formation of stratigraphic successions that display repetitive, orderly arrangement of different kinds of sediments or rock types. Studies of high-frequency cyclicity span all of geologic time from the Proterozoic (e.g., Grotzinger, 1986; Eriksson and Simpson, 1990; Clough and Goldhammer, 2000) to the Pleistocene (e.g., Mesolella *et al.*, 1969; Bloom *et al.*, 1974).

The essential concept of cyclic sedimentation is that of repetition of a series of events rather than their mere recurrence or random distribution. Thus, the term “cycle” refers to a series of connected events which return to a starting point. When applied to a sedimentary sequence, “cycle” refers to a distinctive series of lithologies that are arranged vertically in a predictable pattern in which at least one rock type, which is regarded as the starting point, is repeated (Schwarzacher, 1975). Accompanying the concept of “lithologic cyclicity” is the notion of “time cyclicity” (Schwarzacher, 1975). The term “cycle” should refer to regularities in rock pattern, whereas the term “rhythm” should be reserved for identical rock types that have been formed at equal time intervals. However, often this distinction is not made (Wells, 1960), or is impossible to judge. In this review I will address both lithologic cycles and temporal rhythms, at the macro-scale (i.e., outcrop-scale through seismic-scale), and exclude varve-scale laminations (mm-scale; see Einsele *et al.*, 1991 for a summary).

Types of cycles: allocycles versus autocycles

Vertical facies successions and their lateral distribution observed in the stratigraphic record are the results of changes in the environment of deposition through time, and these changes may be induced by autocyclic or allocyclic phenomena (Figure C81; Beerbower, in Merriam, 1964). Autocyclic processes are internal to a sedimentary system, totally independent of external influences. To develop cyclic deposits, these processes have to be self-regulating and include a built-in feedback mechanism. Excellent examples of autocyclic processes which lead to clastic cyclic deposits are: (i) delta lobe switching due to repeated progradation and retreat perhaps due to local compaction of pro-delta deposits or changes in rates of sediment supply; and (ii) migration and superposition of channel and lobe systems in fluvial environments. Other examples include non-periodic storm bed deposition and deep-water turbidite deposition. As these processes are limited areally to the basin depocenter itself, resultant “cycles” will be of limited lateral extent. Additionally, the time period of autocyclic deposits is often less than that of allocyclic deposits (Einsele *et al.*, 1991).

Allocyclic processes are external to the depositional system and they impart a net effect on stratigraphic accumulation. Fundamentally, external variations are driven by changes in climate and/or regional (or global) tectonics. Climate can affect sea-level changes through the advance and retreat of continental glaciers, and obviously influences deposition of evaporites in closed (lacustrine) or semi-enclosed marginal marine settings. Tectonic movements influence sea-level changes which in turn effect *accommodation space*, that is the vertical space available for sediment accumulation, as well as water depths which influence facies. In contrast to autocyclic processes, allocyclic packages may extend over great distances within a basin, as well as from one basin to another, and their time periodicity is often greater than that of autocycles (Einsele *et al.*, 1991).

Terminology, cyclic hierarchies, and orders of cyclicity

Perhaps the largest impediment to furthering our understanding of cyclicity is the development and utilization of a

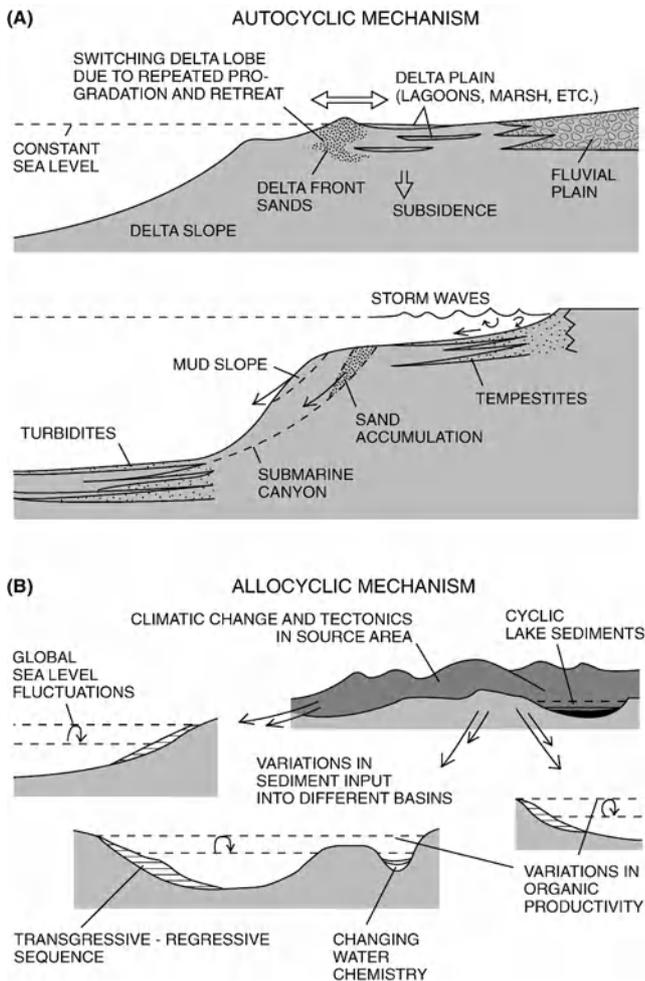

Figure C81 Autocyclic (A) and allocyclic (B) mechanisms (after Einsele *et al.*, 1991).

consistent terminology which satisfies a person's perception of the nature of cyclicity in the stratigraphic record. As advances are made in the accuracy of age-dating, cycle duration will become better constrained and this will certainly assist in a more widely adopted terminology and classification scheme. At present, however, absolute age dates fall short of the required precision, and thus geologists continue to wrestle with a consistent terminology. Perhaps a more severe problem is the fact that workers have different criteria regarding the recognition of cycles and particularly the surfaces that separate them.

For example, the high-frequency building block of shallow-marine clastic deposits is termed the *parasequence* defined by Van Wagoner *et al.* (1990) as "a relatively conformable succession of genetically related beds or bedsets bounded by marine-flooding surfaces or their correlative surfaces". A marine-flooding surface is defined as "a surface separating younger from older strata across which there is evidence of an abrupt increase in water depth. This deepening commonly is accompanied by minor submarine erosion or nondeposition (but not by subaerial erosion), with a minor hiatus indicated".

This definition of the highest frequency building block in shallow marine clastic systems, which many workers would equate with the term "cycle", emphasizes the physical bounding surface to the point of excluding the internal succession of rock types or facies from the definition.

By contrast, in shallow marine carbonate systems, Goldhammer *et al.* (in Franseen *et al.*, 1991; 1993), following Wilson (1975), James (1984) and Hardie and Shinn (1986), define the high-frequency building block as a *cycle* which they define as:

a relatively conformable succession of genetically related subtidal subfacies bounded by peritidal subfacies, subaerial exposure surfaces, and/or marine flooding surfaces (very thin intervals characterized by slow rates of deposition). Cycles are the thinnest recognizable allocyclic or autocyclic depositional unit and they may be progradational and/or aggradational and thus subfacies within cycles shoal upward. Individual cycles typically contain both a "transgressive" and "regressive" component, and the relative proportion of these components within any given cycle is a function of the cycle's position within a lower frequency cycle or sequence.

Cycles by this definition are highly accurate depictions of laterally coeval facies or subfacies associations in accordance with Walther's Law.

Goldhammer *et al.* (in Franseen *et al.*, 1991, 1993) recognize two types of shallow marine platform carbonate cycles, based on physical bounding surfaces: cycles bounded by features indicative of subaerial exposure (e.g., mudcracked peritidal laminites, caliches, etc), termed "exposure cycles" or "peritidal cycles", and those that do not shoal to fill level which are bounded by marine flooding surfaces across which subfacies deepen, termed "subtidal cycles" (see also Osleger and Read, 1991). Below, I briefly review the approaches to a consistent terminology and classification, attempting to provide some historical context.

Hierarchical subdivision based on duration of the "cycle"

The sedimentary record throughout all of geologic history is characterized by stratigraphic cycles of different orders of magnitude, both in terms of thickness, duration and regional extent. Suess (1888) early on appreciated the notion that several orders of cyclicity existed within the stratigraphic record and Barrell introduced the term "composite cycle" to successions in which cycles of different wavelengths are superimposed upon each other (Schwarzacher, 1975). This concept is now well-established as indicated by Exxon's global cycle charts (Vail *et al.*, 1977; Haq *et al.*, 1987) constructed for the Phanerozoic, which consist of three superimposed orders of cyclicity. Extending Sloss' original idea of regional "unconformity-bounded sequences" Vail and his Exxon co-workers proposed the existence in the stratigraphic record of "global cycles of relative sea level change" and they presented a hierarchy of global cycles based on their inferred temporal duration (Figure C82): (1) first-order cycles with durations of 200–300 m year; (2) second-order cycles with durations of 10–80 m year; (3) third-order cycles with durations of 1–10 m year (Vail *et al.*, 1977). At that time, in the Exxon scheme, cycles referred strictly to relative sea-level changes and the term "sequence" was reserved for the stratigraphic record

Tectonic-Eustatic/Eustatic Cycle Order	Sequence Stratigraphic Unit	Duration (m year)	Relative sea-level amplitude (m)	Relative sea-level rise/fall rate (cm/1,000 years)
First		>100		<1
Second	Supersequence	10–100	50–100	1–3
Third	Depositional Sequence	1–10	50–100	1–10
	Composite Sequence			
Fourth	High Frequency Sequence	0.1–1	1–150	40–500
	Parasequence and Cycle Set			
Fifth	Parasequence High-Frequency Cycle	0.01–0.1	1–150	60–700

Figure C82 Orders of stratigraphic cyclicity (modified from Goldhammer *et al.*, in Franseen *et al.*, 1991, and Kerans and Tinker, 1997)

of such a global cycle of relative sea-level change, such that a depositional sequence was defined as “a conformable succession of genetically related strata bounded by interregional unconformities or their correlative conformities (i.e., sequence boundaries)”. Extending their 1977 concepts, Vail *et al.* (1984), Vail (1987), and Van Wagoner *et al.* (1987) expanded on the Exxon viewpoint such that a depositional sequence was interpreted to be deposited during a cycle of eustatic change in sea level starting and ending in the vicinity of the inflection points on the falling limbs of a eustatic sea level curve. Hence the term sequence was originally linked to “third-order” changes in accommodation driven by relative sea-level changes interpreted as eustatic in origin.

Making the logical connection between low-frequency seismic-scale “sequences” and outcrop-scale “high-frequency” cycles, Miall (1984) proposed a logical extension of the original Vail *et al.* (1977) terminology for stratigraphic cycles and introduced the term fourth-order cycles for cycles with durations between 0.2 m year and 0.5 m year. Soon the hierarchy was expanded further for both clastics (Van Wagoner *et al.*, 1990) and platform carbonate cycles (Goldhammer and Harris, 1989; Koerschner and Read, 1989; Goldhammer *et al.*, 1990) and the term fifth-order cycle was proposed for high-frequency cycles with durations between 0.01–0.1 m year. Vail *et al.* (in Einsele *et al.*, 1991) introduced yet another subdivision with the term sixth-order cycle for cycles with durations between 0.01 and 0.03 m year, a term also recognized and used by Grammer *et al.* (1996).

Currently, many stratigraphers use the “order” subdivision realizing that although absolute age durations are nearly impossible to obtain and thus define the duration of a cycle with precision, the idea of a “building-block” approach with a hierarchy of cycles based on some inference of duration is a valid and useful first approach, regardless of the type of deposit (e.g., Mutti, 1992; Kerans and Tinker, 1997; Miall, 1997). A limitation of this approach is that each of these “orders” implies a temporal order-of-magnitude for a given rock-stratigraphic unit, independent of origin, whether relative sea-level, climate, or sediment supply, thus potentially suggesting some link between duration and process. Although these terms are useful order-of-magnitude indicators of cycle duration, as pointed out by Sonnenfeld (1996) predictions with regard to associated rate or amplitude of sea-level change, vertical thickness, lateral extent, correlation range, or even depositional style for a given sequence cannot be confidently made simply based on “order.”

Subdivision for clastic successions based on a hierarchy of stratal units

This approach, set forth by Van Wagoner *et al.* (1990), recognizes a hierarchy of stratal units from the mm-scale lamination to the km-scale seismic sequence. Although divorced from the “order” approach of his Exxon colleagues and the inferred eustatic interpretation of cycles, the Van Wagoner scheme recognizes that the basic building-block, the parasequence (defined above) is equivalent to the “upward-shoaling cycle” (Van Wagoner *et al.*, 1990, p. 3), and thus it is reviewed in this overview of cyclicity. Principally, an objective approach based on stratal attributes, each stratal unit in the hierarchy is defined and identified only by the physical relationships of the strata, including lateral continuity and geometry of the surface bounding the units, vertical stacking patterns of the units, and lateral geometry of the strata within the units. Significantly, thickness, time for formation, and the interpretation of regional or global origin are not used to define stratal units or place them within the hierarchy.

As related to this discussion of cyclicity, the following terms were proposed by Van Wagoner *et al.* (1990):

- (1) the *parasequence* (defined above) would be the highest-frequency “fundamental building block” of clastic sequences, which could be either autocyclic or allocyclic in origin. For example, within a parasequence from a beach deposit, Van Wagoner *et al.* (1990) recognize predictable vertical successions in lower-shoreface, upper-shoreface, foreshore and backshore subenvironments and associated variations in bed and bedset thickness, sand-shale ratios, and ichnofossil assemblages.
- (2) the *parasequence set* defined as “a succession of genetically related parasequences forming a distinctive stacking pattern bounded by major marine-flooding surfaces and their correlative surfaces” (Figure C83). A “stacking pattern”, as defined by Sonnenfeld (1996) represents the progressive lateral translation in space of a set of cycles forming a geometric arrangement describable by the terms “retrogradational” or “landward-stepping,” “progradational” or “seaward-stepping,” and “aggradational” or “vertically stacked”. Cycle stacking patterns are interpreted as the product of systematic changes in the ratio of accommodation to sediment supply (Van Wagoner *et al.*, 1990; Sonnenfeld and Cross, 1993; Sonnenfeld, 1996), and such patterns form the basis for recognizing

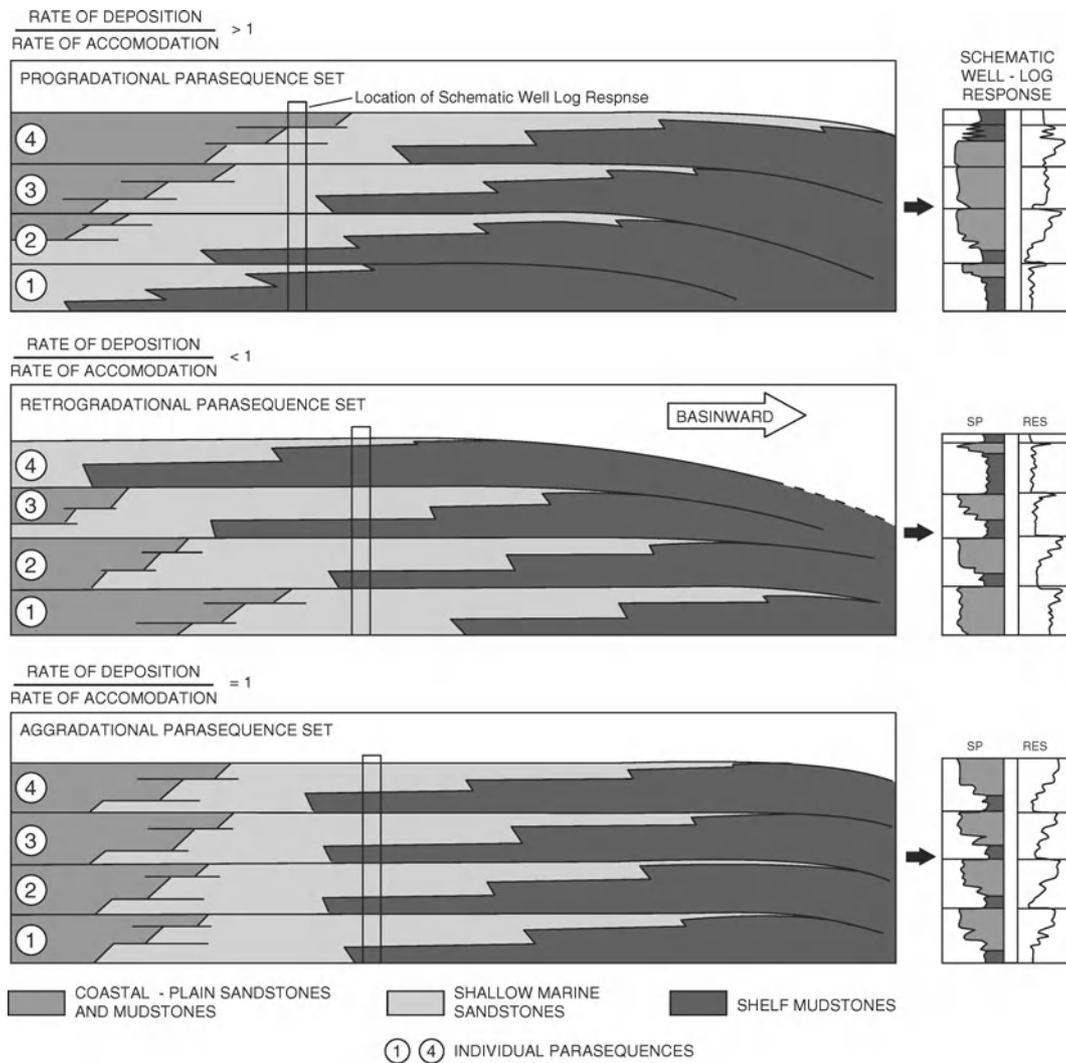

Figure C83 Parasequence set stacking patterns (modified form Van Wagoner *et al.*, 1990).

progressively larger-scale sequences within a hierarchy (e.g., Goldhammer *et al.*, in Franseen *et al.*, 1991, 1993). Accommodation is defined as the cumulative sum of space available for potential sediment deposition; it is the product of eustasy, subsidence, and compaction and is equivalent in shallow marine settings to relative sea-level. Although two-dimensional in implication (Van Wagoner *et al.*, 1990; Fitchen, 1997), where lateral continuity of cycles is lacking owing to limited outcrop or in the case of subsurface cores, stacking patterns may be inferred from one-dimensional analysis of vertical cycle trends (Kerans and Tinker, 1997; Read and Goldhammer, 1988; Lehrmann and Goldhammer, 1999).

- (3) A *sequence* is defined as “a relatively conformable succession of genetically related strata bounded by unconformities or their correlative conformities” (Van Wagoner *et al.*, 1990). Parasequence sets are the building blocks of sequences. The “transgressive” portions of sequences are marked by retrogradational parasequence

sets, and the “regressive” portions of sequences are marked by progradational parasequence sets.

Hierarchical subdivision based on accommodation/sediment supply ratios: expansion of the Van Wagoner *et al.* (1990) scheme

In this scheme proposed by Sonnenfeld and Cross (1993) and Sonnenfeld (1996), a cycle or sequence of any physical or temporal scale is defined as the stratigraphic record of a full cycle of increasing followed by decreasing accommodation/sediment supply ratios (A/S)—the base-level transit cycle of Wheeler (1964). Cycles, of any scale, that are bounded by conformable surfaces cannot be defined solely based upon the erosive or altered nature of the bounding surfaces; in such cases, the cycle boundary is defined as the “turnaround” from decreasing to increasing accommodation/sediment supply ratios as inferred from stacking pattern analysis (e.g., Van Wagoner *et al.*, 1987; Lehrmann and Goldhammer, 1999).

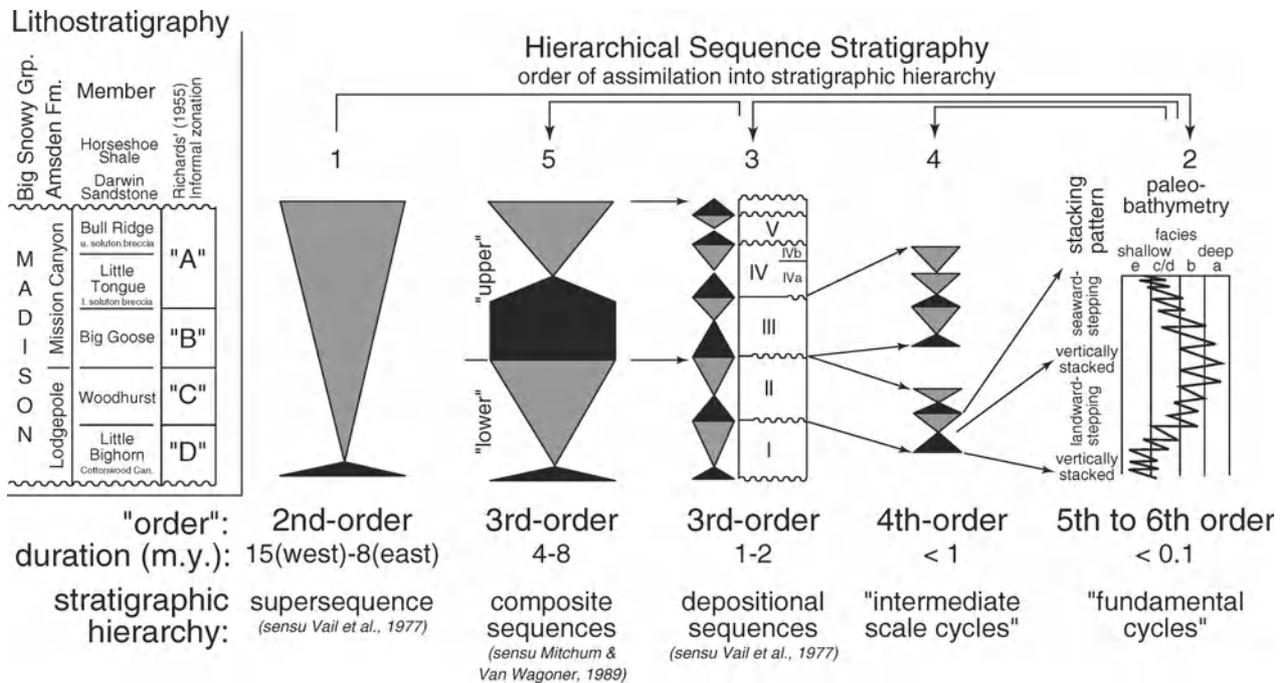

Figure C84 Hierarchical subdivision of cyclicity based on accommodation/sediment supply ratios (modified from Sonnenfeld, 1996).

In the Sonnenfeld (1996) scheme (Figure C84) triangles pointing down are used to graphically depict portions of sequences at any scale characterized by decreasing accommodation/sediment supply ("A/S") ratios as inferred from progradational stacking patterns. Conversely, triangles pointing up denote inferred increasing "A/S" as inferred from retrogradational stacking patterns. Squares separating the triangular symbols represent a condition of balanced "A/S" (=1) as inferred from aggradational stacking patterns. The triangles described above may be drawn for cycles of any physical and temporal scale, and provide an effective graphical shorthand for portraying the hierarchical embedding of sequences within sequences.

Sonnenfeld (1996) introduces the term "fundamental cycle" as the "smallest resolvable vertical facies succession which forms a "small-scale" cycle (<1–20 ft), and define cycle boundaries at their accommodation minima. Fundamental cycles are in turn grouped into "intermediate-scale cycles" which are the highest-order cycle that can be correlated across large areas (e.g., >100 km). These in turn are nested into "third-order depositional sequences" (in the sense of Vail *et al.*, 1977), which make up third-order "composite sequences" (defined below), in turn grouped into "second-order supersequences". Cycle boundaries of lower-frequency sequences occur at the "turnaround" from decreasing to increasing "A/S". Note that these critical turnarounds may either be represented by a unique surface or an interval of rock.

Integrated hierarchical subdivision utilizing sequence stratigraphic terminology

In a practical effort aimed at subsurface geologists, a scheme has evolved which integrates much of the previous approaches,

balancing both the objective approach (emphasizing physical attributes and facies relationships observed in core and outcrop) with the somewhat subjective approach of assigning temporally-constrained orders (Figure C85). This "sequence stratigraphic" approach proposed by Kerans (1995), and utilized by Kerans and Fitchen (1995), Kerans and Tinker (1997), Fitchen (1997), and Tinker (1998), recognizes an ordered hierarchy of cycle types based on a number of objective, rock-based criteria used to define the terms and orders of the cycles. These include: vertical lithofacies successions, cycle stacking patterns, lithofacies proportions, cycle symmetry, stratal preservation, lithofacies tract offset, and stratal geometry.

The technique first defines the "high-frequency cycle" (the basic building block, equivalent to the parasequence for clastic deposits) as "the smallest set of genetically related lithofacies deposited during a single base-level cycle, which can be mapped across multiple lithofacies tracts, which include multiple vertical lithofacies, and thus are inferred to be chronostratigraphic units" (Kerans and Tinker, 1997). High-frequency cycles are grouped into "cycle sets" which are "bundles of cycles that show a consistent trend, either progradational, aggradational, or retrogradational (transgressive)" (Kerans and Tinker, 1997). The next level of the hierarchy introduces the term "high-frequency sequence" which are intermediate-order cycles bounded locally by unconformities. High-frequency sequences may have all the attributes of the original Vail *et al.* (1977) sequence, with the complete suite of systems tracts defined by parasequences and parasequence sets, and they are bounded by surfaces or thin intervals (zones) which demonstrate "base-level fall to base-level rise turn-arounds" (Kerans and Tinker, 1997). High-frequency sequences can equate to or can be part of "composite

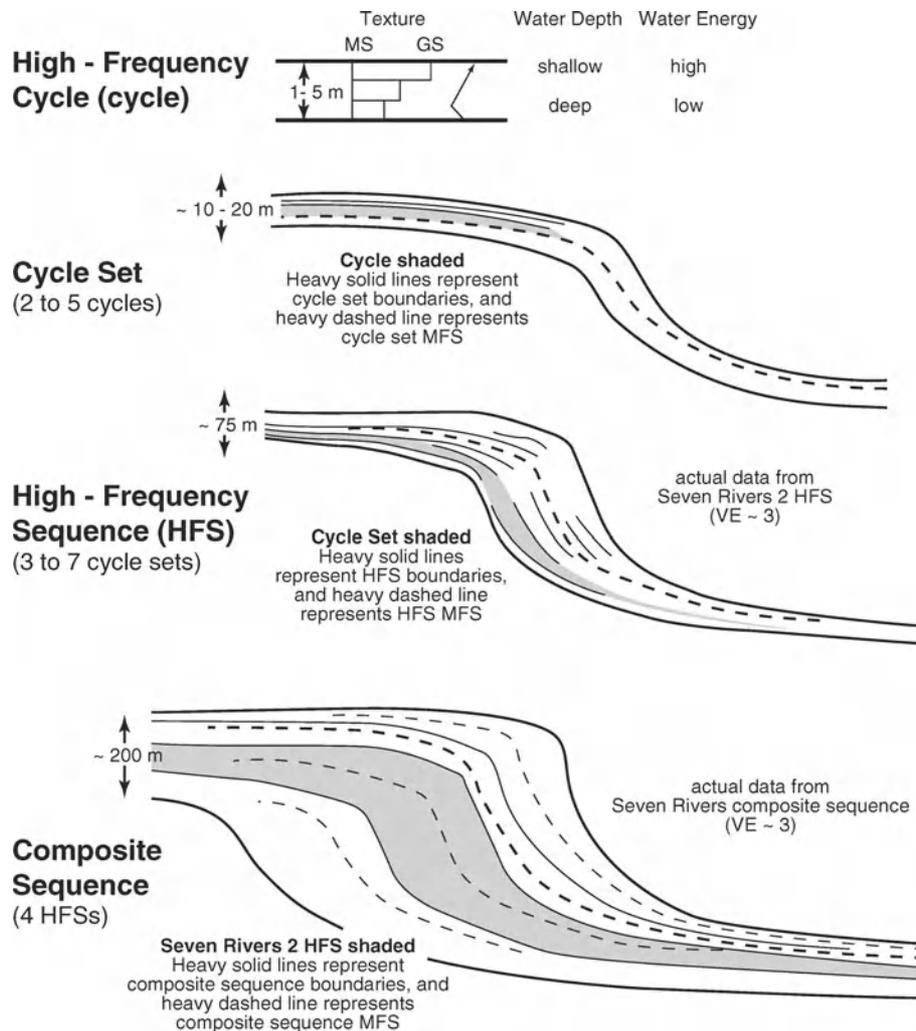

Figure C85 An integrated hierarchical subdivision utilizing sequence stratigraphic terminology (modified from Tinker, 1998).

sequences” which is the next level in the hierarchy, often, but not necessarily, reserved for the Vail *et al.* (1977) original “third-order” sequence.

The term composite sequence, proposed by Mitchum and Van Wagoner (1991), resulted from the realization by these workers that in clastic depositional systems the original Vail *et al.* (1977) “sequence” itself could be composed of several unconformity-bounded packages or “sequences”. On a parallel course in the carbonate arena, Goldhammer *et al.* (in Franseen *et al.*, 1991) grouped sets of “fourth-order sequences” (30–50 m thick) bounded by subaerial exposure surfaces into “third-order” sequences for mixed shallow marine clastic and carbonates.

In summary, the hierarchical approach universal in the recognition, classification and interpretation of cycles recognizes that cycles of progressively shorter duration, or “higher-order,” are physically contained within longer-term cycles (Goldhammer *et al.*, 1990; Mitchum and Van Wagoner, 1991). Unraveling the hierarchy of cycles should be a task which is independent of assigning an origin to the cycles or quantifying

forcing functions responsible for cycle formation (e.g., calculating amplitudes of relative sea-level rise/fall). The cyclo-stratigrapher’s goal is to create a physical stratigraphic hierarchy of cycles contained within cycles contained within cycles, whereby one can then evaluate the manner by which facies arrangements within cycles change in a progressive, organized manner according to position within the next larger scale (e.g., “lower-order”) cycle (Goldhammer *et al.*, 1993; Sonnenfeld, 1996). Goldhammer *et al.* (1990) termed this concept “the hierarchy of stratigraphic forcing” in their study of cyclic Alpine Triassic carbonates, an objective hierarchy which they state is independent of the forcing function (allocyclic or autocyclic).

Postulated causes of cycles—first, second, and third-order

Once one accepts the plausibility of an ordered, yet imperfect, existence of stratigraphic cycles, the next challenge is unraveling the causes of cycles, at all scales. For ideas, concepts and

discussions of this topic, the reader is referred to Allen and Allen (1990), Einsele *et al.* (1991), Walker and James (1992), Miall (1990, 1997), Reading (1996), and Emery and Myers (1996). Stratigraphic cycles at all orders result from the interplay of tectonics (typically in the form of basin subsidence), eustatic sea-level changes (of differing magnitude and duration), and sediment supply. Other more localized factors, such as antecedent topography, compaction, windward-leeward effects, etc, while clearly significant and worth evaluating, are generally not regarded as the prime suspects influencing the development of cycles. Together, tectonics and eustasy basically create accommodation space available for sedimentation, and stratigraphic cycles result from the intricate interplay of accommodation and sediment supply.

Allen and Allen (1990), Miall (1990, 1997), Walker and James (1992), and Reading (1996) summarize both tectonic and eustatic mechanisms that dictate the creation of accommodation within different types of basins. These sources and many others provide numerous examples of how such space is filled, and what influences sediment supply which together generate the cyclicity observed in the stratigraphic record. Reduced to the essential (Allen and Allen (1990), tectonic mechanisms that effect accommodation include: (1) effects of lithospheric flexure in (divergent margin) basins due to stretching (either brittle crustal extension or thermal subsidence); (2) the effects of flexural rigidity on peripheral bulge formation within (convergent margin) foreland basins; (3) changes in regional stress fields of the lithosphere inducing vertical movements ("intra-plate" stress).

Mechanisms for inducing eustatic changes in sea-level (Allen and Allen, 1990) which in turn influence accommodation include: (1) continuing differentiation of lithospheric material as a result of plate tectonic processes, whereby the volume of water in the oceans may be added by contributions from mid-oceanic ridge and island arc volcanism; (2) changes in the volumetric capacity of the ocean basins caused by sediment accumulation or by sediment abstraction, such that inequalities might exist between rates of erosion and sediment input into oceanic basins versus rates of sediment removal at subduction zones; (3) changes in the volumetric capacity of the ocean basins induced by volume changes in the mid-oceanic ridge system; as the bathymetry of the ocean is dependent on age, variations in rates of spreading causes major ridge-volume changes with the faster spreading ridges being hotter and thus more voluminous; (4) reduction of available water by locking up in polar ice caps and glaciers (and the reverse), termed "glacio-eustasy"; (5) desiccation events due to evaporation of inland basins and marginal seas, for example the Miocene Mediterranean salinity crisis; such events could cause global sea-level rise in other oceanic basins.

As these factors control accommodation space over potentially large regions, it is the interaction of these factors, at different magnitudes and over varying timescales that yields the cyclic rock record. Given the fact that these variables operate independently and their effects (in terms of magnitudes and rates of space creation or destruction) are not accurately constrained, it is little wonder why the origin of cycles has long been and continues to be a major issue of heated controversy in the geologic community. Having stated the obvious there is general agreement over the postulated origins of the different orders of cyclicity. First-order cycles (200–400 m year duration) are ascribed to supercontinent assembly (i.e., Pangaea) by seafloor spreading and their subsequent breakup and dispersal.

Eustatic sea level falls during times when supercontinents are assembled and rises during times of rapid seafloor spreading when continents have rifted apart and are drifting. Two, first-order, or supercontinent, cycles appear to have occurred during the Phanerozoic (Figure C86), and global first-order global climate fluctuations, from icehouse to greenhouse conditions, have accompanied these cycles.

Second-order cycles are attributed to volume changes in oceanic spreading centers—with more rapid spreading and hotter ridges, ridge volume increases and eustatic sea level rises; with a decrease in spreading rate and cooler ridges, ridge volume decreases and sea level falls. As discussed above, broad, regional cycles of changes in basement elevation due to lithospheric flexure which occur in response to divergent, convergent and transcurrent plate motions are also candidates. For example the Sloss (1963) second-order supersequences, major unconformity-bounded packages that correlate not only across North America, but also with other regional cycles on other continents demand a global origin.

Of the various possible causes of third-order eustatic changes only two are plausible candidates for third-order cyclicity (see Fairbridge, 1961; Donovan and Jones, 1979; Allen and Allen, 1990; Einsele *et al.*, 1991; Walker and James, 1992; Miall, 1990, 1997; Emery and Myers, 1996; Reading, 1996): (1) waxing and waning of polar ice caps (glacio-eustasy), and (2) changes in the volume of ocean basins (tectono-eustasy). Glacio-eustatic rates of change (up to 1 cm/year) and total amount of change (150 m) can readily account for third-order rates and magnitude (rates = 1–10 cm/1000 years; magnitude = 50–300 m; Kendall and Schlager, 1981; Hancock and Kauffman, 1979; Hine and Steinmetz, 1984) but for geologic periods lacking evidence for major continental glaciation, tectono-eustasy must be invoked as the cause. Hays and Pitman (1973) and Pitman (1978) have illustrated that changes in rates of mid-oceanic spreading centers can induce sea-level changes of up to 300 m at a maximum rate of 1 cm/1000 years. However, tectono-eustasy is unable to account for all of the third-order cycles in the stratigraphic record, because most third-order cycles demand faster rates. Thus the origin and control of third-order cycles remains problematic, especially for periods lacking evidence for major glaciation.

Postulated causes of cycles—fourth and fifth-order

Essentially four mechanisms have been proposed to explain the successive stacks of fifth/fourth-order cycles that characterize shallow marine platform carbonate, shallow shelf clastic, mixed clastic-carbonate, and mixed carbonate evaporite deposits of all ages: (1) high-frequency glacio-eustatic oscillations forced by deterministic Milankovitch climatic rhythms; (2) high-frequency aperiodic eustatic oscillations forced by stochastic processes; (3) autocyclic mechanisms specific to either carbonate or clastic systems; (4) tectonic pulsing of marine shelves related to successive down-dropping of platform tops or tectonic "yo-yoing".

(1) Glacio-eustatic (Milankovitch) cycles

Recently, many workers have sought to explain the origin of high-frequency cycles through a glacio-eustatic, allocyclic mechanism driven by climatic cycles under orbital control (Hays *et al.*, 1976; Berger, 1984; Imbrie, 1985; Hinnov, 2000),

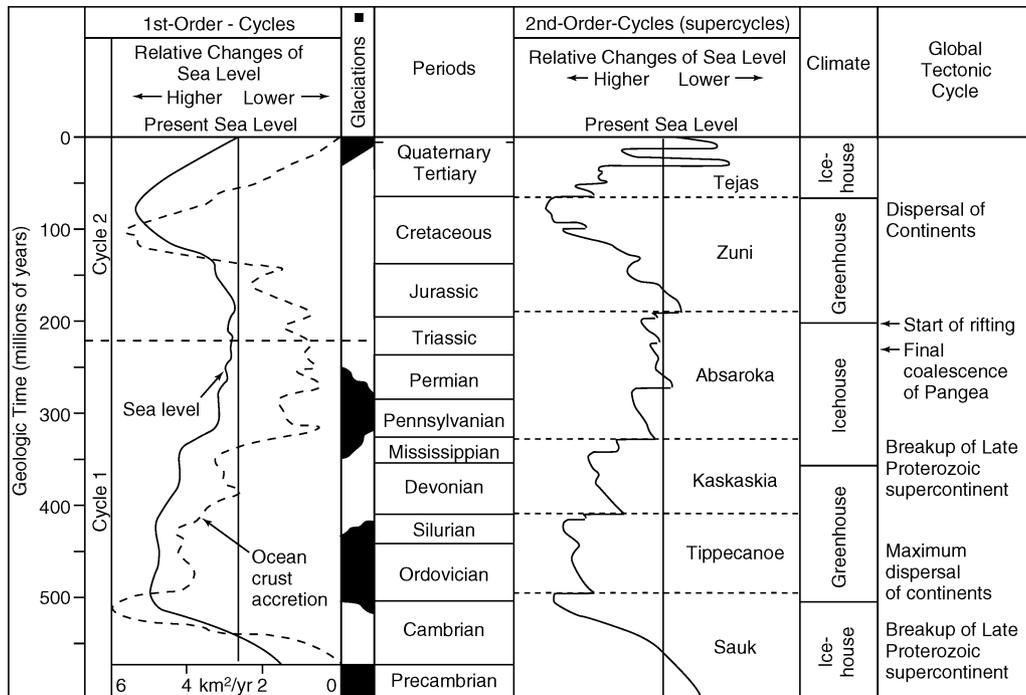

Figure C86 Illustration of first-order and second-order global sea-level cycles (after Boggs, 2001).

which is a rather deterministic mechanism. Deterministic processes are in essence entirely predictable and involve order with periodicity. Deterministic systems are appealing because of their predictive capability. The general acceptance of the Milankovitch theory for Pleistocene cycles has been provided by the correlation of the Pleistocene deep sea and coral reef record with Milankovitch climatic rhythms, for example, as suggested for the Pleistocene carbonate stratigraphy of south Florida (Broecker and Thurber, 1965; Osmond *et al.*, 1965; Perkins, 1977). An outgrowth of the Milankovitch revival is the question of whether orbital variations have produced a legible stratigraphic signal in pre-Pleistocene cyclic stratigraphy. Pursuit of the feasibility of pre-Pleistocene Milankovitch forcing in carbonate systems is exemplified by studies published over the last several years (Grotzinger, 1986; Goldhammer *et al.*, 1987; Strasser, 1988; Koerschner and Read, 1989; Jimenez De Cisneros and Vera, 1993; D'Argenio *et al.*, 1997; Hinnov, 2000).

Milankovitch astronomical rhythms might influence clastic, carbonate and evaporite sedimentation in three ways: (1) by causing variations in continental ice cap volumes, which in turn would cause eustatic sea-level changes; (2) by causing ocean temperature to change sufficiently that ocean water volume would change; (3) by causing climatic changes in the tropics so that shallow water carbonate production would change.

Waxing and waning of continental ice sheets would yield rhythms of submergence and emergence across shallow marine shelves (Hardie and Shinn, 1986). Such submergence-emergence glacio-eustatic oscillations would produce repetitive shallowing-upward cycles, given proper conditions of sedimentation and subsidence. More specifically, the earth experiences three climatic cycles: (1) approximately 20,000 year

precessional cycle; (2) approximately 40,000 year obliquity cycle; (3) approximately 100,000 year eccentricity cycle. Each results from the gravitational interaction of the Earth with the moon and other planetary bodies (see *Milankovitch Cycles*, and Hinnov, 2000). These climatic cycles occur with different, yet somewhat predictable frequencies, and cause the Earth's average temperature in and around the polar regions to increase and decrease in a cyclical manner. Alternate warming and cooling of the polar regions triggers the melting and growth of land-locked glaciers, which in turn modulates sea-level change.

To establish the existence of Milankovitch forcing, some workers have simply compared calculated cycle periods or a range of periods with Milankovitch values (e.g., Heckel, 1986; Koerschner and Read, 1989). Others have noted the bundling of small-scale, fifth-order cycles into larger-scale fourth-order cycles and compared this stratigraphic hierarchy to the Milankovitch hierarchy of superimposed orders of climatic cyclicity (Goodwin and Anderson, 1985; Goldhammer *et al.*, 1987; Strasser, 1988; Crevello, in Franseen *et al.*, 1991). In light of age-date errors, the calculation of cycle periods and a comparison with predicted Milankovitch frequencies is fraught with hazards (Hardie *et al.*, 1986; Algeo and Wilkinson, 1988). Analysis of cycle stacking patterns and comparison of cycle bundles with Milankovitch ratios alone provides ambiguous results.

Time series analysis provides the most reliable means of demonstrating Milankovitch frequencies within platform carbonates (e.g., de Boer and Smith, 1991; Einsele *et al.*, 1991; Hinnov, 2000). This approach basically scans stratigraphic data sets for cyclic signatures and compares the extracted frequencies with known Milankovitch frequency ratios. However a serious problem regarding time series

analyses of ancient platform cyclic sequences pertains to the completeness of the cyclic succession. Inherent in traditional time series analysis is the assumption that the cyclic record is complete and that each recorded stratigraphic rhythm equates directly to one rhythmic pulse of the cyclic-producing mechanism (e.g., glacio-eustasy; Duff *et al.*, 1967, p.13). In examining the relationship between cyclic events in time (i.e., rhythms) and the resulting stratigraphic record, it must be pointed out that shallow marine shelves (clastic or carbonate) may depict at best a rather "faulty recording mechanism" (Swarzacher, 1975). Despite a regular, rhythmic time pattern of cyclic-producing events (e.g., Milankovitch-driven glacio-eustasy), the corresponding stratigraphic record may not preserve each and every potential cyclic-producing pulse due to complexities of sedimentation.

Glacio-eustatic control on cyclicity has received considerable attention for mixed clastic-carbonate cyclothems of the Mid-continent USA and Europe, which have been inferred to result from the waxing and waning of large Gondwanan ice caps (Wanless and Shepard, 1936; Wheeler and Murray, 1957; Wanless and Cannon, 1966; Crowell, 1978; Ramsbottom, 1979). More recently, Heckel (1986, 1989) and Ross and Ross (1987) have advocated a direct Milankovitch control on the cycles characteristic of the interior and southwestern regions of the USA. Original glacial proponents (Wanless and Shepard, 1936) drew upon the widespread distribution of cyclothems, extreme lateral continuity of lithofacies, and the occurrence of age-equivalent cyclothems on different continents to support their viewpoint.

(2) High-frequency stochastic cycles

The "Milankovitch revival" is currently under attack largely due to the difficulties associated with "proving" a connection between cyclic sections and deterministic astronomical forcing (Drummond and Wilkinson, 1993a,b,c; Satterly, 1996; Wilkinson *et al.*, 1997). This has opened the door for evaluating the influence/control of stochastic mechanisms. Stochastic processes are entirely random and depict disorder without periodicity. Stochastic phenomena are unpredictable. High-frequency eustasy may be in-part or entirely stochastic. Either the periodicity of high-frequency oscillations, or the amplitudes, or both, may be forced by stochastic mechanisms. Likewise, carbonate, clastic and evaporite sedimentation processes, or the manner whereby such processes act to fill accommodation space may be stochastic. Either way, it is feasible that high-frequency cycles in the geologic record may be the result of stochastic high-frequency eustasy.

For example in shallow marine carbonate platform systems, an emerging "random" camp has attacked the fundamental concept of a hierarchical grouping of cyclicity in carbonates as part of an effort to demonstrate that cycle stacking patterns are entirely random (Drummond and Wilkinson, 1993a,b,c; Satterly, 1996; Wilkinson *et al.*, 1997). They maintain that cycle populations are erratic, bounced about by random unpredictable factors wiping out whatever deterministic signal may exist. These authors are thus shifting attention away from the predictive capacity of cyclic stratigraphy and the utility of using carbonate cycle stacking patterns as a tool for evaluating the origin of depositional sequences. This camp has applied statistical analyzes to cyclic carbonate successions and conclude that the vertical arrangement of high-frequency cycles and subfacies is random. Furthermore, as the

distribution is random, they claim that the process is more than likely random and appeal to autocyclic phenomena in the spirit of complex Holocene facies models. In contrast, Sadler *et al.* (1993), using similar statistical tests, concluded that the vertical organization of long strings of high-frequency cycles are decidedly non-random.

Time series analyzes of stratigraphic sections typically do not reveal resonant periodicity and thus it is tempting to conclude that stochastic processes dominate the formation of cyclic carbonates. But recalling that the stratigraphic machine is at best a faulty recording mechanism, a deterministic driver may yield a stochastic output via the "stratigraphic filter". The burden of proof is just as challenging as with deterministic systems. If empirical observations of vertical stacking patterns, and the vertical/lateral distribution of facies are rendered entirely unpredictable, then perhaps the system is random and stochastic stratigraphic models are appropriate. It is this author's opinion however that there is always some element of order, and this is both age-dependent reflecting secular geologic changes, and scale-dependent (e.g., Lehrmann and Goldhammer, 1999).

(3) Autocycles

Based on Holocene insight, Ginsburg (1971) formulated a progradation-driven autocyclic mechanism that readily accounts for repetitious stacks of meter-scale fifth- and fourth-order platform carbonate cycles. This model couples continuous carbonate sedimentation and progradation of tidal flat complexes across gently sloping carbonate platforms under conditions of constant subsidence and stationary sea-level (e.g., Hardie and Shinn, 1986). The subtidal carbonate factory provides the sediment source which is transported shoreward, accreting against exposed land masses or islands. The tidal flat complex progrades out and over the subtidal deposits yielding a shallowing-upward cycle capped by progradational tidal flat facies. The key aspect of the model is that carbonate production rates will be unable to keep pace with subsidence as tidal flat progradation diminishes the size of the "subtidal factory" and eventually the progradational cycle will halt. With passive subsidence, a minimum "lag depth" (the depth required to resume carbonate production) of a meter or two is achieved initiating carbonate sedimentation, and hence a new cycle.

Utilizing typical rates of passive margin subsidence (1–20 cm/1000 years) and known Holocene tidal flat progradation rates (0.5–20 km/1000 years), Ginsburg autocycles can easily prograde across platforms up to 100 km in width within the Milankovitch time band (Hardie and Shinn, 1986). During geologic periods when no continental land masses covered the polar regions, for example the Cambrian and Lower Ordovician, the influence of Milankovitch-forced glacio-eustasy would be minimized, and the feasibility of autocycles would be enhanced.

In clastic systems, autocyclic processes are well-known. For example, in Pennsylvanian mixed clastic and carbonate cycles, autocyclic influences were suggested by Van der Heide (1950) who speculated that compaction of peat layers in clastic portions of cyclothems in the Netherlands could have induced sudden marine transgressions contributing to cyclic deposition. More recently, autocyclic models of delta-lobe shifting have been applied to Upper Pennsylvanian mixed clastic-carbonate cyclothems (Galloway and Brown, 1973; Elliot, 1976).

Recognizing that most of the deltaic deposits occur within the regressive portions of cyclothem, Heckel (1989) viewed autocyclic delta-lobe switching as a subordinate process operating within an overall eustatic framework. Other examples of clastic autocyclicity include fluvial avulsion in nonmarine deposits, channel avulsion in deep marine submarine fan deposits, and so on. Other examples of proposed autocyclic control on cyclic sequences includes Bosellini and Hardie (1973), Matti and McKee (1976), Mossop (1979), and Wilkinson (1982).

(4) Tectonic cycles

Another viable cycle-producing mechanism is that of tectonically dictated cycles. Repeated tectonic pulses of down-dropping and uplift (reversal or "yo-yo" tectonics) could induce meter-scale cyclicity by alternately submerging and exposing (subaerially) shallow shelf areas (Hardie and Shinn, 1986). Episodic, meter-scale down-dropping driven by faulting could also create accommodation space leading to shallowing-upward cycles (Hardie *et al.*, 1991). With both models, the accommodation space required for each cycle would be controlled by meter-scale pulses that might be somewhat rhythmic if a threshold stress must be achieved to induce crustal rupturing (Hardie and Shinn, 1986).

Modern data concerning reversal tectonics is scarce and information regarding recurrence frequency, amount of vertical displacement, and the size of areas involved is lacking. Cisne (1986) has outlined a model of stick-slip faulting at the edges of carbonate platforms that demands a fault-bounded shelf-edge. In this model, the platform edge and the updip area located within a hundred kms of the shelf edge would experience high-frequency crustal oscillations due to reversal tectonics (Cisne, 1986). While this model is intriguing, there is no way of estimating recurrence frequencies and it necessitates block faulting coincident with a platform shelf edge.

Presently, there is sufficient data regarding tectonic forcing through step-wise subsidence to render episodic subsidence a plausible mechanism for the generation of meter-scale sedimentary cycles and larger sequences (Hardie *et al.*, 1991). For example, modern manifestations of coseismic subsidence over large areas (equal to or greater than the size of many carbonate platforms) associated with very large earthquakes are reported along convergent margins and in intraplate regions (Plafker, 1965; Atwater, 1987). Although large areas can be down-dropped a few to several meters, data regarding recurrence frequencies is sparse, suggesting only that recurrence frequencies span the 10–100 ka band (Hardie *et al.*, 1991).

Early proponents of tectonically-driven high-frequency cyclicity include Stout (1931), who interpreted Mid-Continent cyclothem in Ohio as records of periodic down-dropping of the basin, inducing transgression, followed by steady sediment infill (i.e., a form of episodic subsidence). Weller's (1930, 1956) "diastrophic control theory" centered upon alternate pulsating uplift and depression (reversal tectonics) of large continental areas with the magnitude being greatest in the uplands, declining basinward. Periodic episodes of uplift resulted in termination of marine deposition (inferred to occur at the top of a cyclothem), erosion and influx of clastic (nonmarine) material.

Quantitative analyzes of cycles

Our understanding of cyclic sedimentation has been greatly advanced through the use of quantitative analyzes and computer-aided modeling of cycles and sequences. There are basically two approaches: (1) inverse modeling, whereby stacks of cyclic strata are analyzed by some statistical method, rigorous time series or spectral analysis, and graphical techniques for evaluating long strings of cyclic successions; (2) forward modeling, which normally entails computer-assisted simulations of synthetic stratigraphic sections by user-defined manipulation of the stratigraphic governing factors such as eustasy (periodicities, amplitudes, curve shapes), subsidence (rates, curve shape, compaction corrected, etc.), and sedimentation (carbonates, clastics and evaporites, etc.).

Statistical evaluation of vertical facies successions which define cycles has often been invoked (e.g., Merriam, 1964; Duff *et al.*, 1967; Krumbain and Dacey, 1969; Carr, 1982; Davis, 1986) either to assist in defining cycles, or to verify their inferred existence. More recently, (Drummond and Wilkinson, 1993a,b,c; Satterly, 1996; Wilkinson *et al.*, 1997; Lehrmann and Goldhammer, 1999) have employed statistical routines, including runs tests, Durbin-Watson test, and entropy analysis (Hattori, 1976) to evaluate the long-term order of thick stacks of cyclic platform carbonates. The point of such analyzes is to somehow quantify the degree of order in vertical successions of high-frequency cycles. Application of time series and spectral analysis (e.g., Schwarzacher, 1975; Schwarzacher and Fischer, 1982; Weedon, 1989; Hinnov and Park, 1998; Bazykin and Hinnov, 2001) to a succession of cycles enables one to detect superimposed orders of relative sea-level changes expressed as a hierarchy of stratigraphic cycles. The main assumption is that of equal periodicity per cycle and essentially no gaps in the data set.

Perhaps the most popular graphical technique applied to the analysis of cyclic strata is the method of Fischer (1964), coined "Fischer Plots" by Goldhammer *et al.* (1987) and Read and Goldhammer (1988). These plots graphically portray deviations in a successive string of cycles from the mean thickness for the string as a whole (Sadler *et al.*, 1993). Such plots are intended as a graphically-appealing manner by which one can visualize long-term stacking patterns of one-dimensional stacks of cycles, particularly when used in conjunction with cycle-specific facies proportions (e.g., Goldhammer *et al.*, 1993; Kerans and Tinker, 1997). Several workers have used Fischer plots to attempt to correlate third-order cyclic sequences from one part of a basin to another or from one basin to another (Read and Goldhammer, 1988; Osleger and Read, 1991; Montanez and Osleger, 1993).

The development of computer simulation models that simulate synthetic stratigraphy dramatically evolved from rather simple one-dimensional models of the early 1980s (Turcotte and Willeman, 1983; Read *et al.*, 1986; Goldhammer *et al.*, 1987) to sophisticated two- and three-dimensional models through the mid-1990s (Dunn, 1991; Franseen *et al.*, 1991; Miall, 1997). The essential features of these and many other simulation programs are similar in as far as they all allow the user to define a variety of parameters (such as eustasy, subsidence, etc.) according to a variety of rules (e.g., depth-dependent sedimentation, sedimentation driven by diffusion gradients, etc.) and generate synthetic (and often very realistic) output. In this author's opinion, their value lies not in the

precise simulation of a particular section; rather they are invaluable as an educational tool which can aid one in evaluating the effects of certain parameters and the manner in which they interact.

Conclusions

Sedimentary cycles have several important implications for furthering our understanding of the stratigraphic machine, including: (a) as shallow-marine siliciclastic and carbonate (and evaporite) sedimentation normally exceeds background subsidence, such deposits often accrete to sea level, and hence repetitive shoaling sequences (i.e., cycles) record information about relative changes in sea level; (b) high-frequency cycles commonly show remarkable lateral continuity and the cycles, as well as associated unconformities, are normally regarded as synchronous, not diachronous stratigraphic deposits. Thus their potential for stratigraphic correlation should not be overlooked; (c) marine high-frequency cycles often correspond to one relative rise and fall of sea level and cut across lateral facies changes and thus they are high-resolution time-stratigraphic units; (d) if cycles are indeed rhythmic, then cycles can be used to calibrate geologic time, provided the cycle periodicity is known; (e) high-frequency evaporite cycles in marginal-marine and nonmarine settings, and lacustrine cycles record perhaps the clearest record of stratigraphic accumulation driven by ancient climate variations controlled by orbital forcing (Milankovitch theory of climate).

DEBRIS FLOW

A debris flow is a type of sediment gravity flow. It is a rapid mass movement of a concentrated mixture of sediment, organic matter, and water that can flow like a liquid yet can stop on sloping surfaces and form a nearly rigid deposit. Observed debris flows commonly have been likened to flowing masses of wet concrete. Generically, debris flow includes mudflow (debris containing mostly sand, silt, and clay), lahar (volcanic debris flows), and till flow (debris flow from active or stagnant ice).

Debris flows are a significant geomorphological and sedimentological agent in a wide range of geologic and climatic settings. Subaerial debris flows pose a natural hazard that can cause fatalities, damage structures, and diminish land productivity. Subaqueous debris flows can produce turbidity currents, and they can transport sand from continental slopes to abyssal plains, threatening underwater infrastructures and creating important hydrocarbon reservoirs. Modern debris-flow deposits that line numerous mountain channels and blanket many subaerial and subaqueous fans, and ancient debris-flow deposits that form distinctive strata in many sedimentary sequences attest to their widespread sedimentological importance. Although the discussion below describes recent developments regarding subaqueous debris flows, it focuses primarily on subaerial debris flows.

Debris flows have distinctive physical characteristics. They have bulk densities approximately twice that of clear water, and they can easily transport clasts larger than 1 m in diameter. Debris flows have volumes that range from a few tens of cubic centimeters to more than 1 billion cubic meters; they have maximum velocities that range from a few to a few tens of meters per second; they can affect lowlands more than 100 km from their initial source; and they can flow tens to hundreds of km across nearly flat subaqueous plains. A single subaerial debris flow can transport about as much sediment as that transported annually by small mountainous rivers, and it can introduce abundant organic matter (trees) to river channels, modifying channel dynamics and affecting aquatic habitat.

Debris-flow origins

A debris flow forms when a mass of sediment is mobilized and transformed into a flowing slurry. Most commonly, a debris flow results from a landslide triggered by torrential rainfall, rapid snowmelt, or an earthquake, and in subaqueous environments by additional combinations of rapid sedimentation, gas release, and storm-wave loading. A debris flow can form during a volcanic eruption when hot volcanic debris melts and mixes with snow and ice, or when crater lakes or near-surface groundwater are explosively expelled. A debris flow may also form when pore water is expelled during consolidation of a landslide deposit. A rapidly released flood surge, resulting from a glacier outburst or from breaching of a natural or engineered dam, may entrain a sufficient amount of sediment to become a debris flow.

Behavior of flowing debris

A debris flow moves in an unsteady and nonuniform manner. It commonly flows in a series of surges having periods that range from a few seconds to several minutes or longer. Debris surges commonly develop bulbous heads that contain a concentration of the coarsest particles and precede gradually waning, finer-grained bodies, but surges can also have agitated watery flow fronts that precede more sediment-rich waning flow. Despite its commonly coarse grain size, a debris flow can move across very gentle slopes. When a debris flow stops, it commonly leaves a lobate or digitate deposit having a steep terminal snout and coarse-grained, steep-sided lateral levees. A more watery debris flow forms a deposit that drapes valley slopes and terraces and leaves a thin veneer near its inundation limit.

Scientific advances in understanding debris flows

Conceptual mechanics

Concepts and analyses of debris-flow motion and deposition have evolved over several decades. From the 1920s through 1970s, debris-flow studies progressed from descriptive accounts of flows and deposits toward efforts to model flow

behavior and interpret deposit character in terms of material rheology (e.g., a Newtonian fluid, Sharp and Nobles, 1953; a Bingham viscoplastic material, Johnson, 1970, 1984) or particle collisions (e.g., Takahashi, 1978, 1991). Although many studies proposed various constitutive equations that relate shear stress to shear strain rate, support for these models remains largely anecdotal or based primarily upon small-scale laboratory experiments. Small-scale experiments, however, do not necessarily scale appropriately with natural processes. Many laboratory-scale experiments lack gravel and use amounts of silt and clay that are disproportionate for most debris flows. Physico-chemical effects related to cohesion, important at the small scale, are negligible at the field scale, and inertial effects important at the field scale are poorly simulated at the small laboratory scale.

Debris flows undergo significant changes of state from initiation through deposition (Iverson and Vallance, 2001). As a result, others view debris flows as granular materials having flow behavior modified by interstitial fluid (Iverson, 1997). Iverson's research has challenged efforts aimed at describing and modeling a debris flow in terms of fixed rheology. Most debris flows are fundamentally granular materials mixed with water; therefore, Iverson (1997) hypothesized that a debris flow can be modeled most parsimoniously as a simple grain-fluid mixture having properties that depend on position and time. In his model, the Coulomb criterion for frictional material relates shear stress to normal stress, and intergranular pore-fluid pressure that varies with position and time mediates the frictional resistance of the granular debris. Rather than treating a debris flow as a material having a fixed rheology, Iverson's model focuses on conserving mass and momentum in a deformable body and allows debris-flow "rheology" to evolve as a flow forms, moves, and deposits sediment. Iverson and colleagues (e.g., Iverson, 1997; Major and Iverson, 1999; Iverson and Denlinger, 2001) tested Iverson's hypothesis in a series of large-scale flume experiments using up to 10 m³ of poorly sorted sandy muddy gravel. The experiments demonstrate that fluid pressure, solids concentration, and mixture agitation evolve as a debris flow proceeds from initiation to deposition and that the evolution of these variables strongly influences flow dynamics, depositional process, and the characteristics of the deposit.

Depositional process and deposit characteristics

At any given location, debris-flow deposition can occur abruptly or it can be prolonged over a significant time interval. Recent field and experimental studies show that common characteristics of debris-flow deposits, such as poor sorting, massive to stratified texture, and graded to ungraded bedding can result from progressive, incremental accretion rather than exclusively by abrupt *en masse* deposition. Debris flows that are longitudinally segregated—those having coarse flow fronts followed by finer-grained flow bodies, and those that coarsen from head to tail—can produce massively textured deposits exhibiting normally graded or inversely graded clastic fragments (Vallance, 2000). Deposits having pervasive particle alignment, strong vertical changes in particle composition or sorting, and clear evidence of emplacement by recurrent debris surges also result from incremental accretion (Vallance and Scott, 1997; Major, 1997, 1998). Unfortunately, single outcrops of a debris-flow deposit commonly do not display clear evidence of depositional process. Owing to possible

accumulation by prolonged accretion, deposit thickness cannot be used to infer rheological properties of a debris flow, contrary to a common field procedure that assumes deposition by a Bingham viscoplastic material (Johnson, 1984).

Advances in theoretical and experimental studies indicate that flow-margin dynamics play a pivotal role in debris-flow deposition, contrary to previous suggestions that deposition is controlled by intrinsic rheological properties of flow, such as uniform yield strength, or pervasive dissipation of pore-fluid pressure. Iverson (1997) demonstrated that leading edges of experimental debris flows of 10 m³ exhibited little or no positive pore-fluid pressure, whereas trailing flow was nearly liquefied, and he successfully modeled the experimental debris flows by incorporating high-resistance flow fronts dominated by solid forces. Major and Iverson (1999) further demonstrated that high pore-fluid pressure developed within debris-flow interiors during flow initiation and acceleration persisted during flow deceleration and deposition. Deposition of the experimental debris flows was therefore controlled by grain-contact friction concentrated at flow margins that acted as dynamic debris dams rather than by an intrinsic uniform material strength or by pervasive dissipation of high pore-fluid pressure. The dynamic dams that developed in these flows resulted from segregation and concentration of the coarsest clastic material at surge fronts.

Flow-front dynamics affect deposition by submarine debris flows as well as subaerial debris flows. For example, Mohrig *et al.* (1998) observed that the fronts of subaqueous experimental debris flows, composed of nearly equal mixtures of sand and silt, accelerated rapidly and sometimes detached from flow bodies if the flow fronts hydroplaned over the substrate. Hydroplaning occurs when a debris flow cannot displace leading ambient fluid rapidly enough and as a result high basal fluid pressure develops at the flow front. Thus, when high fluid pressure is developed at the flow front, flow resistance markedly declines, a finding compatible with results from subaerial debris-flow experiments.

Sustained high pore-fluid pressure within bodies of debris flows can influence deposit characteristics as well as depositional process. This can be demonstrated by monitoring post-depositional pore-fluid pressure in debris-flow deposits. Major and Iverson (1999) demonstrated that significant dissipation of high pore-fluid pressure in a debris flow occurs only after deposition, except in narrow regions around flow margins, and Major (2000) demonstrated that high pore-fluid pressure in a debris-flow deposit dissipates over minutes to months depending on deposit thickness and material diffusivity. By comparing typical periods of debris surges with characteristic times of dissipation of deposit fluid pressure, Major (2000) demonstrated that freshly deposited debris could be remobilized easily. Deposit remobilization may be preserved as soft-sediment deformation (e.g., Mohrig *et al.*, 1999). However, deposit remobilization may simply mute or obliterate stratigraphic distinction among recurrent debris surges and lead to a homogeneous, incrementally accreted deposit that appears to be the product of a single debris surge.

Regardless of depositional process or depositional environment, all debris-flow deposits share common sedimentological characteristics. In general, debris-flow deposits typically are unstratified, poorly sorted mixtures of sediment ranging in size from microns to meters. Deposits may show little particle-size segregation or exhibit normal or inverse grading of their coarsest fragments. Deposit thicknesses typically range from

several centimeters to several meters. Elongate clasts in deposits may show preferential alignment or imbricate structure, particularly along deposit margins. Deposit termini, where preserved, typically are lobate and have blunt margins that commonly are studded with the coarsest debris. Although deposit interiors may appear to represent deposition from a single debris surge, deposit surfaces can exhibit arcuate ridges, clusters and bands of gravel or sand, and particles that align along debris-surge perimeters, all sedimentologic features that indicate that deposition resulted from emplacement by multiple debris surges.

Debris-flow transformation

Although the composition and size distribution of sediment in a debris-flow deposit is commonly similar to that of the source material, debris-flow character and volume can evolve during transit and result in a deposit having characteristics that are different than those of the initiating flow. After mobilization, a debris flow can entrain channel-bed and bank sediment and increase in volume several fold. Such “bulking”, which usually occurs in steep, proximal channel reaches (e.g., Vallance and Scott, 1997), can modify the initial particle-size distribution and introduce “exotic” clasts into the mixture. In more distal reaches a debris flow can interact with streamflow and undergo volume loss and a gradual transformation into so-called *hyperconcentrated streamflow* (Pierson and Scott, 1985; Vallance, 2000) and eventually into sediment-laden floodflow. A hyperconcentrated-streamflow deposit typically is composed of massive to weakly stratified, moderately sorted sand, and has a sedimentologic texture that is intermediate between those of debris-flow and alluvial deposits (Scott, 1988).

Summary

Researchers have made significant strides developing greater insights regarding debris-flow initiation, transport, and deposition since the 1980s. Studies have moved from descriptions of flow behavior and sedimentologic properties of deposits toward analyses of event frequency and magnitude, development of more realistic mechanical models, and quantification of the subtleties that influence mobilization, transport, and deposition of debris. New insights show that a debris flow can be modeled as a simple grain-fluid mixture having flow behavior that is influenced by distributions of fluid pressure and solids concentration, which evolve with position and time. Characteristics of deposits formerly thought to form only by sudden *en masse* deposition have been shown to develop through prolonged, incremental deposition as well.

DEDOLOMITIZATION

Introduction

The term “*dedolomitization*” refers to the partial to wholesale transformation of former dolomite rocks (dolostones—see *Dolomites and Dolomitization*) to limestones, or partial to complete transformation of dolomite to calcite on the scale of

individual crystals. The transformation process includes both neomorphic replacement (recrystallization—see *Neomorphism and Recrystallization*) of the dolomite by calcite, and dolomite dissolution followed by calcite cementation.

Dedolomitization has been recognized as an important process in the diagenetic histories of a wide range of Precambrian to Phanerozoic marine, and to a lesser extent, lacustrine carbonates. As with dolomitization, dedolomitization histories can be multistaged and protracted. Dedolomitization has also been shown by geochemical modeling to be an ongoing and important reaction in modern-day karstic aquifers (Plummer *et al.*, 1990; Raines and Dewers, 1997).

Dedolomitization process

Several authors have described the dedolomitization process as the reverse but analogous situation to replacement dolomitization (e.g., Fairbridge, 1978; Dockal, 1988). As with dolomitization, dedolomitization involves consideration of thermodynamics, kinetics, and fluid flux. But unlike replacement dolomitization, dedolomitization can also refer to a pore-filling process. Porosity changes associated with dedolomitization are inconsistent and difficult to predict.

Dedolomitization can be represented simply by the following reaction:

The above reaction should proceed to the right if $a\text{Ca}^{2+}/a\text{Mg}^{2+} > 1$ (Abbott, 1974). Ca^{2+} is usually supplied by dissolution of a mineral source, for example gypsum or anhydrite. Mg^{2+} liberated into solution may accumulate, causing the solution to reach saturation with respect to both calcite and dolomite, and thus halting the reaction. Alternatively, dedolomitization may continue until one of the reactants is no longer present if Mg^{2+} is incorporated into another diagenetic phase, or if the fluid flux is sufficiently high that dolomite saturation is not attained. The above reaction reverses, theoretically, when $a\text{Ca}^{2+}/a\text{Mg}^{2+} < 1$ and dolomite is precipitated. The dedolomitization reaction is generally considered to be slow under natural geological conditions, but reactive transport modeling by hydrogeologists has suggested that, in some instances, the process is geologically quite rapid, occurring in hundreds of years.

von Morlot (1847) considered the dissolution of evaporites (gypsum or anhydrite) to be essential in the dedolomitization process, as shown in the following reaction:

Numerous others have also suggested that evaporite dissolution was essential in driving dedolomitization, where the continual addition of Ca^{2+} from gypsum or anhydrite results in the precipitation of calcite due to the common ion effect (e.g., Back *et al.*, 1983; Plummer *et al.*, 1990). Decreases in pH, calcium and carbonate from solution cause further dissolution of dolomite. Back *et al.* (1983) and others, have also suggested that dedolomitization will not occur in low-temperature environments unless gypsum, or some other source of additional Ca^{2+} ions, is present to maintain a high $\text{Ca}^{2+}/\text{Mg}^{2+}$ ratio. Oxidation of pyrite has also been proposed

as a source of aqueous $(\text{SO}_4)^{2-}$ in some situations (e.g., Zenger, 1973). Others have indicated that the presence of $(\text{SO}_4)^{2-}$ is not a prerequisite for dedolomitization to occur (e.g., Stoessel *et al.*, 1987).

Numerous field, petrographic and geochemical studies have supported the conclusion that dedolomitization is a surficial phenomenon, related to post-burial surface weathering and other near-surface processes associated with subaerial exposure, including the development of unconformities and karstic aquifers. Dedolomite often occurs within the most readily weathered parts of the rock and grades into “fresh” dolomite away from weathered surfaces. Dedolomites from near-surface diagenetic settings may show negative carbon and oxygen isotopic values reflecting soil-gas influences in meteorically-derived water, including fluids derived from buried paleoaquifers.

Dedolomitization can occur during deeper burial diagenesis and may be associated with stylolites, hydrocarbons and other late diagenetic mineral phases, including fracture or vug-filling calcites (e.g., Budai *et al.*, 1984). The influence of hydrocarbons may be recognized in light carbon isotopic values of the dedolomite. Light oxygen isotopic values should reflect precipitation at elevated temperatures characteristic of the burial environment. Other authors have noted dedolomitization associated with mixing zones, contact metamorphism and hot Ca-rich brines derived from albitization of plagioclase in nearby sandstones.

Recognition of dedolomite

Limestone formed by dedolomitization may have very little in common with the parent dolostone, or its precursor limestone. In the field, the occurrence of limestone in otherwise dolomitic strata in the vicinity of faults, or along weathered surfaces and below unconformities, may indicate dedolomitization.

A range of microscopic fabrics can be used to identify dedolomitization (Figure D1), although not all are reliable indicators. Empty rhomb-shaped pores indicate dissolution of dolomite and perhaps dedolomitization if it can be shown that calcite once occupied these pores. Calcite partially or entirely filling rhomb-shaped pore space, or replacing dolomite crystals, constitutes the most straightforward evidence of dedolomitization. Differentiation of calcite precipitated as cement versus replacement is made on the same type of textural evidence used to interpret aragonite to calcite transformations. Isolated calcite rhombs may represent very selective dedolomitization because calcite does not commonly develop a rhombohedral habit in limestones. However, exceptions have been reported.

Mosaics of calcite crystals showing rhombic patterns of ferric oxides or other inclusions could represent the palimpsest remnants or “ghost” outlines of former dolomite crystals or internal zoning in these crystals. In some dedolomite rocks, the dedolomite matrix is characterized by a clotted “grumeleuse” texture resembling peloidal grainstone. This fabric results from the retention of impurities from the cloudy, inclusion-rich cores of the original dolomite crystals in the newly formed dedolomite crystals, which otherwise obscure the former dolomite crystal boundaries (Evamy, 1967; Kenny, 1992).

Ferroan dolomites appear to be more susceptible to dedolomitization due to their metastability in the surface environment, resulting in the oxidation and hydration of the ferrous iron previously bound in the dolomite lattice, and a

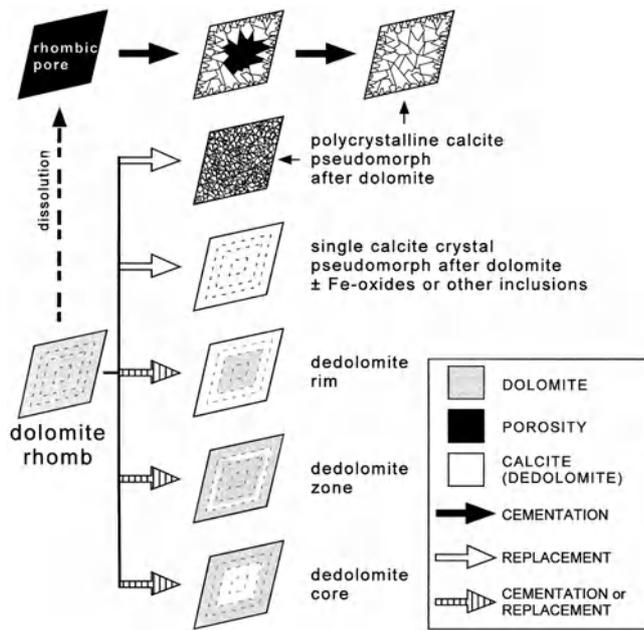

Figure D1 Schematic summary of common dedolomite microfabrics.

close association of hematite and goethite with the newly formed dedolomite. These iron-bearing minerals are usually responsible for the rusty weathering color of many dedolomitized rocks, and they may also retain a secondary chemical remanent magnetization useful for dating diagenetic events. Dedolomitization can also be zone-selective, typically after ferroan or calcian internal zones, rims or cores of dolomite crystals, leaving more stoichiometric dolomite relatively unaltered (Figure D1).

Terminology

Modern usage of the term *dedolomite* typically infers calcite as the mineral occupying the rock volume formerly taken by dolomite, but other minerals, such as quartz, celestite, and iron oxides, are also known to replace dolomite. As terms, *dedolomite* and *dedolomitization* have been criticized as being ambiguous and inconsistent with the nomenclature for other types of mineral replacements, where names of newly formed minerals were based on mineralogy of the replacement, rather than the replaced phase (Smit and Swett, 1969). *Dedolomitization* has also been used as an all-encompassing definition to refer to any alteration affecting dolomite (Fairbridge, 1978). However, the terms *dedolomite* and *dedolomitization*, as used in this article, are well-entrenched in the modern literature and their current meanings are clear.

DEFORMATION OF SEDIMENTS

Introduction

Most sediments undergo some degree of deformation after deposition. Burial under later sediment leads to expulsion of pore fluids and to adjustments in grain packing, involving both physical and chemical processes. The main result is a reduction in thickness of sedimentary units and, in some cases, the development of horizontal fabrics of platy and elongate grains. In the case of fine-grained sediments, containing clay minerals and deposited with high initial porosities, such compactional reduction in thickness can be large so that depositional lamination and bedding are compressed beyond recognition. For coarser sediments, the depositional grain framework usually involves lower initial porosities and a greater resistance to compaction. In the extreme, organic-rich sediments such as peat may undergo compaction to only 10 percent of initial thickness whilst, for well-sorted sands, thickness changes are negligible. Where sediments of contrasting grain size are interbedded in a lenticular fashion, differential compaction can

distort depositional geometries (see *Compaction*). Sediments that have undergone compaction and other diagenetic changes are typically lithified. In this more rigid state, they may be deformed by tectonic processes, most typically compressional folding and thrusting or extensional faulting, often at great depths where temperatures are high and rates of deformation slow. These processes fall within the realm of tectonics and are not dealt with here.

Prior to significant compaction, sediments may be deformed, in appropriate circumstances, soon after deposition and this early, soft-sediment deformation is the subject of this article. Some early deformation is virtually contemporaneous with deposition whilst some occurs because of shallow burial and early compaction. In all cases, the sediment experiences a loss of strength and behaves, for a short period, as a plastic or a fluid. In some cases, loss of strength may result in total remobilization of the sediment and transformation into a gravitational mass movement, leading to a phase of re-sedimentation. This section concentrates on situations where the loss of strength is sufficiently short-lived for sediment to regain its strength and preserve structures that record more or less *in situ* deformation. However, these distinctions are not always clear-cut. Tectonic structures are often geometrically identical with syndepositional structures and boundaries between tectonic stress regimes and more local, sediment-induced regimes may be blurred.

Deformation within a body of sediment occurs when intergranular forces are unable to resist applied stresses, which are usually, but not exclusively, of gravitational origin. The shear strength of sediment is normally expressed by the equation:

$$\tau = C + (\sigma - p)\tan \varphi$$

where τ is shear strength, C is grain cohesion, σ is pressure normal to shear, p is excess pore fluid pressure, and φ is the angle of internal friction. This means that sediment will fail when the applied stress exceeds τ and such a condition will be favored by lower cohesive strength C , by changes in grain packing to reduce $\tan \varphi$ or by pore fluid pressure p increasing beyond some critical value. Such conditions can occur for several reasons, which are discussed below. Failure, when it does occur, may be isotropic, extending throughout the body of sediment or it may be concentrated on discrete surfaces.

Loss of strength

Loss of strength and sediment deformation are most likely in sands and finer-grained sediments. They are rare in conglomerates unless these are very poorly sorted with a high proportion of fine-grained matrix. The presence of fine-grained, especially muddy sediment tends to increase the role of cohesive strength, which is largely a function of grain size; in better sorted, mud-free sediment, frictional forces dominate. In both cohesive and non-cohesive sediments, elevated pore-water pressure is the main means by which strength is lost but that condition can have different causes and durations in contrasting sediments.

In fine-grained, muddy sediments, excess pore fluid pressures are created by relatively rapid deposition. Low permeabilities inhibit escape of pore water and hence sediment compaction, giving over-pressured conditions. In addition, the decay of organic matter within a body of sediment can generate gases, which, if unable to escape, also contribute to pore pressure. Over-pressured conditions can occur close to the

sediment surface where highly mobile mud may be susceptible to deformation or flowage. They can also develop at a larger scale and on a longer timescale within a thick pile of sediments such as that produced by a prograding delta or deltaic margin (e.g., Mississippi, Niger). In such cases, increasing pore-water pressure with burial may eventually exceed lithostatic pressure, leading to failure. This may result in plastic flowage (Fig. D2) of a thick, over-pressured layer or it may result in the development of discrete slip surfaces, which cut up section as listric faults or the bounding surfaces of sediment gravity slides. Such conditions, and the resultant movements, develop and persist over long periods of time, in the case of the largest deltaic margins, over millions of years.

Rapidly deposited sands, lacking significant fine-grained sediment, commonly have rather loose grain packing. They are particularly susceptible to shock, such as might be generated by an earthquake, by heavy wave action, by further rapid deposition or by a sudden rise in water level. Shock breaks grain contacts and induces tighter packing and, as a result, excess pore water will be present, raising the pore-water pressure and causing temporary liquefaction (Fig. D2). The duration of liquefaction will be determined by the rate at which pore water escapes. In the case of sands, high permeability usually means that liquefaction is short-lived. Whilst liquefied, the sediment-water mixture deforms readily as a Newtonian fluid, in response to gravitational and other applied stresses. As pore fluid escapes, usually upward to the sediment surface, grain contacts are re-established as a rising front of reconsolidation “freezes” the deformed sediment. Deformation is usually visualized as the distortion of original depositional lamination but, in the case of extreme or sustained liquefaction and deformation, depositional lamination is destroyed and structureless sand or slurried textures are produced. Upward movement of escaping pore water may also create deformation, both by distorting depositional laminae and by creating new vertical structures such as dishes, pipes and sheets within which sediment-water mixtures move as fluidized flows (Fig. D2).

Deforming forces

Virtually all the forces that act upon sediment weakened by the above processes are gravitational in origin. These can be divided into two major classes, a down-slope component of gravity and the action of gravity on inverted density gradients. In addition, deforming forces can also be produced by shear at the sediment surface caused by flowing water, ice and sediment gravity flows.

Where muddy sediment occurs on a slope, the down-slope gravitational component may be sufficient to overcome its cohesive strength. This can lead to both detachment of a slab of sediment on a basal shear surface and to internal deformation within the moving layer. The style of deformation will vary depending upon the position within the moving sheet. Stretching, particularly in the up-slope end, may lead to tensile failure and to the development of brittle extensional structures whilst compression, commonly in a down-slope setting, causes plastic folds. These styles of deformation are associated with a family of mass movements (see *Mass Movement; Slide and Slump Structures*). Also partly driven by down-slope gravitational components are sedimentary growth faults. These are related to failures in deeply buried over-pressured muds. Extension on the faults is also driven by lateral flowage

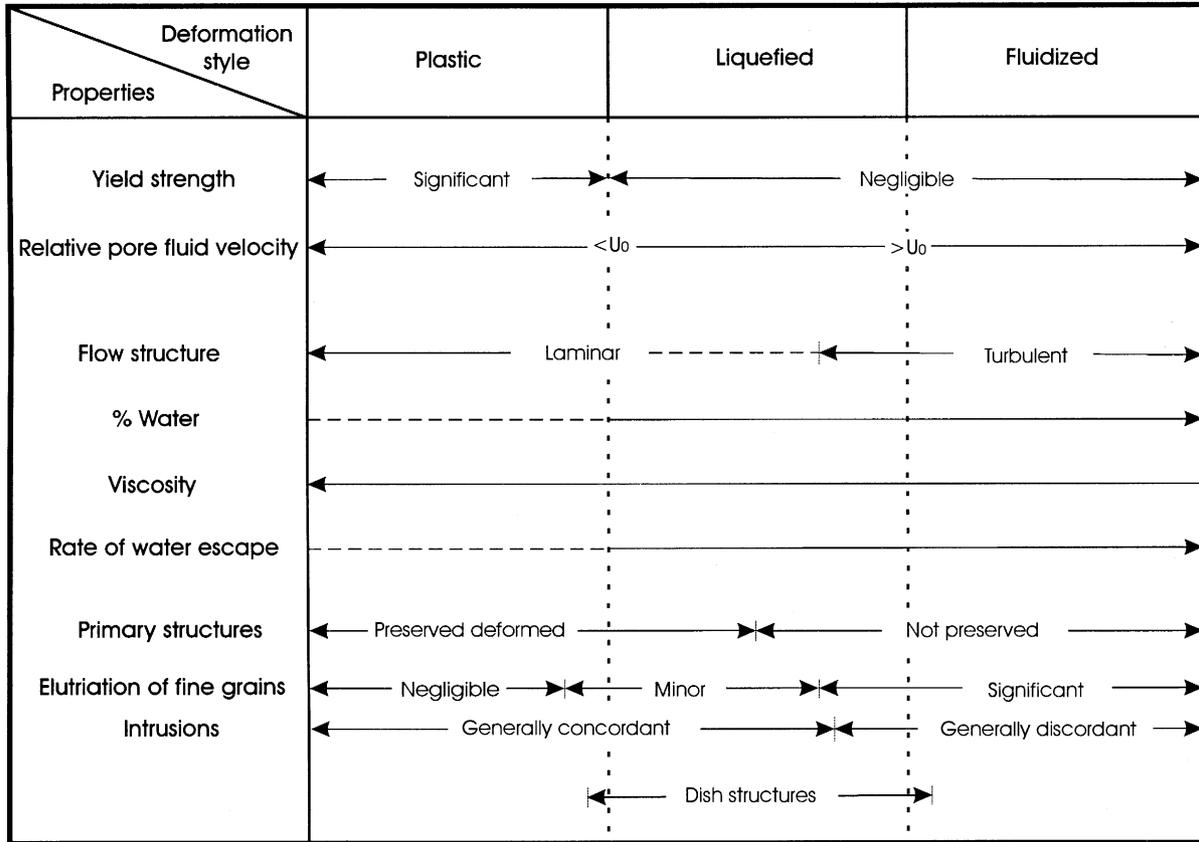

Figure D2 Main processes of sediment deformation, the associated characteristics and the resultant effects and products. Based on Lowe (1975).

of those muds due to vertical loading by the overlying sediment pile.

Density inversions occur commonly, as a result both of depositional processes and of early loss of pore water. A sand layer, deposited on mud, will commonly have a higher density than the mud and, if the mud is sufficiently weak, the instability may lead to loading of sand into the mud (see *Load Structures*). Where the sand is of uneven thickness, as with ripple lenses or erosional sole marks, loading may be concentrated where the sand is thickest. Extreme cases of loading show detached balls of sand, usually encased in slurried mud or silt.

Within liquefied sand layers, which commonly result from shock, patterns of density inversion may be more subtle. Internal depositional lamination may be contorted in convolute lamination (*q.v.*) some of which reflects the upward escape of water or low-density sediment-water mixtures. Very rapidly deposited sands may lack depositional lamination and undergo liquefaction as part of the depositional process. De-watering of such sands and the associated elutriation of fines can lead to the development of subtle structures such as dish structures and water-escape pillars and pipes.

Deeper burial and associated differential compaction due to gravitational loading may lead to deformation of larger-scale depositional geometries. The cross-sections of channel sand-bodies, in particular, are susceptible to change from

planar-convex forms to concavo-convex patterns where encased in muds. Where channel sands are encased in mud, as in some deep-water depositional settings, de-watering of the muds during burial can lead to high pore-water pressures in the sands. This can eventually lead to rupture of the mud seal and to injection of liquefied sands as sills and dykes (see *Clastic (Neptunian) Dykes and Sills*). When injection occurs close to the sediment surface, liquefied sand may be extruded as slurry flows or as sand volcanoes.

Where sands are deposited by powerful currents as dunes or sand waves, they may be susceptible to liquefaction as a result mainly of rapid deposition on the lee slope of the bed form. If this happens whilst the current is still active, the cross-bedded sands, developed by lee-side deposition, may be sheared and the foresets dragged into folds, giving overturned cross-bedding.

The movement of ice over unconsolidated sediment also generates large-scale and intense deformation of those sediments. This occurs near the front of a glacier, where glacial advance operates as a bulldozer to fold and thrust proglacial deposits. In addition, basal layers of a mobile glacier may be rich in sediment and shearing across the basal layers can lead to intense deformation though the rheology has more to do with the plastic deformation of ice than with processes of liquefaction or sediment cohesion.

DEFORMATION STRUCTURES AND GROWTH FAULTS

This section deals with so-called soft-sediment deformation. It documents how different types of deforming stress, acting on sediment that has been temporarily weakened, lead to a range of deformational structures. The physical processes are described in more detail in the section on *Deformation of Sediments*. The structures themselves do not fall naturally into well-defined classes but Figure D3 shows a scheme, which helps to relate structures to processes. This diagram illustrates interactions between different causes of loss of strength and deforming forces and shows that processes are gradational with tectonic deformation and with re-sedimentation. It shows the wide range of scales across which deformation can occur, from micro-loading to growth faults at the scale of continental slopes and highlights differences in timing and duration of deformation. Structures that form during deposition, such as overturned cross-bedding, contrast with structures dependant upon significant later burial, such as growth faults. The most common deformation structures are described below, roughly in order of increasing scale but moderated by considerations of process. Several are described in more detail in other sections.

Load casts and pseudo-nodules

These distortions occur at the interface between a mud layer and an overlying sand layer. Downwards-facing bulbous load casts of sand are separated by upward-pointing flame

structures of mud. Some occur on otherwise flat bedding surfaces whilst others accentuate erosional or depositional irregularities. In extreme cases, sand may be detached from its source bed and occur as isolated load balls or pseudonodules (*q.v.*) within highly disturbed muds or silts. Internal lamination within both sand and mud is highly contorted. Loading is caused by gravity acting on an unstable density stratification where the sand layer is denser than the muds and where both layers are weakened by excess pore fluid.

Convolute lamination

This commonly occurs within sand or silt units and involves distortion of depositional lamination by folding of variable intensity. In some cases, the folding is chaotic whilst in other cases upward movement of escaping water has dragged lamination into upright folds. Cuspate folds with sharp anticlines and more rounded synclines are typical. In many cases, depositional lamination can still be identified, commonly cross-bedding or cross-lamination. The good sorting and high porosities of eolian sands makes them particularly susceptible to liquefaction (*q.v.*) when water table rises rapidly through them.

Convolute lamination (*q.v.*) is a common feature of turbidite sandstones, often associated with ripple laminated (Bouma C) interval of internal lamination. Some of the largest examples occur in eolian sands where a rising water table has caused instability. All examples reflect liquefaction of the sand, which can happen for a variety of reasons, including seismic shock, rapid sedimentation, breaking waves or a shift of water table. Where seismic shock was the cause of liquefaction, deformed layers may have very widespread distribution. Upward escape of excess pore water, internal density inversions and down-slope components of gravity may all contribute to deformation. De-watering leads to reconsolidation of the sediment from the bottom up, “freezing” the deforming laminae. Protracted liquefaction may lead to total homogenization.

Overtaken cross-bedding

Overtaken cross-bedding is a special case of convolute lamination where liquefaction occurred in an actively migrating bed form. Current shear on the sediment–water interface dragged the liquefied sand in a down-current direction in an essentially laminar style. An upward migrating front of reconsolidation allowed higher parts of the sediment to be sheared longer, giving down-current facing recumbent folds.

Dish and pillar structures

These structures, which are most common in thick, otherwise massive sands, result from rapid de-watering following rapid deposition. Dish and pillar structures (*q.v.*) are direct products of de-watering and are not distortions of pre-existing lamination. Dish structures are thin concave-upward, sub-horizontal zones of slight clay enrichment produced by local filtering out of the elutriated fines. Their upturned edges merge with pillar structures, which are vertical conduits of water escape and record fluidized or near-fluidized conditions.

Figure D3 Styles of sedimentary deformation classified in terms of the interaction between the cause of loss of strength and the applied deforming force. Adapted from Owen (1987).

Sand injection structures

Where a sandbody is encased in mud and progressively buried, compaction and de-watering of the muds can lead to overpressure in the sands. If the fluid pressure exceeds the tensile strength of the overlying mud, rupturing occurs and complex networks of dykes and sills of liquefied sand are intruded into the muds. This is quite common in channel sandbodies in deep-water and slope settings though outcrop examples are rare.

Small-scale injection dykes occur in mudstones of inter-bedded sandstone and mudstone successions. These may be folded tectonically because of differential compaction. Sand within dykes is typically structureless though some examples show foliation parallel with dyke margins.

Sand volcanoes and extruded sheets

Some upward-intruding liquefied sand, both dykes and pipes, penetrates to the free sediment surface where it is extruded. Where the escape conduits are pipes, sand volcanoes form, at scales from a few centimeters to a few meters. Where the intrusions are dykes, fissure extrusion occurs and liquefied sand may flow as sheets before de-watering and “freezing”. Where sand dykes penetrate muddy debris flows, extruded sand may become inter-folded with the upper levels of the debris flow.

Desiccation and other cracks

When surface layers of mud or silt dry out they contract and create isotropic horizontal tension. If this exceeds the tensile strength of the mud, polygonal (commonly hexagonal) cracks

develop which may be filled with wind-blown or water-lain sand. Dimensions of polygons are a function of mud layer thickness, and several scales may coexist. Sub-aqueous shrinkage of surface mud layers also leads to cracks though these often form less regular patterns. They are thought to result from volume changes of clays within the surface layer. Large-scale polygonal cracks also develop through protracted freeze-thaw processes in periglacial settings.

Slumps and slides

Gravitational body forces acting on sediments lying on a slope lead to slumps and slides where cohesive (plastic) and tensile (brittle) strengths are exceeded. In both types of movement, most shearing is concentrated on discrete basal surfaces. They differ principally in their internal deformation. Slides are essentially undeformed but may have internal faults whilst slumps show plastic folding. The two styles commonly co-exist in the same mass movement. Internal deformation falls short of the total mixing and homogenization that characterizes debris flows but both slumps and slides may develop into such flows.

Mud diapirs

Overpressure develops where muds are buried quite rapidly, as in a prograding delta. The resultant loss of strength and the significant overburden lead to both vertical and horizontal flowage of the muds. Where the overlying sediment is denser than the mud, as in an upward-coarsening deltaic succession, mud may rise vertically as a diapir or mudlump, pushing aside or penetrating mouth-bar sands. In the Mississippi delta, mudlumps rise to sea level and create short-lived islands

offshore the distributary mouths. Mud diapirs lead to very variable thicknesses in the mouth bar sands, which thicken into withdrawal synclines between diapirs.

Horizontal flowage of overpressured muds leads to extrusion of muds at the base of the prograding slope as imbricate thrusts and folds. The same motion is partly responsible for extensional stresses that drive sedimentary growth faults in deltaic successions.

Growth faults

Sedimentary growth faults occur in many deltaic successions. They are large-scale features and commonly require exceptional exposures to be readily identified at outcrop. In small exposures, they may be confused with later tectonic faults though a lack of mineralization and sediment smearing on the fault plane may suggest a syndepositional origin. Growth faults are more commonly imaged in seismic data where upward truncation by overlying undisturbed sediments can be a criterion for their recognition. They are caused by shear failure at discrete surfaces within the sedimentary pile, and they commonly occur as listric surfaces that sole out on a basal decollement. In smaller examples, confined within a single progradational cycle, the basal surface may be a thin bed of particularly fine-grained mudstone. In larger examples, which penetrate several progradational units within a delta complex at a continental margin, the decollement may be within a thick interval of overpressured muds. Lateral flowage of those muds toward the free surface slope and gravitational forces on the hanging wall block both help to drive the movement of that block down slope. Growth faults are characterized by slow and continual movement and are aided by progressive sediment loading. Their hanging wall areas act as local depocenters in which thickened delta-front sediments are deposited and preserved. With continued progradation of individual deltas or of the continental slope the position of active faulting shifts progressively basinwards.

Large-scale examples imaged on seismic at continental margins show complex fault geometries with both synthetic and antithetic fault elements. In plan, the major faults have cusped traces, concave toward the basin. Protracted fault movement and the listric geometry of the faults leads to roll-over anticlines in the hanging walls which may be important hydrocarbon traps as they also coincide with enhanced reservoir thickness. Clay smearing on the fault surfaces may enhance the hydrocarbon seal.

DELTA AND ESTUARIES

Definition of a delta

A delta is a discrete bulge of the shoreline formed at the point where a river enters an ocean, sea, lake, lagoon or other standing body of water (Figures D4 and D5). The bulge is formed because sediment is supplied more rapidly than it can be redistributed by basal processes, such as waves and tides. Deltas are thus fundamentally regressive in nature, which means that their deposits record a seaward migration or progradation of the shoreline. The term delta has also been used to describe any regressive deposit built by any terrestrial feeder system into any standing body of water (Nemec, 1990 in Colella and Prior, 1990). In this scheme, terrestrial feeder systems can be alluvial (rivers, alluvial fans, braidplains, scree-cones) or non-alluvial (volcanic lavas or pyroclastic flows). The terms ebb- and flood-tidal delta have also been generally applied to sediment accumulations that form around tidal inlet channels in barrier-lagoon depositional systems (see *Tidal Inlets and Deltas*), but these do not fit the above definition of a delta because they are not linked to a river or terrestrial feeder. This entry focuses on river deltas as a discrete depositional system in which both environments and their deposits will be described.

Definition of an estuary

Sedimentologists define an estuary (Figure D5) as the seaward portion of a drowned river valley which receives sediment from both fluvial and marine sources (modified after Dalrymple *et al.*, 1992). An estuary may be affected by tide, wave, and river processes and is defined as extending from the landward limit of tidal influence to the seaward limit of coastal influence.

The term estuary is also defined on an oceanographic basis as a semi-enclosed body of marine water that is measurably

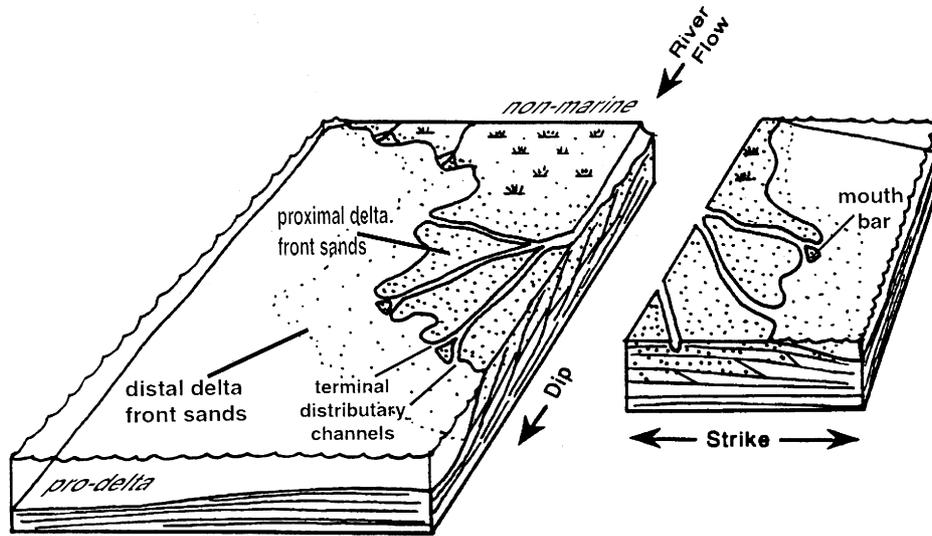

Figure D4 Block diagram of a lobate, river-dominated delta showing numerous channel bifurcations. Terminal distributary channels fed triangular-shaped mouth bar deposits. Seaward progradation forms a series of offlapping inclined strata in dip-view. The strike view shows a lens-shaped sediment body with beds dipping away from the depositional axis of the delta lobe.

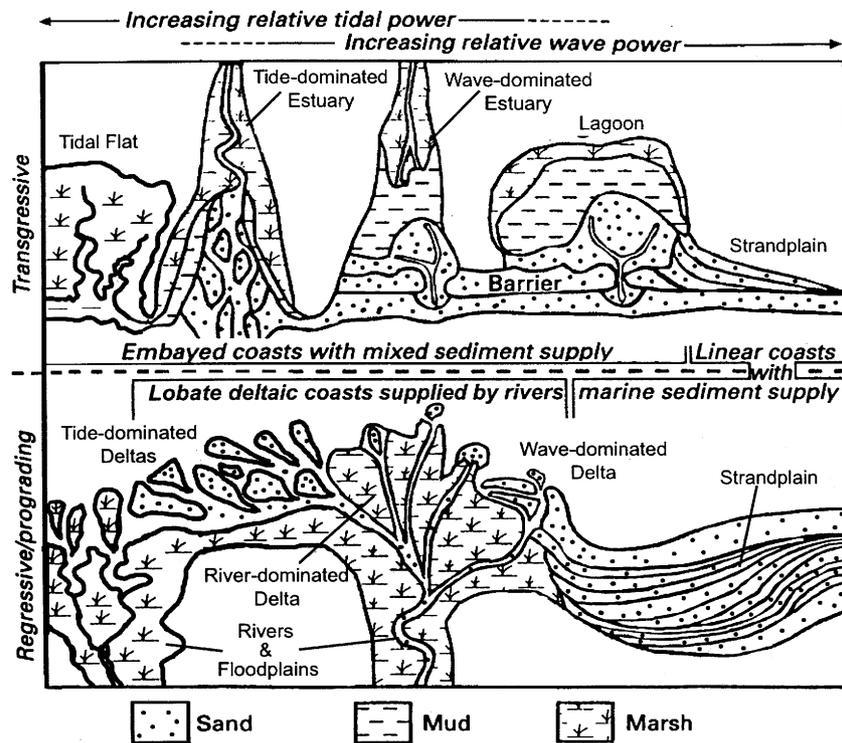

Figure D5 Comparison of regressive versus transgressive coastal depositional systems. Deltas form lobate sediment bodies. The character and distribution of sediment in a delta is highly sensitive to the relative proportion of wave, tide, and fluvial processes. Differences in these processes result in different shaped sand bodies. Also, note river-dominated delta at the head of the wave-influenced estuary. Deltas can thus form smaller components of other types of coastal depositional systems. Changes in sediment supply and sea level change can cause one type of depositional system to evolve into another type (modified from Reading and Collinson, 1996 based on Heward, 1981, and Boyd, Dalrymple, and Zaitlin, 1992).

diluted by land-derived fresh water (Pritchard, 1967; Nichols and Biggs, 1985). Sedimentologists tend to reject this usage as being too broad since it includes all brackish water environments including lagoons and many marine-influenced delta fronts which are not generally thought of as estuarine by sedimentologists. The etymology of the word estuary also means tides, so by definition all estuaries are formed adjacent to a marine body of water. There are no entirely fresh-water estuaries because measurable tides do not occur in lakes. Consequently, drowned river valleys filled during rising lake levels are not generally considered as estuarine.

In an estuary, the seaward portion of the valley is filled with marine sediments and estuaries are fundamentally transgressive in nature, unlike deltas, which are regressive. Deltas and estuaries are not mutually exclusive, however, because regressive bayhead delta deposits can readily form within the up-valley reaches of an estuary (Figure D5). In this case, the delta deposits would form a minor component of a larger, overallly transgressive estuarine valley-fill. If fluvial discharge became high enough to "flush out the valley" and begin to form a broadly regressive deposit then the estuary would evolve into a delta.

Estuaries form by the interaction of waves, tides and fluvial processes. Two end members have been described (Figure D5). In tide-dominated estuaries (such as the Bay of Fundy in Nova Scotia, Canada) the mouth of the estuary is kept open by strong tidal currents. The center of the estuary tends to be dominated by sandy bedforms and tidal bars whereas the margins tend to be muddy tidal flats. In wave-dominated estuaries, the mouth of the estuary is partly closed by a wave-formed barrier island. A brackish lagoon or bay lies behind the barrier and is commonly filled with fine-grained mud. At the head of the bay, fluvial or tide-influenced bayhead delta deposits form, which may be sandy or muddy. Mud accumulates primarily in the so-called "central basin" bounded by the barrier and bay head delta.

Distinguishing deltas, barriers, estuaries, and strandplains

Most of the sediment in a delta is derived directly from the river that feeds it; in contrast with estuaries in which much of the sediment is derived from the marine realm and in which deposits are fundamentally transgressive. In barrier-island systems (Figure D5), sediment is supplied by alongshore transport. Alongshore transport occurs because waves approaching the shoreline are deflected and migrate parallel to the shoreline causing longshore drift. The longshore drift system may carry sand and gravel, which can be deposited as linear shoreface deposits, or they may carry large quantities of fluidized mud that can be deposited to form muddy coastlines. In mud-dominated coastlines, silt, sand, or shelly material may be winnowed out in the intertidal zone, forming thin and narrow beach deposits termed cheniers. Barrier-islands may also form components of wave-influenced deltas. Rivers can act as a baffle or groin that causes sediment carried in the longshore drift system to be deposited on the updrift side of the distributary channel (see wave-dominated delta in Figure D5).

Where basinal processes redistribute sediment to the point that the fluvial source and delta morphology can no longer be recognized, more general terms such as paralic, strandplain or coastal plain may be preferable.

Scale and importance of deltas

Deltas occur at a wide variety of scales ranging from basin-scale depositional systems, such as the modern Mississippi delta with an area of about 28,500 km², to smaller components of other depositional systems, such as bayhead deltas within estuarine or lagoonal systems. Many large deltas, such as the Danube in Romania and the Mississippi in the Gulf of Mexico, contain several scales of delta lobes associated with the fact that as a channel splits into several smaller channels, each new channel can feed its own lobe.

A large number of the earth's peoples live on or near deltaic coastlines and they are thus important from an environmental perspective. Ancient deltas are also economically important because they are commonly associated with major coal, oil and gas reserves. As a consequence, much has been written about deltas, although there is still much interest in new delta research. There has recently been an increase in documented examples of delta types that have been historically lacking, such as tide-influenced systems (e.g., Maguregui and Tyler, 1991; Reading and Collinson, 1996; Willis *et al.*, 1999). Readers are referred to several summaries for general information on deltas (Reading and Collinson, 1996; Bhattacharya and Walker, 1992; Colella and Prior, 1990; Whateley and Pickering, 1989; Coleman and Prior, 1982; Broussard, 1975) and estuaries (Nichols and Biggs, 1985; Dalrymple *et al.*, 1992; Dalrymple *et al.*, 1994).

History of delta research

Historical overviews of delta research are provided by Bhattacharya and Walker (1992) and Reading and Collinson (1996) and summarized here. The concept of a delta dates back to the time of Herodotus (*c.* 400 BC) who recognized that the alluvial plain at the mouth of the Nile had the form of the Greek letter Δ. The first study of ancient deltas was that of Gilbert, 1885 (see Bhattacharya and Walker, 1995), who described Pleistocene fresh-water gravelly deltas in Lake Bonneville, Utah. Gilbert recognized a threefold cross-sectional division of a delta into topset, foreset and bottomset deposits (note sigmoidal stratal geometry in Figures D4 and D7). Barrell (1912 *ibid.*) extended these subdivisions to the much larger scale of the Devonian Catskill wedge in the Appalachians, and also provided the first explicit definition of the essential features of an ancient delta deposit. Barrell considered the recognition of overlying nonmarine facies crucial in recognizing ancient deltas, although recent research demonstrates that in a significant number of deltas, non-marine topset facies may not be preserved (e.g., Bhattacharya and Willis, 2001). Barrell actually wrote his 1912 paper in order to address what he perceived as an over-application of an estuarine interpretation to many ancient sedimentary successions that contained a marine to non-marine transition and that he believed should be better interpreted as deltas.

The Mississippi river and its deltas have long been a focus for understanding continental-scale delta systems (see summary of early papers by LeBlanc, 1975). Scruton (1960, see LeBlanc, 1975) recognized that deltas are cyclic in nature and consist of a progradational constructive phase usually followed by a thinner retrogradational destructive phase coinciding with delta abandonment. He also illustrated a vertical facies succession of coarsening- and sandier-upward facies related to the progradation of bottomset, foreset and topset strata

(Figure D7). Kolb and Van Lopik (1966, see LeBlanc, 1975) summarized much of the work that described the way in which the Mississippi river constructed its delta plain over the past 9000 years, suggesting that the development was autocyclic. This work was critical in establishing the idea that apparently cyclic vertical successions of sedimentary strata can result from the intrinsic way in which river channels naturally avulse and cause switching of delta lobes.

Coleman and Wright (in Broussard, 1975) compiled data on 34 modern deltas and developed a sixfold classification based on sand distribution patterns. One of the most widely used classification schemes still used today is that of Galloway (in Broussard, 1975), who subdivided deltas according to the dominant processes controlling their morphology; rivers, waves and tides (Figure D5). This scheme has since been expanded to include grain calibre (Orton and Reading, 1993; Reading and Collinson, 1996). This scheme has also been extended to show how deltas, estuaries and barrier-lagoons may evolve into one another in the context of changing sea-level and sediment supply (Dalrymple *et al.*, 1992).

Improvements in seafloor-imaging and seismic data acquisition led to the recognition of the abundance and importance of syndimentary deformation in the subaqueous parts of modern deltas (Coleman, Prior and Lindsay, 1983; Winker and Edwards, 1983; Bhattacharya and Walker, 1992). Similar features have now been recognized in ancient deltas (e.g., Bhattacharya and Davies, 2001).

More recently the evolution of modern deltas has been interpreted in the context of sea-level changes and plate tectonics, rather than just sediment supply (e.g., Dominguez *et al.*, 1987; and Boyd, *et al.*, 1989; see Bhattacharya and Walker, 1992; Hart and Long, 1996). This resulted in widespread abandonment of the idea that apparently cyclic sedimentary successions are autocyclic, but rather are controlled by allocyclic processes such as subsidence, sea level change, and climate change (see *Cyclic Sedimentation*). Integration of basin-scale seismic stratigraphic concepts with ideas about cyclic sea-level change were applied to many ancient deltas in the development of *sequence stratigraphy* (e.g., Galloway, 1989; Van Wagoner *et al.*, 1990; Bhattacharya, 1993). More recent work is beginning to elucidate the nature of tide-influenced deltas that have heretofore been under-recognized in ancient sedimentary rocks because of lack of well-studied modern or ancient examples (e.g., Maguregui and Tyler, 1991; see Reading and Collinson, 1996; Jenette and Jones, 1995; Willis *et al.*, 1999).

River mouth processes

A delta forms when a river of sediment-laden freshwater enters a standing body of water, loses its competence to carry sediment, and deposits it. Much of the active sand deposition occurs in distinctive *tributary mouth bars*, formed directly at the mouth of the channel (Figure D6). The mouth bars form naturally as a consequence of the decrease in discharge and bed shear stresses associated with the loss of flow competence, although very little work has been done that quantifies the mechanics of how mouth bars scale to the flow behavior at the river mouth. River mouths may be deflected downdrift by waves and can be scoured and modified by tidal currents (Figure D5).

The general form of the deltaic deposit depends upon (1) whether the river outflow is more dense (*hypopycnal flow*),

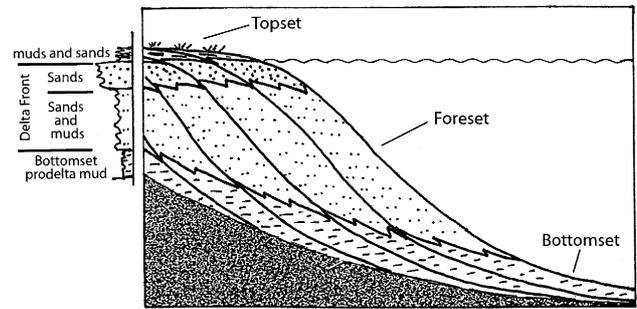

Figure D6 Seaward migration (termed progradation or regression) of a delta builds an upward coarsening facies succession, that shows a transition from marine into nonmarine topset deposits (modified after Scruton, 1960). Topset facies may be eroded by waves as the sea floods back over the land during transgression.

equally dense (*homopycnal*) or less dense (*hypopycnal*) than the standing body of water (Figure D6), and (2) the extent to which the deposits are reworked by wave and tidal processes, although tidal processes are insignificant in lakes. At any given river mouth, inertial, frictional and buoyant forces may be operative in varying proportions (Figure D6). In hyperpycnal deltas that have exceedingly high sediment concentrations at the river mouth, the slurry-like mixture of sediment and water just keeps on moving downslope as a sediment gravity flow (see sediment gravity flow). These sediments can end up being deposited in deepwater systems. Hyperpycnal rivers tend to be small and/or “dirty” such as the modern Sepik River, in Papua New Guinea, the Eel River in Northern California, and the rather larger Yellow River (Yangtze) in China (Mulder and Syvitsky, 1995). In hypopycnal settings buoyant, less dense fresh water rides over a marine salt-wedge and carries suspended mud far offshore. Sand tends to be segregated and deposited at the mouth of the channel as a distinct sandy mouth bar with muddier sediments deposited farther offshore in the prodelta area (Figure D6). In homopycnal deltas a great degree of mixing occurs and frictional forces cause rapid deposition of all of the mud, sand, and/or gravel carried by the river (Figure D6). This results in deposition of a large poorly sorted “Gilbert-delta”-type mouth bar commonly with angle-of-repose foresets (Figure D6).

Rapid sedimentation in all delta types can cause sediment instability at the river mouth (see *Synsedimentary Structures and Growth Faults*). Slumping commonly occurs after the mouth bar builds up to a slope that exceeds the failure threshold. Mouth bars are especially susceptible to failure because of the high amount of water trapped within the sediment that causes high pore pressure. Slumped sediment at the river mouth can evolve into various types of sediment gravity flows and are an important way of providing sediment to the deep oceans.

Many rivers will experience dramatic changes in discharge as a function of seasonal climate change or as a result of major storms. Sediment discharge and sediment calibre of the river plays an important role in determining the sediment concentration discharged at the river mouth (Figure D6). These changes in sediment concentration can cause a river to change from hypopycnal to hyperpycnal, even in fully marine settings (Mulder and Syvitsky, 1995). Recent work has attempted to distinguish the relative importance of these processes in

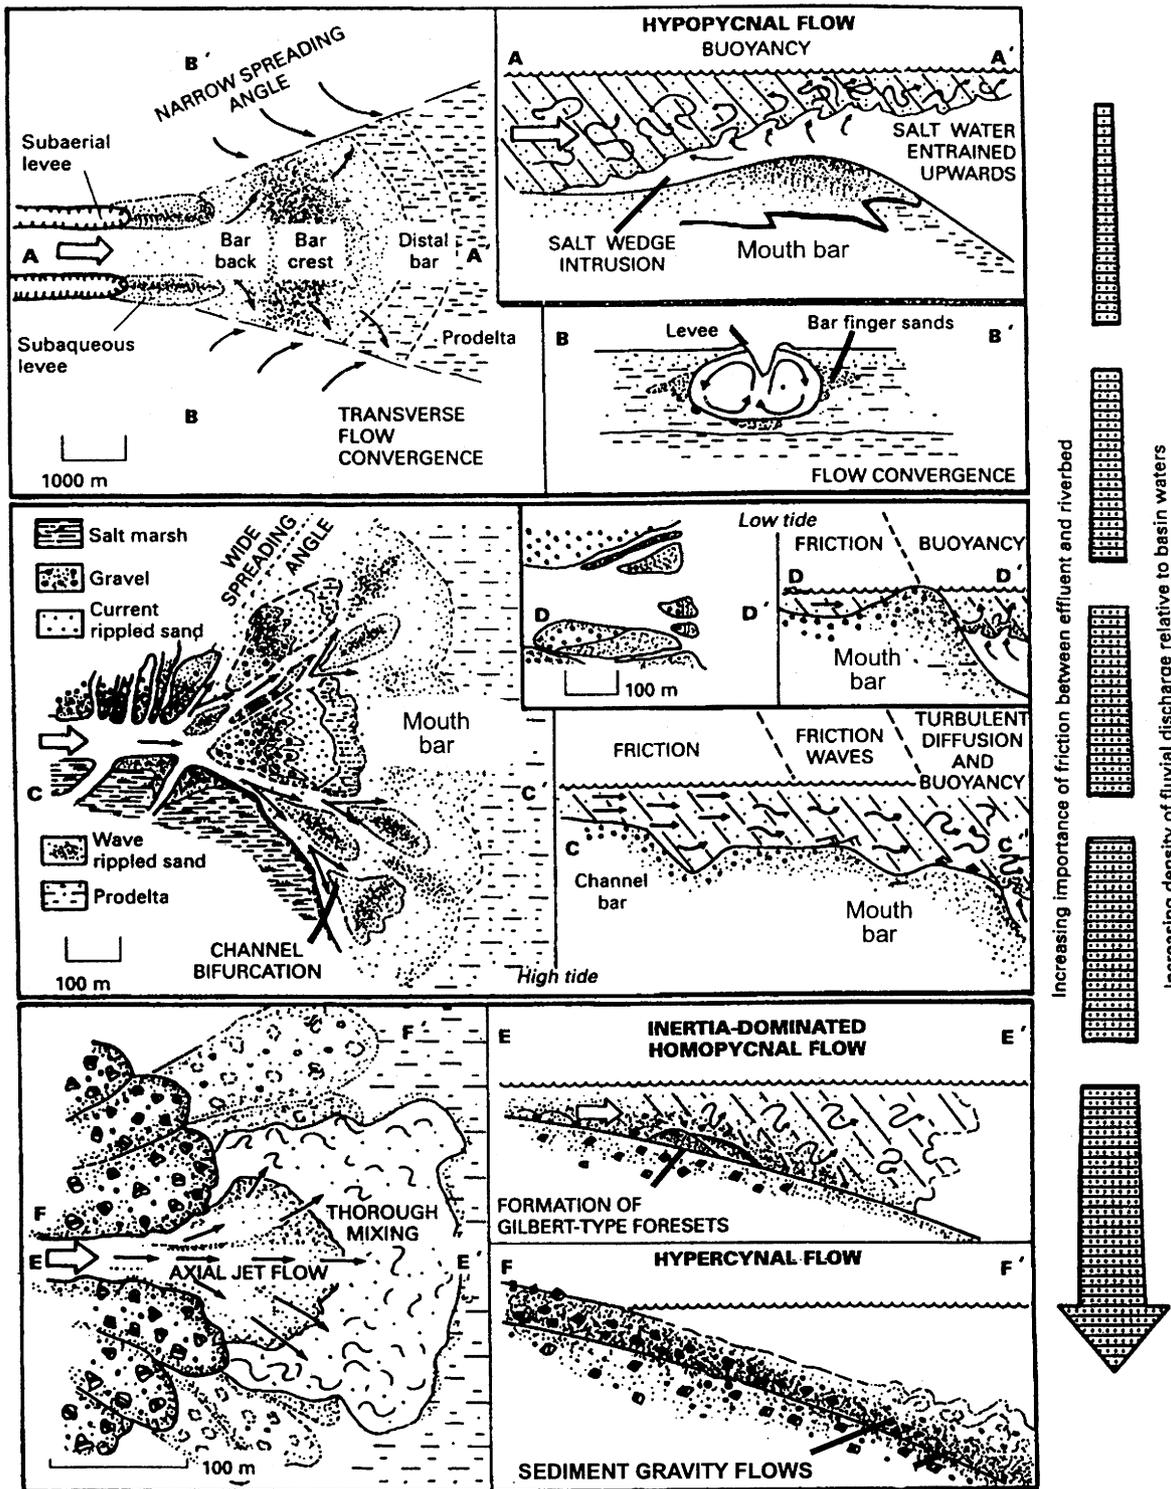

Figure D7 River Mouth processes and their deposits. Hypopycnal flow (top panel) is defined where inflowing water (typically fresh) is less dense than water in the receiving basin (typically saline). This favors the formation of a salt wedge and elongate bar-finger type mouth bars. The less dense fresh water is buoyed-up by the denser seawater and mud is carried far offshore. These delta fronts are typically referred to as buoyancy dominated. As the sediment becomes coarser-grained (middle panel), more friction is generated. This is common where the density of inflowing and receiving waters are the same (homopycnal) such as in many lacustrine deltas and in rivers with high sediment loads. These delta fronts are sometimes referred to as friction-dominated and favor development of triangular (radial) mouth bars. In rivers with exceptionally high sediment concentrations (lower panel), especially small muddy rivers, hyperpycnal conditions may result. In these cases, sediment-laden water is more dense than water in the receiving basin. The inflowing mixture of water and sediment may have enough inertia to continue flowing down the sea bed as a sediment gravity flow. These types of delta fronts are said to be inertia-dominated. These types of deltas may be linked to deep water depositional systems and provide a means of supplying sediment to submarine fan deposits. These mouth bar types are not mutually exclusive. Rivers can change from hypopycnal to hyperpycnal as discharge increases during exceptional flooding events and the degree of buoyant, frictional and inertial forces can vary across a bar (middle and lower panel). Modified after Reading and Collinson, 1996, based on Orton and Reading, 1993.

classifying ancient river mouth sediments (e.g., Martinsen, 1990; see Reading and Collinson, 1996).

River mouth processes can also be important in the autocyclic process of river avulsion that results in delta lobe switching. In this process, the river builds a large deltaic edifice that creates enormous form friction at the mouth of the river. This friction causes a loss of discharge at the river mouth. In addition, the river extends seaward, which decreases the effective slope. The loss of discharge and decreasing slope propagates upstream and eventually causes the river to avulse.

At a more local scale, friction at the river mouth may cause upstream deposition of sand. In a study of Cretaceous-age growth faulted deltaic strata in Utah, growth faults initiate both upstream and downstream as the loci of rapidly deposited sands shift (Bhattacharya and Davies, 2001).

Delta environments

No one environment is characteristic of a delta. In plan view, deltas comprise three main environments: the delta plain (where river processes dominate), the delta front (where river and basinal processes are both important) and the prodelta (where basinal processes dominate). In cross-sectional views, these three environments roughly coincide with the topset, foreset and bottomset strata of early workers (Figure D7).

Delta plains usually contain distributary channels and a wide variety of nonmarine to brackish, paralic environments including swamps, marshes, tidal flats, and interdistributary bays (Figure D4). The line that demarcates the landward limit of tidal incursion of seawater is referred to as the bay line and marks the boundary between the upper and lower delta plain. In ancient settings, the bay line may be indicated by the landward limit of marine or brackish-tolerant fossils or trace fossils. Lacustrine deltas have no bayline as such, since there are no significant tides in lakes.

Many deltas contain distributary channels that show different sizes and shapes in different positions on the delta. There is therefore no such thing as "a distributary channel" in many deltas. Typically, a trunk fluvial system will first avulse at the point where the river becomes unconfined forming a nodal avulsion point (Mackey and Bridge, 1995). Delta plain channels tend to be few in number and are separated by wide areas of interdistributary bays, swamps, marshes, or lakes in the upper delta plain, although these interdistributary areas can be replaced with channel deposits depending on the avulsion frequency (Mackey and Bridge, 1995). Upper delta plain channels may be exceedingly difficult to distinguish from fluvial channels, especially in lacustrine deltas. In fact, these types of distributaries are, strictly speaking, non-marine in nature and have been described in the context of fluvial depositional systems (Mackey and Bridge, 1995). Distributaries can show several orders of branching. The smallest scale channels are referred to as terminal distributary channels and are associated with the proximal delta front. Commonly these are only a few meters deep and will tend to lie on top of associated distal delta front deposits.

In many ancient examples, thick channelized deposits overlying marine prodelta shales have been interpreted as distributary channels (e.g., Rasmussen *et al.*, 1985) eroding into their associated delta fronts. Some of these sandstones are over 30 m thick and cut into delta front sandstones that are only 10 m or so thick. Terminal distributaries should actually be difficult to recognize in subsurface because they tend to be

shallow and completely contained within the sandy delta front facies. Some of these deeply incised channels are now interpreted to be fluvially-incised valleys (e.g., Dalrymple *et al.*, 1994; Willis, 1997).

The delta front is the site of much of the active deposition, particularly at the mouths of distributary channels, where the coarsest sediment is deposited in distinct bars. Much of the deposition occurs in distributary mouth bars (also referred to as stream mouth or middle-ground bars) separated by shallow "terminal" distributary channels (Figures D4 and D6). Mouth bars can be on the order of several hundred meters wide and several kilometers long, such as in the Atchafalaya delta in the Gulf of Mexico (e.g., Van Heerden and Roberts, 1988). These mouth bars typically coalesce to form broader depositional lobes. Sediments deposited in mouth bars can also be profoundly reworked by waves, to form shore-parallel beach and strandplain deposits, or they can be reworked by tides to form shore-normal tidal bars (Figure D5).

Some distributary channels are fixed in the same position for long time periods, especially in deep-water mud-dominated deltas that build into relatively quiet marine basins (low tidal range, low wave action, Figure D6). The seaward building forms elongate bar fingers, as in the modern Mississippi "birdfoot" delta and in many bayhead lagoonal deltas. By contrast in siltier or sandier systems, deposited in shallower water, distributary channels switch more rapidly and coalesce to form more lobate sediment bodies, as in the Lafourche and Atchafalaya deltas in the Gulf of Mexico. Some researchers have used the term "braid" delta or "braidplain" delta to refer to a sandy or gravelly delta front fed by a braided river and characterized by a fringe of active mouth bars such as in the Canterbury Plains of New Zealand or in many glacial outwash plains (e.g., McPherson, Shanmugam and Muiola, 1987; see Reading and Collinson, 1996).

The seaward-dipping slope associated with distributary mouth bars is referred to as the distal delta front and can form a relatively continuous sandy fringe in front of the active mouth bar (Figure D4).

The prodelta is the area where fine material settles out of suspension. It may be burrowed or largely unburrowed, depending on sedimentation rates. Prodelta muds tend to merge seaward with fine-grained sediment of the basin floor. The preservation of silty or sandy lamination is commonly taken to mark the influence of the river, as opposed to total bioturbation of the basin floor sediments in areas away from the active river. Where the sediments are rhythmically laminated, there may be a tidal influence. Also, because of the abundant suspended sediment, certain types of vertical filter feeders and other organisms that produce open vertical burrows of the *Skolithos* ichnofacies tend to be suppressed (e.g., Gingras *et al.*, 1998). Because the delta front and prodelta areas are characterized by high levels of suspended sediment and the mixing of fresh and marine water, they tend to form very stressful environments for organisms resulting in low biological diversity (see *Bioturbation and Trace Fossils*). In New Orleans oyster bars, the best oysters (filter feeders) come from areas away from active river mouths whereas deposit-feeding crawfish favor more muddy prodelta and brackish lake environments.

Vertical facies successions

Progradation of a delta lobe will tend to produce a single, relatively thick coarsening-upward facies succession

(Figure D7) showing a transition from muddier facies of the prodelta into the sandier facies of the delta front and mouth bar environments (see numerous examples in Bhattacharya and Walker, 1992; and Reading and Collinson, 1996). Thicknesses may range from a few meters to a hundred meters depending on the scale of the delta and the water depth. Continued progradation may result in delta plain facies overlying the delta front sands in a continuous succession. However, delta front sands may be partially eroded by progradation of distributary channels or fluvial channels over its own mouth bar. Commonly, progradational delta lobe successions are truncated by thin transgressive abandonment facies.

In deltas deposited at the edge of the continental shelf, thick coarsening-upward delta front successions are commonly completely preserved within thicker deposits of the hanging wall of growth faults (e.g., Winker and Edwards, 1983; see Bhattacharya and Walker, 1992).

The specific nature of the facies in prograding prodelta and delta front successions will depend on the processes influencing sediment transport, deposition, and reworking. In addition, coarsening-upward facies successions can be produced by the progradation of other types of shoreline depositional systems.

Facies successions through distributary channels are erosionally based and typically fine upward. Filling commonly takes place after channel switching and lobe abandonment. At this time, the distributary channel may develop into an estuary, and the fill may be transgressive. The facies succession will tend to fine upward, with some preserved fluvially derived facies at the base, and a greater proportion of marine facies in the upper part of the channel fill. The extent of marine facies development will depend on the degree of fluvial dominance. Numerous examples of these different types are presented in Bhattacharya and Walker (1992) and Reading and Collinson (1996).

The overall proportion of distributary channel facies is a function of the type of delta. In general, the more wave-dominated the delta, the greater will be the proportion of lobe sediment with more limited amounts of interlobe and distributary channel facies.

Interdistributary and interlobe areas tend to be less sandy, and commonly contain a series of relatively thin, stacked coarsening- and fining-upward facies successions. These are usually less than ten meters thick, and much more irregular than the successions found in prograding deltaic lobes (see examples in Reading and Collinson, 1996). The proportion of lobe versus interlobe successions will depend on the nature and type of delta system and will tend to be greater in more river- or tide-influenced systems and less in wave-dominated deltas, although wave-influenced systems, like the Danube Delta in the Black Sea, can contain significant lagoonal and bay mudstones in regions downdrift of the river mouth (Bhattacharya and Giosan, *in press*).

Lateral facies variability

The lateral facies variability of many depositional systems requires a detailed understanding of bedding geometry. Bedding geometry and lateral facies variability can be addressed by the use of seismic data, Ground Penetrating Radar, continuous outcrop data (e.g., Willis *et al.*, 1999), and interpolation of well data. Analysis of lateral facies variability by tracing facies and bedding is termed *Facies Architectural*

Analysis, in which discrete sediment bodies are analyzed on the basis of bounding surfaces and bedding geometry (Miall, 1985). Facies variations associated with bounding surfaces can have significant impact on fluid flow in subsurface reservoirs. Considerable research in the petroleum industry has thus been dedicated to investigating the importance of bounding surfaces at a variety of scales. Much of this research emphasis has been on fluvial systems (see examples in Miall and Tyler, 1991; Flint and Bryant, 1993) but more recent studies of deltaic systems are becoming available (e.g., Ainsworth *et al.*, 1999; Willis *et al.*, 1999; Tye *et al.*, 1999).

Dip-variability

In cross-sectional view, deltas show the distinct topset, foreset and bottomset geometry, with strata typically organized into an offlapping pattern, formed as the delta progrades (Figures D4 and D7). Strata associated with progradation of the entire continental shelf-slope and basins also form larger-scale "clinoforms". Delta-front foreset-dips range from a few degrees up to the angle of repose in coarse-grained Gilbert-type deltas. Prodelta bottomsets typically dip at less than 1° whereas nonmarine topset facies are typically flat to undulating. The seaward migration of these geomorphic areas of deposition builds the vertical facies successions as shown in Figure D7.

Berg (1982, see Bhattacharya and Walker, 1992) discussed typical seismic facies in deltaic depositional systems and suggested that sandy wave-dominated systems tend to be characterized by a more shingled pattern. The muddier river-dominated delta types tend to show more of an oblique-sigmoidal pattern. The steeply dipping, sigmoid-shaped portions are probably characteristic of the mud-dominated prodelta facies whereas the more flat-lying upper reflectors represent the sandier delta front and delta plain facies. Frazier (1974, see Bhattacharya and Walker, 1992) showed a similar geometry based on geological studies of the Mississippi delta plain. Offlapping clinoform geometries have also been recognized in the Late Quaternary wave-dominated sediments of the Rhone shelf (Tesson *et al.*, 1990; see Bhattacharya and Walker, 1992) and in many other studies (e.g., Hart and Long, 1996).

Strike variability

Along strike, facies relationships may be less predictable and depositional surfaces may dip in different directions (Figure D4). This is particularly so in more river-dominated deltas where along-strike reworking is not significant and abrupt facies transitions may occur between distributaries and interdistributary areas. Overlapping delta lobes result in lens-shaped stratigraphic units that exhibit a mounded appearance on seismic lines (Figure D4). 3D bedding geometries have been simulated in computer-based models developed by Tetzlaff and Harbaugh (1989).

Conclusions

A good case can be made for regarding deltas as the single most important clastic sedimentary environment (Leeder, 1999, p. 383) but because of their complexity deltas cannot be classified according to any one simplistic model. Parameters now considered to be essential in understanding facies

distribution in deltas include: feeder type, river discharge, sediment caliber, water depth, basin physiography, storms, waves and tides, sea level, physical position in the basin, and degree of soft-sediment deformation. Clearly, combination of these parameters results in a nearly infinite number of possible delta types reflecting a chaotic, nonlinear, dynamic sedimentary continuum.

Many depositional systems (e.g., barrier-islands, deltas, estuaries) are not mutually exclusive and components of one can be found in another. Also, because of changes in parameters through time, one type of depositional environment can evolve into another. There are now too many end-member delta models. Future facies models must take a more quantitative, dynamic, predictive, parametric approach, such as used by Tetzlaff and Harbaugh (1989) in simulating deltaic deposition. These approaches will necessarily focus on the mechanics of delta formation and resulting facies distribution, informed by focused field studies, rather than merely classifying the type of delta observed in an outcrop or core.

DEPOSITIONAL FABRIC OF MUDSTONES

Definition

The fabric of a rock is the total of all textural and structural features (Whitten and Brooks, 1972). Texture is defined as the relationship between the particles that form a rock, and structure has to do with discontinuities and major inhomogeneities. Both are intrinsic properties of the rock that serve as guides to its origins (Pettijohn and Potter, 1964), as well as providing a basic rationale for the study of mudstone fabrics.

Studying mudstone fabrics

The structural dimension of mudstone fabrics (discontinuities and major inhomogeneities) is best examined in hand specimens (preferably cut and polished surfaces) and in petrographic thin sections (Figure D8). For hand specimens, one starts with visual inspection, followed by closer examination under a binocular microscope. This approach is suitable to

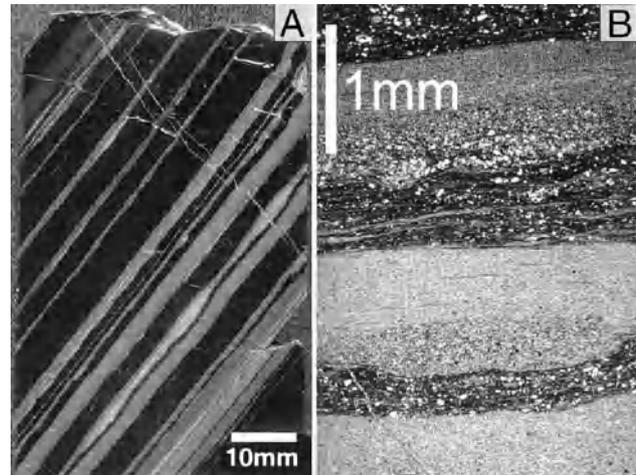

Figure D8 (A) example of hand specimen with alternating carbonaceous layers (black) and silt/clay couplets (light). Note lenticular and cross-laminated silt layer. (B) thin section of same shale as in A. Note graded silt/clay couplets (storm layers), and wavy crinkly laminae in carbonaceous layers (microbial mat deposit; Schieber, 1986).

study features in the millimeter range, such as small-scale sedimentary structures. Petrographic thin sections should initially be examined at low magnification (binocular microscope). Further study by petrographic microscope at higher magnification can reveal additional details (e.g., nature of lamina contacts), as well as providing information on mineral composition.

For the investigation of the textural dimension of mudstone fabrics (relations between particles) high magnifications are required to see individual grains and their contact relations. The scanning electron microscope is the tool of choice here (Trewin, 1988), operating in either secondary (SEM) or backscattered (BSE) mode (Figure D9). Observation in SEM mode is popular because sample preparation is easy (a freshly broken surface will suffice), but BSE imaging has gained popularity because it provides compositional information in addition to much clearer contact relations. The main drawback of the BSE mode is the need for a polished surface.

Fabric elements

From a sedimentologist's perspective, small-scale sedimentary structures tend to be the most informative fabric elements. Inconspicuous or even invisible in outcrop (they range in size from a few centimeters to less than a millimeter), they can nonetheless reveal a wealth of information about depositional conditions and history of a mudstone. When studied in polished slabs and petrographic thin sections, even seemingly drab shales can show a large range and variability of sedimentary features (Figure D10). If density contrasts are sufficient, small-scale sedimentary features may also be enhanced through X-radiography.

Laminae are the most typically observed sedimentary feature in shales, and exhibit a large range in thickness and lamination styles (even, discontinuous, lenticular, wrinkled, etc.), which can represent quiet settling, sculpting of the sediment surface by bottom currents, and growth of microbial

mats respectively (Schieber, 1986). Internal lamina features include: (a) grading; (b) random clay orientation; (c) preferred clay orientation; (d) sharp basal contacts; and (e) sharp top contacts. They may be interpreted as indicative of: (a) event-sedimentation (e.g., floods, storms, turbidites); (b) flocculation or sediment trapping by microbial mats; (c) settling from dilute suspension; (d) current flow and erosion

prior to deposition; and (e) current flow and erosion/reworking after deposition (Schieber, 1990). Silt laminae are usually the most easily observed lamina type in shales because of their somewhat larger grain size. They also imply somewhat more energetic conditions, and may, for example, indicate deposition by density currents (grading, fading ripples), storm reworking and transport (graded rhythmites), wave winnowing (fine even laminae with scoured bases), and bottom currents (silt layers with sharp bottom and top). Gradual compositional changes between clay and silt dominated laminae are another commonly observed feature, and are suggestive of continuous (although slow) deposition, possibly from deltaic sediment plumes and shifting nepheloid flows.

Other small scale sedimentary features that can be observed in shales are mudcracks, load casts, flame structures, bioturbation, graded rhythmites (Reineck and Singh, 1980), fossil concentrations and lags, cross-lamination, and loop structures (Cole and Picard, 1975), all of which carry information about conditions of sedimentation. Shales may also reveal clay-filled mud cracks, brecciation due to desiccation, and sands or conglomerates that consist entirely of shale particles (Schieber *et al.*, 1998). Because in the latter features the fills in cracks and between shale particles consist of the same components as the cracked substrate or the shale particles, there is little compositional contrast to reveal them on broken surfaces in outcrop. Polished slabs or petrographic thin sections are typically required to detect shale-filled cracks and shale sands and conglomerates. The latter, for example, can form as a result of soil erosion (pedogenic particles; Rust and Nanson, 1989), erosion of cracked mud crusts, and submarine scouring of mud substrates by strong currents.

Biologic agents may produce microbial laminae and protection of mud surfaces from erosion (Schieber, 1986; O'Brien and Slatt, 1990), or may manifest themselves as bioturbation and destruction of primary fabrics. In many instances, however, sufficient primary features survive bioturbation, and observation of bioturbation features can thus provide additional information about substrate firmness, event deposits (escape traces), and rates of deposition. Fecal pellets and pelletal fabrics are another by-product of organic activity,

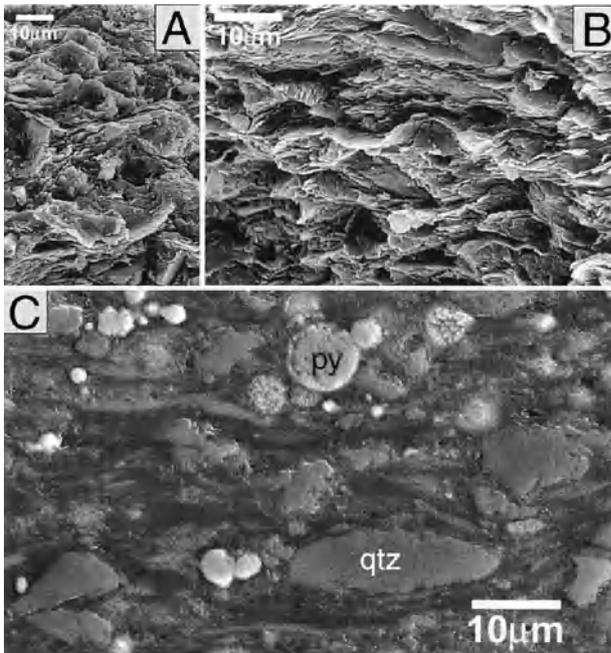

Figure D9 (A) SEM picture of bioturbated mudstone fabric; (B) SEM picture of laminated mudstone; (C) BSE picture of carbonaceous shale. Minerals with high molecular weight (py = pyrite) appear brighter than those of lower molecular weight (qtz = quartz). Gray streaks consist of clay minerals, dark-black streaks are kerogen. Note horizontal alignment of sediment grains, clay streaks, and kerogen stringers.

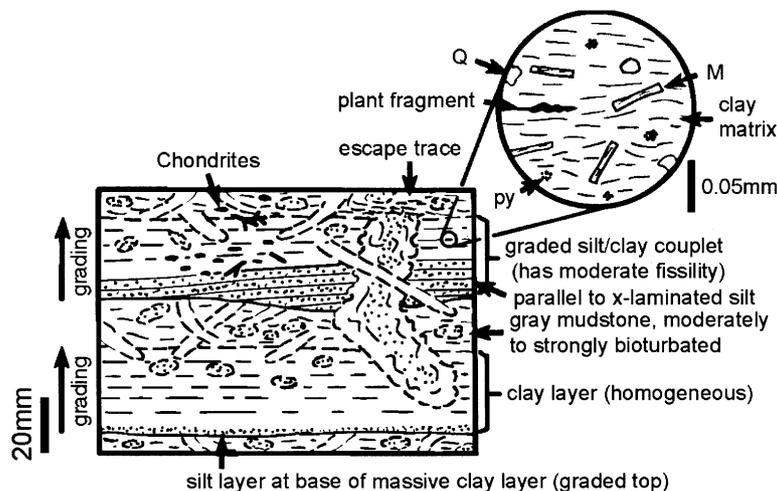

Figure D10 Line drawing that summarizes features observed in a mudstone from the Late Devonian Sonyea Group in New York (Schieber, 1999b). M = mica; Q = quartz; py = pyrite.

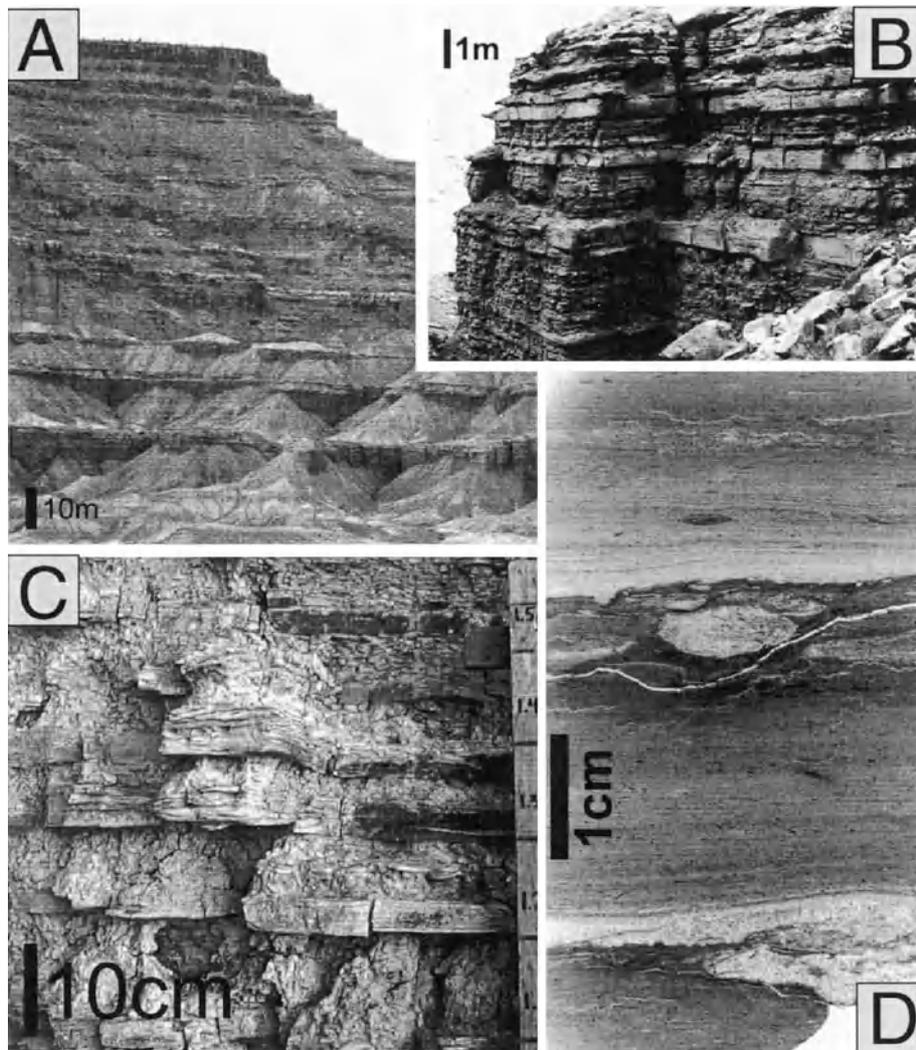

Figure D11 The “self-similar” nature of sediments. Magnification jumps by a factor of 10–20 between successive photos. (A) shale packages alternate with sandstone-rich units (Blackhawk Fm., Cretaceous, Utah); (B) sandstone-rich units from A consist of alternating sandy ledges and shaly intervals; (C) shaly intervals from B show softer shale alternate with centimeter-thick sandstone/siltstone beds; (D) thin section of soft interval from C shows graded siltstone layers and variably bioturbated mudstone. The resistant beds are storm deposits throughout (from HCS beds in B, to distal tempestites in D).

and they are probably more abundant in mudstones and shales than commonly recognized (Potter *et al.*, 1980; Cuomo and Rhoads, 1987). They are indicators of organic activity, and are best seen in thin section, where they typically differ from the shale matrix with respect to texture, color, and organic content. They may range in size from 0.2 mm to 2 mm and are generally of elliptical outline. Compaction tends to flatten the pellets to varying degrees, and if matrix and pellets are similar in composition and composed of particles of similar grain size, their identification can be challenging. The composition of fecal pellets can give clues on whether they were produced by benthic or planktonic organisms. Investigation of modern environments suggests that potential microbial colonization of mud surfaces has to be taken into account when studying ancient mudstones. Although difficult, recognition of microbial laminae is possible, and can lead to

substantially different interpretations of mudstone environments (Schieber, 1999a).

Notwithstanding the usefulness of small-scale sedimentary structures, the study of particle relationships (texture) also constitutes an important avenue of inquiry. This aspect of shale fabrics, studied by electron microscope, is frequently referred to in the literature as *microfabric* (O’Brien and Slatt, 1990). Microfabric features of mudstones record the combined impact of processes active during transport, deposition, and burial at the scale of individual grains and grain aggregations. The *Argillaceous Rock Atlas* by O’Brien and Slatt (1990) contains case examples from a variety of sedimentary environments (as well as many references) and illustrates mudstone fabrics with SEM photos and photomicrographs.

Experimental work has shown that microfibrils can for example be related to depositional processes, such as

flocculation and single-grain sedimentation (Mattiati, 1969; O'Brien and Slatt, 1990). The book *Microstructure of Fine-Grained Sediments* (Bennett *et al.*, 1991) contains a series of papers that employ microfabric analysis in the study of modern muds. A major drawback with the application of modern microfibrils to the interpretation of depositional conditions is the fact that muds undergo serious compaction and diagenetic changes on the way to becoming rocks. To determine from an SEM study which fabrics are secondary and which features are reflective of original depositional fabrics is difficult and requires considerable experience. In many instances the successful interpretation of microfibrils hinges on the availability of other information, such as small-scale sedimentary features, paleogeographic setting, and paleoecological information (e.g., O'Brien *et al.*, 1994). Nonetheless, a comparison of modern and fossil examples suggests that under favorable circumstances, fabrics produced by flocculation, settling of dispersed clays, bioturbation, agglutination on microbial mats, deposition of biosediment aggregates ("marine snow"), compaction, and fecal pellets can still be recognized and differentiated (Bennett *et al.*, 1991).

Fabric and environment

The broader significance of mudstone fabrics relates to the observation that sedimentary rocks and sedimentary successions have an inherent fractal quality (Mandelbrot, 1983). For example, large-scale stratification features can be repeated at different scales within individual stratigraphic packages, in the details of bedding, and even in the minutiae of lamination (Figure D11). Figure D11 illustrates that at increasingly higher levels of magnification, the basic theme of alternating soft and resistant intervals remains unchanged. Likewise, and regardless of scale, scoured bases, cross-stratification, and grading characterize resistant intervals, and bioturbation is more intense in soft intervals. This "self-similarity" from one magnification level to the next is at the heart of fractal geometry (Mandelbrot, 1983), and in our example (Figure D11) it reflects the overall conditions under which the succession accumulated. In that context we may even be tempted to speculate whether the information that can be extracted from fabric elements of a thin section or hand specimen (Figure D11(D)), will lead us to conclusions that are comparable to those derived from the study of an entire outcrop as shown in Figure D11(B). Studies of shale fabrics from rocks ranging in age from Proterozoic to the Tertiary have positively shown that shale fabrics do reflect the conditions of the broader sedimentary setting (Schieber, 1986, 1989, 1990; O'Brien and Slatt, 1990; Schieber *et al.*, 1998). Comparing what can be learned about depositional conditions in a mudstone-rich sedimentary succession from paleoecological observations and the study of interbedded sandstones, with the information derived from a detailed study of shale fabrics, shows that shale fabrics can provide a more concise account of depositional conditions than the other two approaches (Schieber, 1999b).

Summary

Mudstone fabrics are the cumulative record of the history of transport, deposition, and burial of muddy sediments. Their final "look" depends upon the interplay between a whole range of physical, biological, and chemical processes. As such,

successful studies of mudstone fabrics require the integration of all available paleontologic (body and trace fossils), sedimentologic, and petrographic observations. If done thoroughly, the information derived from a sample of mudstone (fabric study of hand specimen and thin section) can accurately portray depositional conditions and environments of the interval from which it was collected. If there is a choice between studying an entire outcrop of more resistant interbedded lithologies (e.g., sandstone), and the careful study of a mudstone sample from the same locality, the information derived from mudstone fabrics may well be superior.

DESERT SEDIMENTARY ENVIRONMENTS

Introduction

Deserts are defined as areas of sparse vegetation due to aridity (cf. Glennie, 1970; Cooke and Warren, 1973; Cooke and others, 1993; Thomas, 1997). The United Nations study of desertification (UNEP, 1992) measured aridity by the ratio of precipitation to potential evapotranspiration and defines hyperarid areas with ratios of less than 0.05 and arid areas with ratios of 0.05–0.20. These areas comprise nearly 20 percent of the earth's land surface, primarily concentrated along the high pressure belts of both the subtropical horse latitudes and the poles. Many large deserts are found along these belts as well as the midlatitude intracontinental steppes of Asia and North America in areas classified as semiarid (0.20–0.50). Smaller desert areas less dependent on latitude occur in orographic rain shadows and in areas associated with cold oceanic upwelling. The distribution of deserts in the geologic past was strongly influenced by the configuration of continental land masses (for instance, the Pangean supercontinent), tectonic activity, and the cycles of variation in solar influx.

The range of sedimentary environments encountered in deserts is summarized in Strakhov (1970), Glennie (1970, 1987), Cooke and Warren (1973), Hardie and others (1978), Warren (1989), Fryberger and others (1990), Smoot and Lowenstein (1991), Cooke and others (1993), Lancaster (1995), and Thomas (1997). Desert sedimentary environments are characterized by: (1) poor vegetation, resulting in greater erosion by wind and water, (2) low rainfall, leading to greater desiccation and evaporation and highly sporadic sedimentation, and (3) water input from outside the desert, producing local facies associations. Desert environments are strongly influenced by the interplay of eolian processes, intermittent wetting and drying of sediment, and evaporation of standing water and groundwater.

The characteristically low vegetation cover of desert environments allows wind to erode surfaces and transport large quantities of sediment. Wind erosion may sculpt bedrock into fantastic forms or polish the surfaces of pebbles and boulders into characteristic forms called ventifacts. Wind erosion (deflation) may form small catchment basins a few tens of feet in diameter or larger basins that are hundreds of meters deep and thousands of square kilometers in area. Precipitation of saline minerals on exposed bedrock enhances its breakdown and makes it more susceptible to wind erosion.

Soils in deserts reflect low vegetation, intermittent wetting, and frequent complete desiccation. Many soils are regoliths with little horizon development. Microphytes (cyanobacteria, lichen, moss, etc.) may form a significant cover to the soil surface, protecting it from erosion or acting as a trap for windblown dust. Microphyte trapping of windblown dust is also thought to contribute to the formation of desert varnish on rock outcrops and boulders. Wetting and drying of desert

soils produce complex desiccation crack patterns and may build up compressive forces that churn the sediment and force pebbles to the surface as pavements. These compressive forces may also produce slickensided shear planes. Vesicular fabrics are produced by air trapped below wet sediment or rock pavements. Windblown dust may introduce soluble minerals that are reworked by rainfall in the soil, forming caliche, silcrete, or evaporite minerals that precipitate as isolated nodules, crystals, or cemented crusts.

Evaporative concentration of solutes in groundwater and surface water makes these waters less hospitable to organisms and may lead to precipitation of saline minerals. Groundwater evaporation occurs throughout the capillary zone and may be aided by evapotranspiration by plants. A process called evaporative pumping has been considered an important source of hydrostatic head in the capillary zone, but Macumber (1995) argues that evaporation actually depresses the surface of regional groundwater discharge. The path of solute concentration is controlled by the initial groundwater composition, which reflects the drainage area lithology, and the early precipitation of less soluble phases (Eugster and Hardie, 1978). Similarly, the initial inflow waters control the composition of lakes or isolated marine embayments. At higher concentrations, the brine composition is complicated by a variety of other parameters, such as temperature, biological activity, mixing of different waters, solute recycling, dehydration, and reactions with minerals in the sediment. Where heavy saline brines sink into the water table, producing a lens-shaped groundwater body, the fresher groundwater may be refracted upward along the contact to produce artesian springs.

The geologically most important desert environments are summarized under the broad headings of eolian, fluvial, lacustrine, playa, and marine coastal environments. The discussions of these environments will focus on the features unique to desert settings. Additional details about these environments can be found under other headings.

Eolian environments

Vast deposits of wind-blown sand, called ergs or sand seas, may dominate the desert landscape. The primary components of these eolian sand deposits are dunes and sand sheets. Eolian dunes have a variety of morphologies and sizes that reflect sediment supply and the variability of the sand-transporting winds. Dune heights may reach hundreds of meters and lengths may extend kilometers. Eolian dunes are primarily classified by their crest configuration. Dune ridges that are transverse to wind direction include barchan, crescentic ridges, and parabolic dunes; ridges parallel to wind direction are called linear dunes; and dunes with complex multiple ridges are called star dunes. All of these dunes internally produce tabular cross-bedding from slip-face migration and low-angle tangential cross-bedding primarily from wind ripple migration. Eolian deposits dominated by transverse dune ridges have largely unidirectional cross-bedding parallel to the net wind direction, whereas those dominated by linear dunes have bimodal cross-bedding at right angles to the net wind direction. Cross-bedding sets are divided by erosional bounding surfaces that represent the stoss-side erosion of climbing dunes, or larger scale bounding surfaces that represent the stoss-side erosion of large compound dunes (also called draa) or deflation of a dune field to the local groundwater table. Interdune areas may be represented by pebble lags from

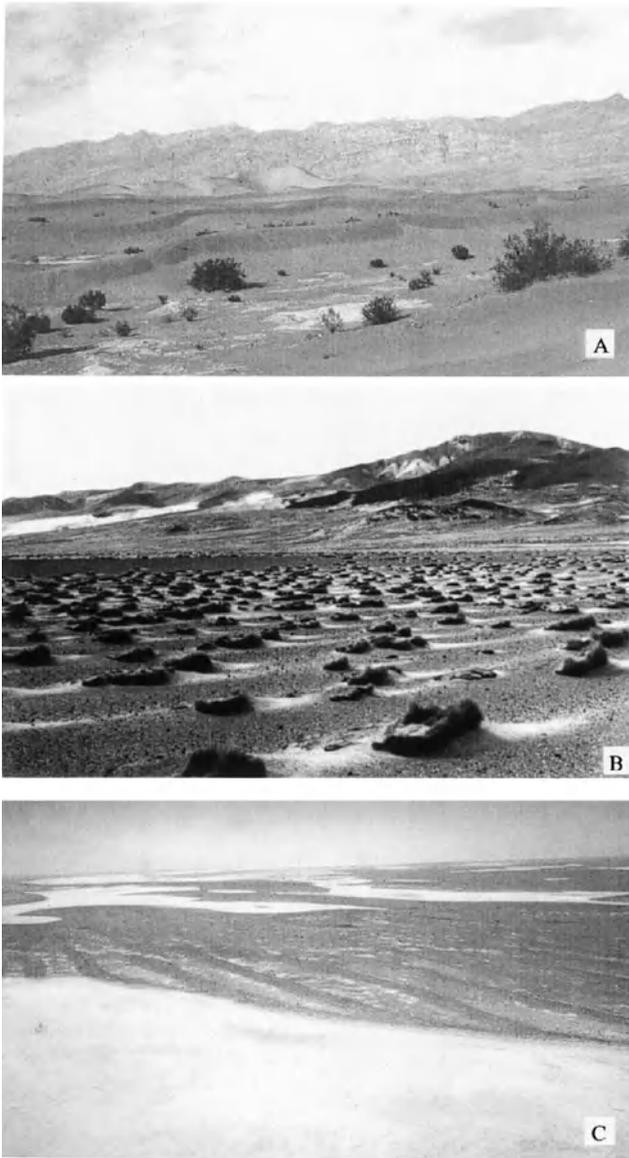

Figure D12 Eolian dune environments. (A) Crescentic ridge dunes in foreground and barchan dunes in background. Note muddy interdune area in foreground. (B) Deflation flat with small coppice dunes. Note alluvial fan in background. (C) Linear dunes cut by ephemeral lake margin.

deflation, thin mudcracked mud layers or evaporites from ponding of water, or flat bedding from the migration of wind ripples or adhesion ripples.

Sand sheets are broad areas of eolian sand that have low relief. These form around the margins of sand seas or in areas that are unfavorable for dune formation due to coarse grain size, vegetative cover, frequent flooding, cementation, or a high groundwater table. Most sedimentation in eolian sand sheets is from the migration of wind ripples producing relatively flat lamination. Zibars are low-relief (1m to 10m) and long-wavelength (100–500m) dune forms with rounded crests and no slip face. These produce low-angle inclined

lamination. Coppice dunes (or nebkhas) are mounds of wind-blown sand that are trapped by vegetation. Eolian sand sheets that form near evaporite-producing areas may have their surfaces cemented and deformed by efflorescent salt crusts. Sedimentary layers may be deformed into upturned polygons or blister like knobs. Wind-blown dust trapped on the efflorescent salt crust surface produces irregular thin mud partings that accentuate these features.

Large areas of some deserts are dominated by wind deflation leaving exposed bedrock eroded into characteristic shapes and lags of wind-blasted cobbles. Deflation surfaces covered by lags of wind-smoothed pebbles and cobbles are also called gibber plains or regs. Windblown dust (loess) may form thick deposits in areas marginal to deserts that have some vegetative cover, and it is often incorporated into the deposits of other desert environments. Blowouts may produce small depressions that host lakes or saline pans. Mud pellets and sand eroded by wind may accumulate on the downwind edges of these basins, producing lunettes or parna dunes. Salts eroded from the flats, particularly gypsum, may contribute significant portions of sand to adjacent dune fields.

Fluvial environments

Fluvial systems in desert regions can be divided into those whose drainage extends out of an arid region (allogenic) or those whose drainage area is entirely within the arid environment (endogenic). Allogenic fluvial systems typically have flowing water all the time as perennial streams and rivers. Endogenic fluvial systems frequently are dry, flowing only during sporadic rainfall events. These fluvial systems include ephemeral streams and alluvial fans. Endogenic streams terminate within the arid region (endoreic), whereas allogenic streams and rivers may be endoreic or they may flow through the desert region (exoreic).

Perennial rivers and streams in deserts may have meandering, braided, or anastomosing channel morphologies similar to rivers of more humid regions. The size and distribution of cross-bedding from bedforms and bars in a channel deposit and the lateral distribution of channel deposits reflect the channel morphologies similar to rivers in humid regions. Since perennial rivers in deserts are a rare source of fresh water, vegetation tends to cluster around channel margins. Roots may preferentially obscure channel bedding features rather than those of the adjacent floodplain unlike the relationship for humid regions.

Ephemeral streams have channels that are dry except during sporadic floods. Most ephemeral streams have small braided channels that are dominated by horizontal lamination and low-angle tabular foresets. Ephemeral streams dominated by pebbles and cobbles display gravel bar lenses, pebble clusters, and shadow fabrics. Larger ephemeral streams include abundant trough cross-bedding and other features similar to perennial braided streams. Channel deposits of ephemeral streams may be capped by mudcracked mud drapes or they may have eolian overprints. Mud intraclasts derived by reworking of mud drapes or desiccated flood-plain deposits may be a major component of ephemeral stream deposits.

Fluvial floodplain deposits in deserts lack the vegetative cover typical of humid floodplains. Thick muddy floodplains are disrupted by complex desiccation cracks and may have desert soil features such as evaporites, caliche, or silcrete. Windblown sand may fill desiccation cracks. Sandy floodplains

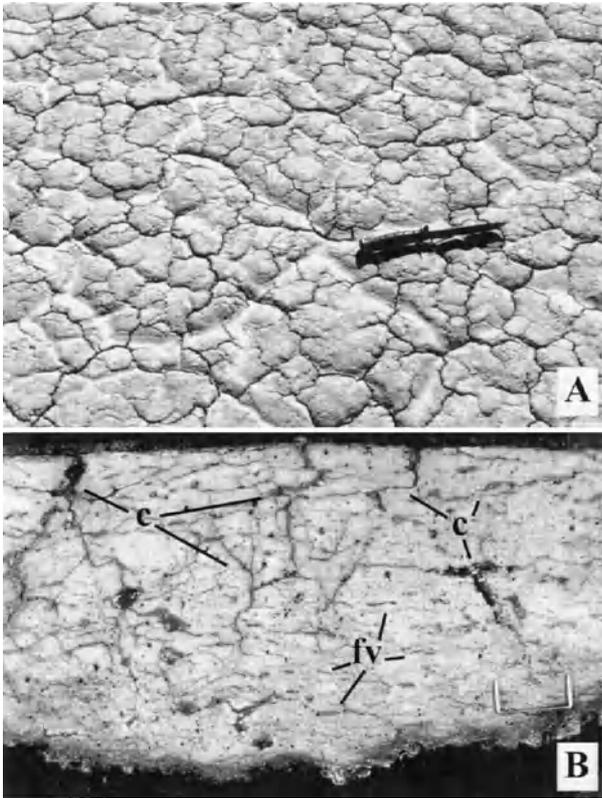

Figure D13 Mudcracked dry mudflat. (A) Surface view of complex mudcracks including partially filled older cracks cut by newer open cracks. Knife is 35 cm long. (B) Cross-section of above showing narrow irregular cracks (c), ovate vesicles (black), and flattened vesicles (fv). Scale is 7 mm wide.

may be reworked into eolian deposits including small dunes and sandsheets. Thin mud drapes break up into polygonal cracks that have upcurled edges that may be buried by windblown sand or incorporated as intraclasts in subsequent floods.

Alluvial fans are cones of sediment deposited where stream drainages debouch from mountain fronts. Alluvial fans are not restricted to deserts, but are commonly the dominant fluvial deposits in mountainous desert areas. Sedimentation on alluvial fans occurs during infrequent floods producing stream and/or debris-flow deposits. Streams are typically shallow and high-gradient with deposits of thin, poorly sorted gravel bars and planar bedding. Larger stream channels may develop tabular cross-bedding from bars and low-angle antidune backsets. Debris flows form levees, lobes, and sheets of poorly sorted muddy conglomerates with steep tightly packed boulder-cobble margins. During the long periods between debris-flow events, the deposits are commonly modified by rainfall, stream erosion of fines, and wind deflation. Debris-flow deposits tend to be more sheet-like and thinner at the toes of alluvial fans. Some stream-dominated fans have an apron of unchanneled sand at the toe called a sandflat. These deposits consist of sandy thin beds with thin, mudcracked mud partings. Broad, low-angle alluvial fans may develop where perennial rivers enter a desert basin over a mountain front.

(B) Cross-section of crust above showing mud-rich, porous efflorescent crust (ec) with pockets of aeolian sand (s) that are also visible as patches in poorly sorted mud with scattered microcrystalline evaporites (ev). View is about 30 cm high.

Lacustrine environments

Lakes in desert conditions are commonly temporary features formed by sporadic flooding events. Perennial lakes form at the terminus of allogenic rivers or in basins with high groundwater flow. Like lakes in more humid settings, desert lakes are sites for accumulation of fine-grained sediment with coarser sediment accumulating near the margins. Lake sediments may be massively bioturbated or they may have flat lamination from settling of different grain sizes or types, or they may have layering defined by sandy storm layers. The surface area and depth of the lake controls the amount of wave-sorting that occurs within the lake and the development of shoreline deposits. Wedges of deltaic sediment form where river or streams intersect the lakes. Unlike most lakes in humid regions where lake depth is controlled by the spill level, desert lakes are typically hydrologically closed with their depth controlled by the balance between inflow and evaporation. These so-called terminal lakes change depth and surface area radically over short periods of time, even completely desiccating,

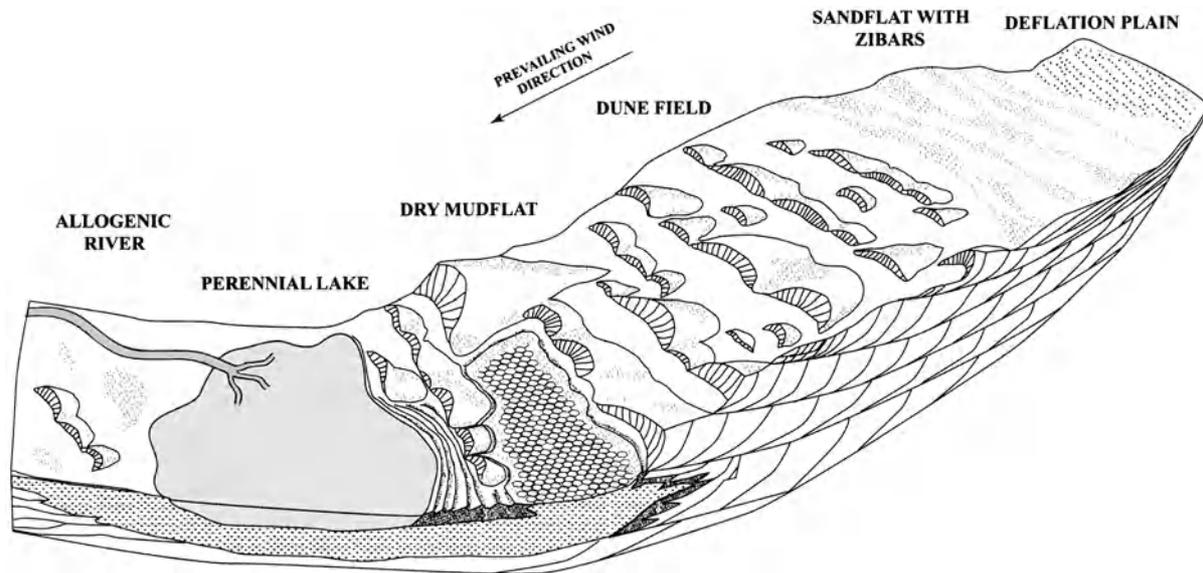

Figure D15 Distribution of sedimentary environments in a sand sea setting. Perennial lake has beach ridges and a birdfoot delta. Dry mudflat remains from a former lake embayment within the dunes.

and they accumulate solutes the longer they remain as standing water bodies.

Shoreline deposits range from well-developed spits and bars to thin sheets of rippled sand or imbricated pebbles. Shifting shorelines often leave the deposits stranded away from the lake to be modified by wind, flooding, and desiccation. Deltaic deposits include steep foreset “Gilbert-type” deltas and stream-dominated birdfoot deltas. The frequent changes in lake level make these delta deposits more sheet-like and may result in stacks of delta fronts separated by subaerial surfaces. Where alluvial fans impinge on lake margins, the boulders and cobbles may be sorted by waves forming tabular sets that dip lakeward. Algal tufa deposits may coat cobbles or form mounds and towers along the shorelines, particularly where spring water mixes with carbonate-saturated lake water.

Desert lakes may accumulate enough solutes over time to supersaturate with saline minerals, such as gypsum, halite, trona, or borates. The minerals precipitated primarily depends upon the composition of the inflow water, but they are also controlled by variables such as temperature, depth, mixing, and organic productivity. Evaporite minerals may precipitate at the water surface producing cumulate crystal layers as they settle, or the crystals may precipitate on the lake floor producing crusts or vertically oriented surface crystals. Dense saline brines may sink through the underlying sediment precipitating crystals or altering matrix composition as they interact with previously deposited sediment or mix with interstitial water. Deep saline lakes are often strongly stratified with dense brine at the lake bottom inhibiting mixing and inducing bottom anoxia.

Playa environments

Playas include a variety of geomorphic features such as salars, salinas, chotts, inland sebkhas, and pans, among others, that comprise the “dry lakes”. These deposits occur in depressions within the desert and are mostly dry with infrequent flooding.

Some playas are superimposed on the remnants of former desert lakes, whereas others are aggrading. Playas may be dry muddy surfaces or they may be dominated by saline minerals. Wind erosion of mud and saline minerals may be very important on playa surfaces, particularly where powdery efflorescent crusts are developed. The major varieties of playa environments are dry mudflats, saline mudflats, and saline pans.

Dry mudflats are muddy surfaces dominated by desiccation cracks. They form in areas of intermittent surface flooding where the groundwater table is well below the surface. Bedding, when present, consists of graded sand-mud layers representing individual flood deposits. More commonly, the only sediment accumulation is within mudcracks producing a massive mud with complex sediment-filled cracks and open vesicles. Dry mudflat surfaces may develop powdery “puffy ground” efflorescent crusts where windblown soluble minerals are dissolved by rainfall or flooding and reprecipitated within the sediment surface.

Saline mudflats are muddy surfaces that contain abundant saline minerals precipitated within the sediment and/or on the surface as efflorescent crusts. These form in areas with shallow groundwater tables or groundwater discharge near the sediment surface and where there are abundant windblown soluble minerals available. Intrasediment crystals form in equilibrium with groundwater along its flowpath as it is evaporated producing large euhedral crystals in the phreatic zone and smaller crystal clusters or dehydrated forms in the vadose zone. Windblown dust may contribute to saline mineral formation in vadose zones when soluble materials are moved down by rainfall or flooding. This produces vertical profiles of upward coarsening crystals, opposite of the groundwater situation. Efflorescent crusts form by the complete evaporation of porewater at the sediment–air interface and are comprised of a mixture of tiny crystals including the most soluble phases. These crusts are rarely preserved as they are dissolved on the bottom by the undersaturated groundwater. Hard efflorescent crusts made of halite trap windblown dust on the crystal

surfaces and coarser material in surface pits and irregularities thereby producing a poorly sorted mud with irregular sand patches. Powdery efflorescent crusts disrupt the upper sediment surface and form pelleted textures in mud that may be redeposited into cracks and surface irregularities.

Saline pans are salt-encrusted surfaces within saline mudflats that are intermittently occupied by shallow saline lakes. Saline pan lakes form during flooding events and the solutes are mostly derived by the dissolution of efflorescent crusts. This causes the saline pans to be dominated by the most soluble minerals. As the temporary lake waters evaporate, crystals are precipitated first as cumulus crystals then a bottom growth crystal crust. During prolonged periods between flooding, the crust may be modified by polygonal expansion cracks with formation of efflorescent crusts along their edges. The sinking brine will precipitate crystals in pore spaces and within sediments. The next flood will dissolve the efflorescent crust and part of the bottom crust before the cycle of deposition begins again. This mechanism may produce thick monomineralic deposits that are thin bedded.

Marine coastal environments

Where deserts border marine environments, the influence of seawater and marine sediment produces distinctive deposits. Many of the environments found within inland deserts may also occur in a coastal setting. Gypsum and halite characteristically dominate saline soils, saline mudflats, and saline pans along desert coastlines due to the influence of seawater chemistry. Eolian sands may contain a significant component of marine shelly material.

Sabkhas are broad, salt-encrusted flats that bound a marine coast. Clastic sedimentation on sabkhas is largely by storm surge tides, producing graded thin beds or lamination, or by wind. Thick algal mats commonly cover the sediment surface in nearshore areas modifying or controlling the sediment layering. Gypsum crystals form within the sediments that are saturated with seawater. Halite efflorescent crusts cover most of the inland part of the sabkha. Saline pans precipitating halite or gypsum crusts are common. Dehydration of gypsum crystals in distal areas produces anhydrite nodules and layers. Marine carbonate sediment is commonly altered to dolomite in this setting. Refraction of groundwater by the hypersaline seawater commonly produces artesian springs or spring-fed ponds along the coast within which carbonate crusts and micritic mud precipitate.

Isolated embayments of seawater in deserts become more saline by evaporation and less hospitable to normal marine organisms. If circulation with normal seawater is strongly curtailed, these embayments may become supersaturated with gypsum or halite producing cumulus crystal layers or bottom crusts similar to those of saline perennial lakes. Shallow, intermittently desiccated marine pools are called salterns. These produce layered evaporites similar to those of saline pans. In the geologic past, large embayments such as the Mediterranean Sea have become hypersaline producing extensive bedded evaporites.

Desert environment associations

Sedimentary deposits of desert environments have been recognized in rocks throughout the geologic record to the Precambrian. The distribution of these desert deposits through

time reflects changes in the Earth's tectonic regime and global changes in climate. Some desert environments appear to have left little record in the pre-Quaternary despite their areal abundance in the modern world. Polar deserts and high-latitude saline lakes have not been noted in the geologic record. Deflation plains have only been recognized within eolian sand deposits and never as a regional surface in the pre-Quaternary. The dearth of these deposits in the geologic record probably reflects the fact that they do not aggrade making them less likely to be preserved.

Although the combinations of desert environments are as varied as the potential combination of climatic and tectonic histories, there are certain associations that are commonly repeated. Sand sea deposits are commonly developed on stable cratons or broad structural sags where low relief is ideal for erosion and transport by wind. Perennial lakes associated with these sand seas are broad and shallow with superimposed dry playa mudflat deposits common. Foreland basins of thrust belts in desert regions produce extensive ephemeral and perennial river plains that terminate into broad basins with perennial lakes and playas. Isolated marine basins may produce thick evaporite deposits ranging from deep water to subaerial. Rift basins produce thick sediment accumulations with alluvial fans, perennial lakes, and playas as the common associations. Thick sabkha and marine embayment deposits may also be associated with alluvial fans in this setting.

Climatic instability can shift a region from humid conditions to arid and back again repeatedly in the span of thousands of years. Desert deposits may be interbedded with non-desert deposits at the meter scale, or desert fabrics may be superimposed on non-desert deposits or vice versa. This is particularly true for orographic desert situations that exist closer to the equator or at higher latitudes than the high-pressure belts. Sea-level shifts in response to global climate change may result in marine inundation of coastal desert deposits or isolation of marine bays to form saline embayments or salterns.

DESICCATION STRUCTURES (MUD CRACKS, etc.)

Desiccation structures originate as shrinkage cracks formed by the evaporation of water from the surface of clay-rich sediment. Previously called *mud cracks*, they are of subaerial origin, and are caused by the slow drying-out of muddy sediments which have been exposed to the action of sun and wind. The volume decrease that results from this loss of fluid gives rise to tensile stresses distributed equally in all directions within the bedding plane, that are relieved by the formation of a characteristic pattern of open polygonal cracks on the surface of the sediment.

Arrays of polygonal cracks resulting from this process are commonly seen on dried-out surfaces in puddles and slurry pits, around the margins of lakes, reservoirs and playas, and on tidal mudflats. Where well-developed, the desiccation structures form striking prismatic columns a few centimeters to several meters across, separated by deep fissures, and divided internally into secondary sets of cracks. Following a change in local climatic conditions and a rise in water level, the cracked surfaces become submerged, and the cracks and fissures may be filled with sediment and preserved. Once these sediments have been lithified, and later exposed at the Earth's surface, the host mudrock is more easily eroded than the sandy material infilling the cracks, and a cast of the sand-filled cracks is generally preserved on the *base* of the overlying sandstone bed.

Ancient desiccation cracks preserved in this way are not only useful as paleoenvironmental indicators, but provide vital evidence of way-up in rock sequences affected by folding and faulting. The crack patterns have geometric features in common with many other types of shrinkage cracks, such as cooling joints in basaltic dykes and sills, ice-wedge cracks in frozen ground (see *Tills and Tillites*), and with microcracks formed during the drying of thin layers of ceramic glaze, polymer, corn starch, paint and other materials. This feature can be used to advantage in experimental and theoretical studies (Weinberger, 1999, 2001), but their similarity to other sedimentary structures, and especially interstratal dewatering structures (Tanner, 1998), and syneresis cracks (see *Syneresis*) means that all sand-filled cracks have to be examined with great care, to determine their origin.

Morphology

The terminology used to describe desiccation structures was reviewed and illustrated by Allen (1984), following

Lachenbruch (1962). The morphology of intertidal desiccation cracks was analyzed in a seminal study by Allen (1987), and that of filled desiccation cracks in vertic paleosols is described by Paik and Lee (1998).

In plan view, desiccation cracks vary from straight to curved. They may form random, unconnected, even radial, patterns (*incomplete cracks*) but are most commonly seen as closed shapes bounded by 3, 4, or 5 cracks, with Y- or T-shaped intersections (*complete cracks*). Although the linked hexagonal pattern (*nonorthogonal type*) is that most commonly portrayed in textbooks for mud cracks, the polygons in naturally occurring desiccation cracks are most commonly 4–5 sided, with the majority of individual cracks meeting at right angles (*orthogonal type*) (Figure D16). Polygon size is a function of the thickness of the desiccated layer, with thick layers producing the larger polygons.

In cross-section, individual desiccation cracks form at right angles to bedding and generally taper downward (V-shaped profile) from the surface of the cracked layer. In three dimensions, the sets of polygonal cracks divide the mud layer into separate columns or pillars which may be cut by horizontal cracks which connect with the bounding fractures. At an advanced stage of desiccation, and especially in thinly bedded mudrocks, bedding laminae at the top of the pillars become dish-shaped and may become distorted to form tricorn shapes or “mud curls” (Figure D17).

The infilling of the cracks with sand and silt grains may occur in a single event, or be multi-stage as is common in intertidal situations. Repeated cycles of desiccation and infilling also occur, leading to a complex internal crack morphology. Vertically stratified crack-infills have been reported from vertic paleosols. Alternatively, cracks formed by drying-out of the surface of a very wet substrate may subsequently be intruded by mud or fluidized sediment from below, to form polygonal patterns of clastic dykes.

History

Geologists working in the Appalachian Mountains had already recognized the environmental significance of mud cracks by the mid-19th century; the first use of mud cracks, or “suncracks”, as a way-up indicator is not known, but according to Schrock (1948) the technique was already established by 1908. This author provides an excellent account of the morphology of desiccation cracks, together with a comprehensive review of earlier work. Fundamental advances in understanding the mechanics of the desiccation process were made by investigators studying the formation of closely related structures: ice-wedge cracks in frozen ground (Lachenbruch, 1962; Corte and Higashi, 1964). This phase was followed by further careful documentation of the morphology of mud cracks, foremost amongst these being the studies by Allen (1984, 1987). It was also a period in which there was considerable debate over the criteria that could be used to distinguish desiccation cracks from syneresis, or subaqueously-formed, cracks (see *Syneresis*). In recent years there has been a revival of interest in these superficially simple desiccation structures and further progress has been made in understanding their mechanics of formation (see below).

Mode of formation

The desiccation process requires subaerial exposure of a muddy layer of sediment. As moisture is lost from the upper

Figure D16 Orthogonal desiccation cracks in lime-rich mud from a tailings pit in SW England (see text for description).

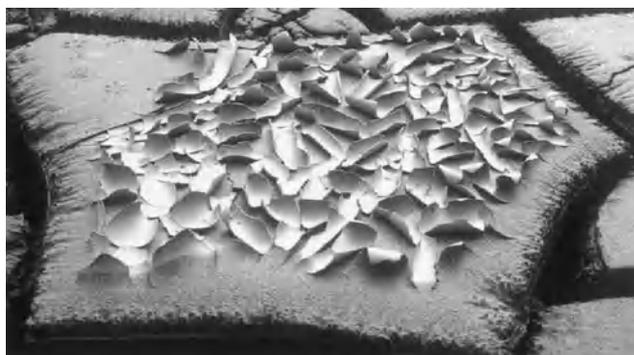

Figure D17 Mud curls surmounting a desiccation polygon at the same locality as Figure D16.

surface of the layer, the traditional model based on field relationships postulates that shrinkage cracks initiate at nucleation points on the surface, that in some cases can be identified as imperfections on the surface caused by bird's footprints, raindrops, bivalve shells, vegetation, etc. Aided by high local stress concentrations at their tips, the early cracks propagate both laterally and downward, and in most cases link up to form closed networks of polygonal cells. As in the case of cooling joints in igneous rocks, the pseudo-hexagonal form of these cells is controlled by the principle of least work: a detailed mechanical analysis of the process was given by Lachenbruch (1962).

Crack formation takes place in stages, with a network of primary or first-order cracks dividing the drying layer into a series of polygonal shapes, each of which is then subdivided by second-order cracks (Figure D16). Once a crack has formed it represents a principal or "free" surface, and new cracks

propagating toward it turn to meet with it at right angles, so explaining the preponderance of orthogonal junctions over "ideal" 120° contacts (Lachenbruch, 1962). The more fine-grained, smectite-rich, and homogeneous the starting material, the more perfectly formed and nearly hexagonal the pattern of cracks which results. A striking feature of some sets of mud cracks is the development of secondary and even tertiary sets of fractures sub-dividing the polygons formed by their predecessors (Figure D16).

Current investigations

Recent work has been aimed at analyzing the desiccation process in detail, both in the field and by studying the formation of desiccation cracks in the laboratory using analog materials such as corn starch–water mixtures.

In both natural and experimental situations, the surfaces of the cracks are commonly decorated with plumose structures, which consist of a series of faint ridges radiating out from a central axis. Plumose markings enable the actual nucleation points for each crack to be identified, as well as showing the direction of propagation of the rupture surface, so enabling a detailed kinematic picture of the growth of the array to be assembled (Corte and Higashi, 1964; Weinberger, 1999, 2001). In contradiction to the accepted model, new field evidence shows that, in some cases at least, desiccation cracks nucleate at the base of the bed and propagate upward (Weinberger, 1999, 2001). In experimental situations the speed of crack propagation can be monitored using a video camera, and was found to vary from 100 mm per second at initiation to <10 mm/min during amplification (Müller, 2001).

Summary

Desiccation structures result from the uniform layer-parallel shrinkage of homogeneous layers of mud that are rich in swelling clays. This process occurs as a result of subaerial exposure of recently deposited sediment and gives rise to familiar patterns of polygonal cracks that are analogous to the cooling joints found in igneous dykes and sills. Individual cracks are V-shaped in cross-section and when subsequently filled with silt or sand, and preserved in the geological record, provide a reliable way-up indicator. A feature diagnostic of sub-aerial exposure is the formation, in thin, dried-out layers of mud at the top of the polygonal columns, of concave-upward plates or "mud curls".

Desiccation structures are indicative of subaerial exposure of muddy sediment whether in an intertidal, lacustrine, or playa-lake environment. However the simple patterns shown by these structures should not be confused with those shown by interstratal dewatering structures (see *Fluid Escape Structures*) or syneresis cracks (see *Syneresis*). Polygonal patterns of sand-filled cracks seen on bedding planes are not necessarily proof of subaerial exposure and their misinterpretation can, and has, led to serious errors in identifying the depositional environment.

DIAGENESIS

Introduction

Diagenesis encompasses all the physical and chemical processes that affect sediments and sedimentary rocks in the portion of the rock cycle that includes the period of burial between deposition and weathering, and also between deposition and the onset of metamorphism. Processes that induce the lithification of sediments constitute a major aspect of diagenesis. Determination of historical sequences of physical and chemical processes is an important element of diagenetic studies. Diagenesis is key to understanding the evolution of rock composition and texture with depth, time, and temperature, and to deciphering the mechanisms by which elements are cycled between the atmosphere, ocean, and crust.

Diagenetic processes are responsible for the generation of coal, oil, gas, and “hydrothermal” ore deposits, and exert a major control on the composition of subsurface water and the distribution of porosity in the subsurface. The effects of diagenesis may erect barriers to fluid flow or establish selective passageways for the migration of fluids. Thus, there are compelling practical aspects to diagenetic studies.

Recognition of the substantial magnitude of chemical and physical reorganization that takes place during transformation of sediments into sedimentary rocks has been a major conclusion of diagenetic studies over the past quarter century. Many processes formerly viewed in terms of a narrow affiliation with either weathering, metamorphism, or tectonic deformation are now seen as integral and essential elements of

diagenesis. Study of the widespread role of microbial activity in diagenetic processes, both physical and chemical, is an area of currently active research.

Conditions of diagenesis

Although it begins at the sediment/water or sediment/air interface, diagenesis takes place largely in the subsurface and primarily under conditions in which the rock pore spaces are filled with water. No particular depth is implied, the scale ranging, potentially, from millimeter to kilometers. Important diagenetic fluids include seawater, meteoric water, hypersaline evaporative fluids, brackish mixed fluids, and pore fluid of any of these types that has been altered in varying degrees by fluid/rock interactions. Extreme degrees of diagenesis can yield pore fluids that are so substantially modified that their original composition (e.g., marine versus meteoric) is undecipherable. The temperature range for diagenesis extends from subzero (in sublimation brines) to 250°C and perhaps as high as 300°C. Rocks heated above this maximum temperature range may still have an identifiable sedimentary protolith, but tend to have lost the fabrics (grain-cement-pore space) and pervasive solid-phase disequilibrium that characterize sedimentary rocks. The pressure regime of diagenesis ranges from the conditions at the Earth’s surface up to and including conditions of fully lithostatic pressure ($P_{\text{fluid}} = P_{\text{load}}$). Few subsurface samples are available below 5 km, but samples obtained from as deep as 7 km are still clearly sedimentary as long as their temperature has not exceeded 250°C for very long.

Rock components in diagenesis

Recognition of the initial versus the modified chemical and textural states of sedimentary rock components is essential to deciphering diagenetic processes. Rock components that exist at the time of deposition are known as *primary*; diagenetic modifications of primary components yield features described as *secondary*. Primary mineral components in sediments and sedimentary rocks are of two types. Primary chemical precipitates are characteristic of evaporative environments and, by definition, must precipitate from fluids concentrated by solar evaporation (Warren, 1999). A larger group of primary minerals are called *detrital* in recognition of their existence as transportable particles or *grains*, either formed within the depositional environment (*allochems*) or derived from older rocks outside the basin of deposition (*terrigenous debris*). Pore space constitutes another important primary component of sediments and may be either *intergranular*, occurring between the detrital grains, or primary *intragranular* pore space, occurring within the grain interior. Primary intragranular pore space is observed in all types of grains, but occurs most commonly and most extensively within allochems.

Some rock types are completely authigenic and diagenetic in the sense that they contain little or no strictly detrital material and instead are constituted almost entirely of minerals precipitated from aqueous solution either at the depositional surface or in the shallow subsurface. Such “chemical sediments” include caliche, chert, and nodular anhydrite, and halite. However, most sediments, at least initially, are constituted primarily of detrital grains and pore space.

All of the primary rock components described above are subject to profound modifications by both chemical and physical processes during diagenesis. Primary pore space can

be substantially reduced by *compaction* and also through partial or complete filling by authigenic minerals (see *Authigenesis*), a process known as *cementation*. With the possible exception of detrital quartz and certain other minerals of high chemical stability, primary detrital minerals are subject to dissolution that can lead to the formation of *secondary intragranular pores*.

Secondary components, both authigenic minerals and pore space, are also subject to modifications during diagenesis. Early-formed authigenic phases may dissolve to leave secondary pores as ambient temperature and fluid composition evolve to conditions unfavorable for the mineral's continued stability. Authigenic phases precipitated during deep burial may be prone to dissolve when exposed to fluid flow at low temperatures following uplift.

Secondary pore spaces, within both primary and secondary minerals, may become filled with authigenic minerals, in a process known as *replacement*. Some of the most notable compositional and textural changes in diagenesis, for example dolomitization and albitization, take place largely through replacement. Replacement of primary or secondary minerals by new crystals of the same gross mineralogy, *recrystallization*, is notably difficult to document with complete certitude. This difficulty arises because a single mineral may be present in both primary and secondary forms or as co-existing authigenic crystals representing multiple episodes of precipitation, yet display only subtle heterogeneity in texture and composition. Demonstration of a cementation versus a replacement (or, recrystallization) origin for microcrystalline components (e.g., clay minerals, micrite) is particularly challenging because heterogeneities in texture and composition that can prove a primary versus an authigenic origin cannot be readily imaged at submicron scales.

Physical processes in diagenesis

Physical processes are important across the entire range of diagenetic conditions, but are prominently observed in the early stages of burial, prior to substantial lithification, when grain rearrangement by bioturbation and compaction are most readily accomplished. Major categories of physical processes in diagenesis include bioturbation, elutriation, compaction, and tectonic deformation.

Physical grain rearrangement in very early diagenesis of unconsolidated sediment is an important control on the subsequent path of chemical diagenesis because of the effects on permeability and grain surface characteristics. *Bioturbation* (see *Biogenic Sedimentary Structures*) is responsible for substantial grain rearrangement in certain depositional environments. Primary depositional fabrics (e.g., sorting, layering, etc.) may be greatly rearranged and new fabrics established by bioturbation, profoundly reducing the permeability of the sediment and the rocks that develop from them if fine and coarse detrital components, for example, clay and sand, become mixed. *Elutriation* is a process by which fine-grained particles are infiltrated through pore spaces following deposition, leading in some cases to rocks with reduced permeability. Thick grain coating clays introduced by elutriation and adhered tightly to grain surfaces by repeated wetting and drying can greatly alter the path of diagenesis in the sediment both by reducing overall permeability and also by creating a partial barrier to reaction between pore fluids and grain

surfaces. This is one illustration of how physical and chemical processes in diagenesis are linked.

Compaction refers to the reduction of primary intergranular space during burial and deformation. Distinct from cementation, compaction arises solely from the rearrangement of detrital grains. In well-sorted sand-size sediments the intergranular volume (IGV), also known as the "minus-cement porosity", is the sum of primary intergranular pore space and intergranular cements. Volume loss by compaction is calculated as follows (e.g., Lundegard, 1992):

Compactional porosity loss =

$$P_i - (((100 - P_i) * IGV) / (100 - IGV))$$

At deposition, the initial porosity (P_i) ranges from around 40 percent of sediment volume for sand-size materials to much larger values (ranging to 80 percent?) for sediments with abundant clay-size particles and sediments containing grains with abundant primary intragranular pores. IGV reduced solely by grain rearrangement is believed to reach a minimum value of around 26 percent. Larger IGV reduction (to a maximum of $IGV = 0$) is observed in both sandstones and limestones, requiring the operation of other mechanisms of compaction such as ductile deformation, grain crushing by brittle deformation (see Pressure Dissolution). Near-depositional values for IGV can be preserved by early cementation, a phenomenon that is more widespread in limestones than in sandstones.

Deformation at a variety of scales is increasingly recognized as an integral element of diagenesis. In addition to prominent grain crushing during burial compaction, grains may also succumb to crushing by stresses applied tectonically, especially if the tectonism occurs while the rock is still relatively porous. Planar zones of crushed and cemented grains known as deformation bands are prominent in some porous sandstones. In rocks that are highly lithified, deformation may be through-going, cutting across detrital and authigenic components. Substantial modifications of porosity, both increases and decreases, can result from deformation. Fracture porosity is one of the main categories of secondary porosity.

Chemical processes in diagenesis

Chemical processes in diagenesis involve interactions between solid phases and fluids contained within the rock's pore spaces. Such aqueous reactions, both dissolution and precipitation, commence in unconsolidated sediment within the depositional environment and continue throughout the range of diagenetic conditions into metamorphism. All reaction in diagenesis manifests a relative slowness of rate compared to reactions at higher temperatures. This tendency for reactions to be sluggish has profound implications for the kinds of mineral assemblages that can exist and also for the kinds of textures that can arise in diagenesis.

It is reasonable to assert that overall chemical equilibrium between solid phases in rocks is not achieved in diagenesis. Even if a phase is in gross equilibrium (e.g., detrital albite in contact with albite-saturated water), the actual crystal lattice may still have trace element, isotopic, and structural disequilibrium with ambient conditions. Such disequilibrium represents a sort of driving force that can ultimately lead to dissolution, even in the presence of fluids that are near equilibrium with the bulk mineral. Transient local, microscale equilibrium between an individual authigenic phase and pore fluid occurs in

diagenesis, at least theoretically, but does not apply more generally to the bulk rock which contains a diversity of phases that are not in equilibrium either with pore fluids or one another. The equilibrium that does exist is important, in the sense that it is the basis for using isotopic and elemental analysis of authigenic phases to interpret the compositions of ancient fluids responsible for precipitation.

Dissolution

A key factor in chemical diagenesis is *metastability*, which refers to the tendency of mineral crystals to persist for geologically long periods under conditions far outside the range of their thermodynamic stability because the rate of their reequilibration is slow. A metastable mineral is said to have a "kinetic barrier" to reaction. Amazingly, some feldspars, originally formed by crystallization from magma, can persist for billions of years in aqueous environments at surface temperatures. Some detrital feldspar persists even in Archean sandstones, having survived erosion, transport, deposition, and a prolonged history of diagenesis.

The degree of metastability differs greatly for different sedimentary materials (both crystalline and amorphous) and can vary greatly even among individual components of similar bulk composition, for example among different grains of K-feldspar in a sandstone or mudrock. Hence, there is a tremendous range in the conditions required to initiate dissolution of primary and secondary mineral components. Most evaporite and many carbonate minerals manifest extensive recrystallization (dissolution followed by reprecipitation of a more stable crystal lattice) over short time periods under essentially syndepositional conditions. Highly unstable materials may recrystallize repeatedly through a range of diagenetic conditions and environments, leading to extensive and complex textural and chemical modifications. For example, dolomites typically retain almost no discernible primary detrital textures at any scale, being so highly prone to recrystallization. In a less extreme case, albitized detrital feldspars may retain a gross sand grain morphology as seen at low magnifications, but as observed on the scale of a few micrometers are revealed to be highly microporous aggregates of the authigenic feldspar albite. In stark contrast with dolomite and feldspars, detrital quartz fails to react with pore fluids and maintains its primary isotopic and trace element composition up through the incipient stages of metamorphism.

Crystal defects are an important control on the microscale localization of dissolution in diagenesis. In scanning electron microscope observation, dissolution of detrital minerals is typically observed to be localized at pits that correspond to the intersection of defects with the crystal surface. Important textural implications arise from the defect control on dissolution. At the scale of a few 10s or 100s of micrometers, dissolution of both primary and secondary minerals is typically observed to be highly irregular. Crystals are not generally observed to dissolve progressively from the outer surface, but rather in patches, at sites anywhere within the crystal that correspond to energetically favorable defects. Secondary pores formed in this manner show a wide range of size, varying from sub-micron micropores to pores of 10s to 100s of microns surrounded only by skeletal remnants of the original grain. Complete dissolution of detrital grains can lead ultimately to the formation of oversized pores. Compactive collapse of oversized pores can completely erase evidence for the former

existence of some detrital grains. Dissolution can ultimately induce a considerable loss of information on the nature of primary rock components. In limestones for example, aragonitic allochems that may have been abundant in the depositional environment are rare in rocks of all ages and have never been observed in rocks older than Pennsylvanian. Such allochems are typically replaced by low-Mg calcite early in their diagenetic history. In the sandstones known as *diagenetic quartzarenites*, detrital quartz is the only remaining unreacted primary mineral, all feldspars having been lost to dissolution.

Precipitation

The sluggishness of precipitation reactions in diagenesis is manifested as a difficulty with nucleation. As a result, in both cementation and replacement, authigenic minerals typically show a highly localized spatial distribution, an effect that is apparent at a variety of scales. For example, some minerals show a marked tendency to nucleate only on the surfaces of pre-existing (i.e., mostly primary) crystals, a phenomenon that is apparent on the scale of a few microns to hundreds of microns. In essence, precipitation of such authigenic crystals enlarges the earlier-formed crystal, forming an outer zone known as an *overgrowth*. Authigenic quartz, feldspar, calcite, and ankerite are all notable examples of this mode of nucleation and growth. In the absence of appropriate substrates, these minerals may fail to grow even in the presence of fluids of appropriate composition. Substrate control of cement localization is observed in all types of porosity. Coatings on the surfaces of potential nuclei, formed through elutriation or early cementation, can markedly inhibit the growth of minerals in later diagenesis.

Replacement can be thought of as cementation occurring within secondary pores (however tiny) and, thus, replacement minerals, too, tend to have highly localized distribution. Replacements tend to occur only at the sites of defect-controlled dissolution, as described above, and thus, typically have a highly patchy distribution within the crystal that is being replaced. As with dissolution, replacement that is localized near the outermost crystal surfaces (halo texture) generally is not observed in diagenesis.

An example of authigenic mineral localization on a somewhat larger scale (typically 100s of microns to meters) is the formation of diagenetic structures known as nodules (mineral aggregates distinct from the host rock and typically formed very early in diagenesis) and concretions (regions of preferential cementation, formed at any time in diagenesis). As with overgrowths, this localization reflects, at least in part, the difficulty of nucleation at low temperatures. Nucleation of one crystal appears to have a dampening effect on further nucleation in its vicinity, leading to subsequent precipitation that is preferred (as overgrowths?) on the early-formed nucleus. The detailed mechanics of how concretions and nodules are localized is one of the enduring enigmas of diagenesis.

Interrelated physical and chemical processes

Some diagenetic processes take place through intimately linked chemical and physical processes. For example, a weak connection between physical and chemical processes is seen in localization of cementation in fracture porosity (vein formation) which takes place partly as a result of generation

of fresh, uncoated surfaces favorable to nucleation and partly as a result of enhanced fluid flow. A stronger link between chemical and physical processes is seen in the case of pressure solution (see *Pressure Dissolution*) including both intergranular pressure solution and the formation of stylolites. In this instance, dissolution is localized along certain crystal contacts (in evaporites, carbonates, and quartz-rich sandstones), leading to prominent porosity loss and development of sutured boundaries. A variety of mechanisms have been proposed for the dissolution step in the pressure solution phenomenon, but the stress field is, in every case, the fundamental determinant of form and orientation of the dissolution surface. In simple burial compaction sutures are oriented parallel to bedding (perpendicular to the principal, compactional stress), whereas in tectonic deformation, stylolite orientation may be determined by the orientation of tectonic stresses. Pervasive tectonically driven stylolite development in late diagenesis, grades, ultimately, into metamorphic foliation. Another intriguing example of closely linked physical and chemical processes is dissolution driven by force of crystallization. In certain circumstances it appears that nucleation of one crystalline phase can actually induce the dissolution of surrounding crystals, an alternative mechanism for overcoming the kinetic barrier to mineral dissolution, leading to replacement (Sorby, 1863; Weyl, 1959; Maliva and Siever, 1988).

Fluid flow and diagenetic heterogeneity

An on-going controversy in diagenetic studies concerns the degree to which diagenetic processes of dissolution, cementation, replacement, and recrystallization are accomplished in so-called "open" versus "closed" chemical systems. The opening volley of this debate was the paper by Land and Dutton (1978) which demonstrated a disparity of tremendous magnitude between the amount of quartz cement in a Pennsylvanian sandstone and the amount of silica available from pore fluids, given the fluid flow limitations of a simple burial compaction model. Similar conundrums immediately became apparent in connection with many instances of cementation, dissolution, and replacement in all types of sedimentary rocks, especially with regard to the transport of components such as Al which are relatively insoluble in pore fluids and also components of volumetrically significant reactions in the deep subsurface. In general, studies that focus on petrographic documentation of authigenic reactions find evidence for a greater degree of "openness" in terms of the amounts of material transport required to accomplish the observed amounts of cementation and replacement. Studies that focus on rock permeability, fluid flow, and fluid compositions generally find potential for lesser amounts of material transport.

One of the obstacles to resolving this controversy concerns the tendency of diagenetic processes to manifest a high degree of spatial heterogeneity, making it difficult to obtain statistically meaningful data on sedimentary rock compositions. Within a given rock unit, the degree of cementation or the degree of replacement can vary due to the controls on reaction localization as discussed above as well as from historical vagaries in primary composition and fluid flow. As a result of compositional heterogeneity it is difficult to ascertain quantitatively whether materials apparently lost from one volume of rock have been gained by another. Likewise, some workers have called into question whether our understanding of

permeability in the subsurface is sufficiently complete. Studies to determine the appropriate scale for rock property observations are continuing as are efforts to better understand the role of endolithic microbes in element mobility in the subsurface.

Microbial influences in diagenesis

Microbial activity is recognized as an important element of diagenetic processes in a wide range of subsurface environments (e.g., Banfield and Nealson, 1997). Mineral surfaces within endolithic pore spaces provide attachment sites and nutrient sources to bacteria, archaea, and fungi across environments extending from near-syn depositional to several kilometers depth. Microbes affiliated with mineral surfaces can, either actively or passively, be a significant factor in overcoming kinetic barriers to both dissolution and precipitation in diagenesis. The mere presence of microbial communities within diagenetic environments may exert controls on the microscale morphology and distribution of authigenic precipitates because biofilms exuded by living cells change mineral surfaces in ways that can promote, inhibit, or modify nucleation.

There is currently vigorous research activity focused on the microscopy and geochemistry of microbe/mineral interactions seen in laboratory and field experiments, in modern surface and subsurface environments, and in ancient rocks. These studies are beginning to contribute a view in which the diagenetic realm is also a vital region of the biosphere on the Earth, and perhaps, other planets.

Boundaries between diagenesis and depositional processes, weathering, and metamorphism

No sharp division between diagenesis and metamorphism, nor between diagenesis and weathering, can be readily specified. Historically, various temperature/pressure conditions, textural, and mineral assemblage criteria have been applied in making distinctions between these different realms of rock alteration. All of these approaches have been rendered somewhat obsolete by the growing recognition of the role of initial composition on textural modification and the fact that many reactions and mineral assemblages once placed within the zone of metamorphism (e.g., zeolite precipitation, albitization) are now known to occur within rocks that are clearly sedimentary. Rocks might be considered to be "metamorphic" once their sedimentary textural components (grains, cements, and pore spaces) have been "erased". Development of through-going metamorphic fabrics such as pressure shadows or foliation is clearly a marker for the transition out of diagenesis. Of course such degrees of textural alteration are achieved under very different conditions for materials of different starting compositions. For example, limestones and especially dolomites may manifest a high degree of textural and chemical modification by one kilometer of burial (<30°C) whereas an interbedded quartz-rich sandstone may survive to nearly 300°C with clearly sedimentary textures intact. The method of observation is another control on such a determination (e.g., rocks that appear as metamorphic "quartzites" in light microscope observation, may still appear as "quartz-cemented sandstones" in cathodoluminescence). Many processes identified as "diagenetic" (e.g., albitization, quartz and feldspar precipitation in fractures, clay mineral

formation) also take place within crystalline rocks at relatively low temperatures.

Both weathering and metamorphism encompass physical and chemical processes, involve aqueous reactions, and assign great importance to metastability. In metamorphism there is a role for solid state diffusion that is not observed in diagenesis (halo textures do occur prominently in metamorphic rocks) and also a degree of solid phase equilibrium. In weathering there is a physical decomposition of rocks that is not affiliated with diagenesis.

Given that the boundaries between diagenesis and metamorphism and between diagenesis and weathering are so obscure, it is especially difficult to subdivide diagenesis in a meaningful and consistent way (Fairbridge, 1967). Diagenetic processes are often divided loosely on the basis of their timing relative to compaction, those processes occurring nearest the depositional interface, prior to substantial compaction, and at temperatures $<50^{\circ}\text{C}$ being designated "early", whereas processes occurring in deeper burial, following substantial compaction, and at temperatures around 80°C and higher, are designated "late".

In general, chemical processes are assigned to diagenesis more broadly than physical processes. For example, dissolution of unstable minerals during transport or through bioerosion (chemical boring) would be widely considered as elements of diagenesis whereas bioturbation affecting unconsolidated sediments within the depositional environment is typically studied by experts familiar with deposition rather than diagenesis. Similarly, growth of clay minerals through replacement of feldspars in weathering would be considered diagenetic whereas physical disaggregation of rock by wind or ice would be most commonly thought of as weathering.

Methods for the study of diagenesis

Documentation of the primary versus secondary character of sedimentary rock components is accomplished through the integrated use of microscopical and geochemical techniques. The pervasive chemical disequilibrium that characterizes rocks throughout diagenesis lessens the importance of bulk methods of chemical analysis in diagenetic studies in comparison to studies of igneous and metamorphic systems. Diagenetic studies over the past several decades have benefited greatly from advances in imaging and spatially resolved chemical analysis. Such methods allow characterization of the micro-scale chemical heterogeneities that persist throughout the realm of diagenesis and permit a correlation of such heterogeneities with information on the sequential development of rock components (e.g., cement stratigraphy).

A technology of particular importance in diagenetic studies is the use of colored impregnation media, first applied in the 1970s, that allows reliable discrimination of natural versus artificially induced porosity in thin sections. Widespread use of this technique in limestones and sandstones led to a revolution in understanding of the importance of grain dissolution in the subsurface and also inspired a renaissance of data collection that greatly improved understanding of compaction. Imaging with scanning electron microscopes and electron microprobes created a vastly greater appreciation of the heterogeneity that exists for any given mineral phase across a range of components (grains, cements, and replacements) within sedimentary rocks. For example, scanned cathodoluminescence imaging and back-scattered electron imaging may permit

discrimination of grains, cements, and grain replacements all composed of the same mineral phase, but having small differences in defect structure or trace element composition. Likewise, different generations of a single authigenic phase can be identified on images that are sensitive to subtle differences in trace element composition. Such distinctions may be highly obscure in other modes of imaging such as transmitted light microscopy that only allows discrimination between phases or different crystal orientations of a single phase. Diagenetic studies typically employ a combination of imaging (for historical aspects) and analysis (in order to quantify T and fluid compositions). Important petrographic methods in diagenetic studies include transmitted plane- and cross-polarized microscopy, secondary electron imaging, back-scattered electron imaging, X-ray mapping, and cathodoluminescence. Important analytical approaches include X-ray diffraction, major and trace element analysis by electron microprobe, and analysis of the stable isotopes of O, C, and Sr. Sampling of detrital and authigenic phases by microdrilling techniques has been widely employed in combination with isotopic analyzes.

Diagenetic studies

Published work on diagenesis is extensive and is summarized in numerous textbooks, review papers, and reprint collections (e.g., Pettijohn, Potter *et al.*, 1973; Bathurst, 1975; Pettijohn, 1975; Berner, 1980; Folk, 1980; Land, 1985; Horbury and Robinson, 1993; Giles, 1997; Land, 1997). Diagenetic studies are found primarily in mainstream geological journals as well as in publications in the areas of petroleum and environmental engineering, chemistry, and physics.

Summary

Diagenesis encompasses all physical and chemical modifications that affect sediments and sedimentary rocks following deposition and prior to the advent of weathering or metamorphism. The tendency of minerals to manifest sluggish reequilibration reactions under diagenetic conditions is responsible for the preservation in sedimentary rocks of considerable historical information concerning both the origins of detrital grains and the progress of chemical reactions involving dissolution, cementation, and replacement. Even though reactions in diagenesis are comparatively slow, modern diagenetic studies have concluded that most primary components in sediments are ultimately subject to profound modifications during burial as metastable components react with the surrounding pore fluids. The microbial role in diagenetic reactions is an exciting area of research that is contributing important new perspectives on the nature of diagenesis.

No absolute boundaries are assignable between diagenesis and either weathering or metamorphism, but rocks in the diagenetic realm are characterized by pervasive chemical non-equilibrium between the various solid phases that comprise the rock and, to a high degree, nonequilibrium between the solid phases in the rock and the contained pore fluids. With the exception of so-called chemical sediments that are constituted almost entirely of authigenic precipitates, sedimentary rocks in the diagenetic realm manifest a clearly sedimentary fabric with distinct grains, pores, and cements. Erasure of such fabrics is a hallmark of the transition into metamorphism.

DIAGENETIC STRUCTURES

The results of diagenetic alterations are visible whenever we examine sedimentary rocks in the field. Indeed, the very hardness of the rocks is the result of the diagenetic process of lithification, in which loose sediment is transformed into solid rock by cementation and compaction. However, there are numerous structures that can be readily observed in outcrop that result wholly from diagenetic alterations. These diagenetic structures include features such as concretions, cone-in-cone structure, geodes, liesegang bands, reduction features, sand crystals, and stylolites. Of these, concretions and stylolites are by far the most common and have been intensively studied, whereas the other features, although locally abundant, are relatively rare and have received less attention in the literature.

Concretions

Concretions are hard masses of sedimentary and, more rarely, fragmental volcanic rock, that form by the preferential precipitation of minerals (cementation) in localized portions of the rock. They are commonly subspherical (Figure D18), but frequently form a variety of other shapes, including disks, grape-like aggregates, and complex shapes that defy description. Concretions often form around a nucleus, such as a fossil fragment or piece of organic matter. This occurs because, for a variety of reasons, the nucleus created a more favorable site for cement precipitation than other sites in the rock. Concretions are usually very noticeable features, because they have a strikingly different color and/or hardness than the rest of the rock. The term nodule is often used as a synonym for concretion, but some workers prefer to reserve the term nodule for concentrations of authigenic minerals that do not enclose detrital grains (Selles-Martinez, 1996) or are relatively small and largely of replacement origin (Bates and Jackson, 1987).

Concretions often preserve features of the original sediment—such as burrows, fossils, and sedimentary layering—that cannot be seen in the rest of the rock (e.g., Kidder, 1985). This occurs because concretions usually begin to form relatively early, before sediment compaction and other processes disrupt the original sediment. Thus, cementation of

Figure D18 Concretion in shale. Lens cap for scale.

the concretions “freezes” the early sediment structure, forming a rigid mass that resists later chemical and mechanical alterations.

Concretions most commonly result from carbonate precipitation, although a variety of minerals also can form concretions, including pyrite, apatite, iron oxides, and silica (as opal, chert, or chalcedony). Of the carbonate minerals, calcite most commonly forms concretions, followed by dolomite, and siderite. Carbonate and iron oxide concretions are most commonly found in shales and sandstones, whereas apatite and pyrite concretions are mainly found in shales, and silica concretions normally form in limestones and shales. Carbonate concretions, given their abundance, and the ease of obtaining trace-element and isotopic data from them, have been studied in much greater detail than any other type. These studies have provided a wealth of information concerning the nature of early diagenetic reactions, and have conclusively demonstrated the importance of the microbial oxidation of organic matter in the early diagenetic environment (e.g., Raiswell and Fisher, 2000).

Concretions grow either by precipitation between grains in the host rock (usually the case for carbonates and apatite) or by replacement of the host rock (usually the case for chert). In either case, the conventional model for concretion growth is concentric, in which the authigenic mineral is progressively added (by replacement or direct precipitation) to the outer edge of the growing concretion. Consequently, early zones are at the center and late zones near the outer edge (e.g., Raiswell, 1971). Most studies of concretions have assumed this mode of growth. However, recent studies indicate that concretion structure and growth often does not follow the concentric model. Small-scale zonation incompatible with such a mode of cementation has been observed in calcite, siderite, dolomite, and chert concretions (Mozley, 1996; McBride *et al.*, 1999; Raiswell and Fisher, 2000). In some cases, it is clear that late-stage and early-stage cements precipitated throughout the concretion, indicating that early cementation was incomplete, and that significant porosity and permeability remained to allow precipitation of late-stage cements in the concretion interior.

Some concretions are cut by a radiating network of fractures (septaria) filled with coarsely crystalline calcite and other minerals. Such concretions are known as septarian concretions, and a variety of hypotheses have been proposed for the formation of the fracture systems, including: (1) Shrinkage of the interior of the concretion, a result of the dehydration or “chemical desiccation” of either a clay-mineral-rich center (Richardson, 1919; Raiswell, 1971), or dehydration of a gel-like precursor (Lippmann, 1955). (2) Expansion of the concretion interior and expansive growth of the fractures (Davies, 1913; Todd, 1913), presumably accomplished by the force of crystallization. (3) Development as tensile fractures in response to stresses induced during burial (Astin, 1986). (4) Fracturing induced by propagation of seismic waves through poorly lithified sediment (Pratt, 2001). Of these various hypotheses, the shrinkage hypothesis remains the most favored. However, the geochemical conditions necessary for significant dehydration of clay mineral centers have not been quantitatively explored. The gel-like precursor model has the problem that the nature of the gel is poorly-defined (some workers have proposed an organic soap), and such gels have never been observed in modern concretions. Thus, the origin of septarian fractures is currently a topic of debate and ongoing research.

Recently hydrologists have become interested in elongate concretions. These concretions range in size from pencil- and cigar-like bodies to those that resemble large fallen logs. They are thought to form from flowing groundwater, with the long axis of the concretion oriented parallel to the groundwater flow direction (McBride *et al.*, 1994; Mozley and Davis, 1996). Elongate concretions have even been found in faults, where they record the past flow orientation of groundwater in the fault zone (Mozley and Goodwin, 1995).

Cone-in-cone structure

Cone-in-cone structure consists of nests of cones of authigenic minerals, one inside another, which form either in thin beds, as veins, or at the margins of carbonate concretions (Figure D19). Concretions that consist almost entirely of cone-in-cone carbonate are also observed. In such concretions, the apices of the cones invariably point toward a shale core that bisects the concretions (e.g., Franks, 1969). Individual cones are often separated from one another by a thin layer of clay. The structure mainly forms in shales, but has been reported for argillaceous sandstones as well. Most cone-in-cone is composed of calcite, but it has also been observed in, siderite, gypsum and pyrite (Carstens, 1985).

The carbonate material making up the cones has variable characteristics. It is often fibrous calcite (6 microns or less in diameter, but up to 3 cm long; Franks, 1969), however, microcrystalline calcite has also been reported. This microcrystalline calcite is generally interpreted to represent recrystallized fibrous calcite, based upon the presence of relict textures (Franks, 1969). When present in sandstone, the cone-in-cone structure is often thinner and less distinct than in shales.

A variety of mechanism have been proposed for the origin of cone-in-cone structure. These include: (1) Volume increase accompanying inversion from aragonite to calcite (Tarr, 1922;

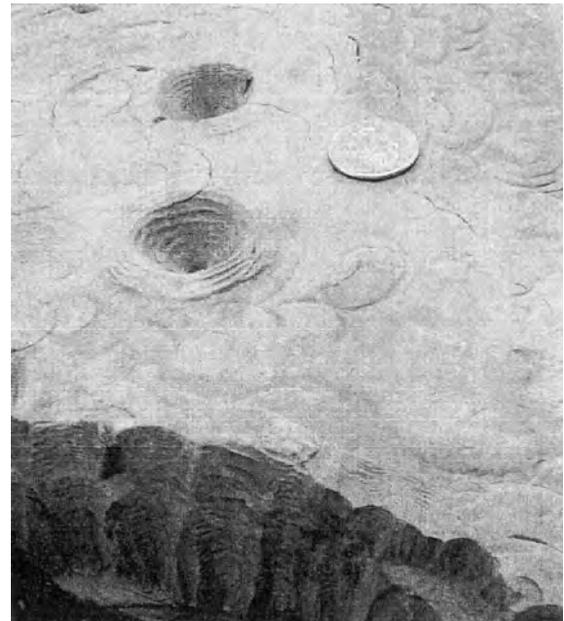

Figure D19 Cone-in-cone structure. Coin for scale.

Gilman and Metzger, 1967), in which expansion of conical aragonite pushed cones apart and allowed clay intrusion; (2) burial-induced pressure solution, with clay films originating as insoluble residues (Tarr, 1932); (3) fracturing of crystalline aggregates that grow in overpressured chambers, with the fractures induced by a decrease in pore pressure (Selles-Martinez, 1994); and (4) formation during early diagenesis by expansive mineral growth (i.e., force of crystallization), in which the cones are produced by the growth of cone-shaped aggregates of fibrous calcite (Franks, 1969), and the clay films originate as the crystals displace and disturb the original clay-rich sediment. By the latter mechanism, the orientation of the growing crystal is assumed to be controlled by the local stress configuration (direction of easiest crystal growth). Of these hypotheses, the displacive crystal growth mechanism has proven to be the most popular, though the debate is by no means settled.

The inferred displacive nature of the crystal growth, and common deflection of host rock laminae around cone-in-cone concretions has led most authors to conclude that much of the precipitation occurs very early, during shallow burial. However, some authors have concluded, largely on the basis of ^{18}O -depleted values of some of the cone-in-cone material, that they can form later, at perhaps hundreds of meters of burial depth (overpressuring would be necessary to allow displacive growth at such depths; Marshall, 1982; Pirrie *et al.*, 1994).

Geodes

Geodes are subspherical accumulations of authigenic minerals (mainly silica minerals and to a lesser degree calcite and celestite) which occur in a variety of rock types, particularly limestone and shale (Figure D20). They are superficially similar to concretions. However, unlike concretions, which contain considerable detrital material, they consist almost entirely of authigenic minerals. Geodes typically have a thin outermost layer of dense chalcedony and a hollow interior, in which well formed crystals project into a central cavity. They can also be completely filled with authigenic minerals (some authors use the term “filled geode” for such features), including a variety of exotic minerals, such as millerite,

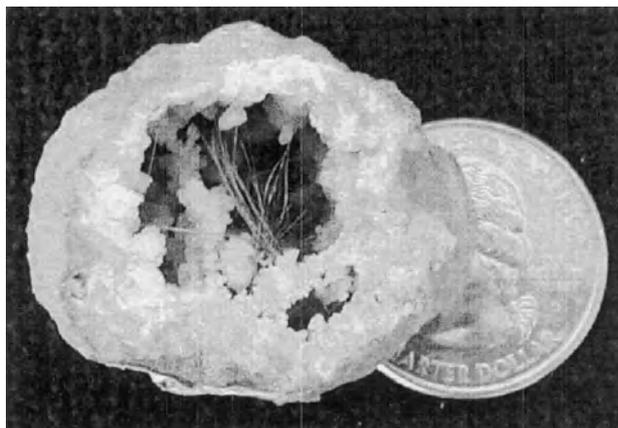

Figure D20 Silica geode. Fibrous mineral in interior is millerite. Coin for scale.

anatase, chalcopyrite, and galena (Goldstein and McKenzie, 1997). Some geodes even contain oil in the central cavity (Anonymous, 1938).

The term geode is sometimes applied to features in volcanic rock, including basalt (precipitated in gas cavities; Garlick and Jones, 1990), though some authors indicate that such features are more properly termed amygdules and that the term should be restricted to features observed in sedimentary rocks (Chowns and Elkins, 1974). Thunder eggs are related structures of spherical or ellipsoidal shape, which contain cores of chalcedony and sometimes quartz. They are completely filled with minerals (i.e., contain no internal cavity) and are found exclusively in welded tuffs and rhyolites (Staples, 1965).

Numerous theories have been proposed to explain the origin of geodes, including: (1) Precipitation within dissolved fossil material, particularly sponges (Van Tuyl, 1916); (2) a complex process of replacement and solution/precipitation alteration of calcite concretions (Hayes, 1964); and (3) dissolution and replacement of evaporite nodules. Of these, hypothesis-3, alteration of evaporite nodules, is the most commonly cited mechanism. Indeed, many workers use the term “silicified evaporite nodule” rather than geode to describe these structures (e.g., Milliken, 1979; Ulmer-Scholle *et al.*, 1993; Ulmer-Scholle and Scholle, 1994). Geodes have been reported in rocks that originated in sabkha environments (Chowns and Elkins, 1974), however, they can also form in “normal marine” sediments that have experienced circulation of concentrated brines (Maliva, 1987). Geode formation (i.e., silicification) can apparently proceed during early diagenesis (e.g., prior to compaction; Chowns and Elkins, 1974), as well as during late-stage diagenesis in association with meteoric influx and hydrocarbon migration (Ulmer-Scholle *et al.*, 1993).

Liesegang banding

Liesegang bands were first described by Liesegang (1896) in experimental precipitates. His original experiment involved placing a drop of silver nitrate solution on a surface of potassium dichromate gel. This resulted in the formation of concentric rings of silver dichromate. Liesegang and subsequent workers noted similar features in rock, which are now referred to as Liesegang bands or rings. These features consist of bands of authigenic minerals arranged in a regular repeating pattern. They typically cut across-stratification and occur in a variety of rock types including sandstone and chert. Despite the frequent occurrence of Liesegang bands in rocks (Merino, 1984), only a few authors have examined their mineralogy and texture in any detail (Fu *et al.*, 1994). Liesegang bands are frequently cited as prime examples of geochemical self-organization, in that their distribution in the rock often does not seem to be directly related to preexisting features (Chen *et al.*, 1990).

The exact mechanism of band formation is poorly understood and remains an area of active research (e.g., Krug *et al.*, 1996). A commonly cited mechanism is precipitation in a Ostwald-Liesegang supersaturation–nucleation–depletion cycle. By this mechanism diffusion of reactants leads to supersaturation and nucleation; this precipitation results in localized band formation and depletion of reactants in adjacent zones (DeCelles and Gutschick, 1983; Sultan *et al.*, 1990).

Reduction features

Gray-green reduction features are common in many redbeds. They occur as isolated, subspherical to irregular reduction spots, and as reduction zones associated with fractures, faults, and permeable sandstone beds (Miller, 1957; Shawe, 1976; Chan *et al.*, 2000). These features result from localized reducing conditions in the pore water, most commonly resulting from the presence of organic matter (in the case of reductions spots), or migration of reducing groundwater along zones of higher permeability (in the case of reduction zones). The exact origin of the reduced areas is poorly understood. Some authors ascribe the phenomenon mainly to reduction of ferric to ferrous iron, without net transport of iron from the reduced area (e.g., McBride, 1974; Mykura and Hampton, 1984). Others note either no change in ferric/ferrous ratio across reduced areas and contend that they are the result of Fe transport (e.g., Manning, 1975), or they describe changes in both ferric/ferrous ratio and total iron content (Keller, 1929; Picard, 1965; Durrance *et al.*, 1978). Significant mineralogical differences occur in association with these features, including dissolution of iron oxides and ilmenite in the reduced portion and precipitation of authigenic feldspars and biotite (Miller, 1957; van de Poll and Sutherland, 1976). Some trace-element results suggest that Fe, Ca, Cr, and Nb are leached, and Co, Ni, V, and Y may be added during production of reduced areas (Shawe, 1976).

Sand crystals

Sand crystals are large (1 to >50 cm long) euhedral to subhedral poikilotopic crystals of authigenic minerals (commonly barite, gypsum or calcite) that formed in sandstone (Figure D21). Such crystals commonly have well-developed crystal faces despite the fact that they can contain greater than 50 percent included sand grains. The percentage of sand within the crystals is variable, and reflects the mode of growth of the crystal. Passive precipitation of poikilotopic crystals results in intergranular volumes (IGVs) that are comparable to that of uncompacted or slightly compacted sand (i.e., 40–50 percent). Expansive crystal growth results in much higher IGVs and disrupted fabrics (Dapples, 1971; McBride *et al.*, 1992). In extreme cases, expansive growth can completely exclude sand

grains from the crystal's interior. Some crystals contain alternating zones of greater and lesser sand percentages, which are interpreted to reflect alternating passive and displacive growth. This is thought to result from alternating fast and slow crystal growth, with exclusion of sand grains occurring during periods of slow growth (McBride *et al.*, 1992; Shearman, 1981).

Stylolites

Stylolites are irregular serrated surfaces in sedimentary rock. They frequently consist of interlocking finger- and column-like extensions that are subparallel to one another and perpendicular to the trend of the surface. This can give stylolites an irregular zig-zag appearance when viewed in cross section (Figure D22). They form by a process of pressure dissolution, in which portions of minerals under relatively high stress, such as at grain contacts, undergo preferential dissolution due to a pressure-induced solubility increase. Stylolites form perpendicular to the maximum compressive stress, which is commonly vertically oriented, due to overburden pressure, resulting in horizontal, bedding parallel stylolites. In areas that have experienced tectonism, however, the principal compressive stress is commonly horizontally oriented, resulting in sub-vertical stylolites that cut across-bedding. Sutured grain contacts are similar to stylolites, but unlike sutured contacts, stylolites are large-scale features, which traverse numerous grains and often entire outcrops. They are most commonly observed in carbonate rocks, which are particularly susceptible to pressure solution, but are found in sandstones and other rock types as well. Undulatory surfaces that show evidence for pressure solution, but are not serrated in cross section, are referred to as solution seams (or wispy pressure solution seams).

Lithologic heterogeneity appears to be the main variable controlling stylolite morphology (Andrews and Railsback, 1997). If the rock is relatively homogeneous, dissolution proceeds equally along the stylolite and a linear or undulatory seam develops. High heterogeneity results in unequal dissolution, with variable amounts of dissolution occurring along the stylolite due to differences in solubility. This results in a “zig-zag” columnar appearance. As dissolution proceeds, the nature of the heterogeneity may too, resulting in changing stylolite morphology through time.

Stylolites commonly contain a concentration of clay-rich material, which is assumed at least in part to be a build-up of

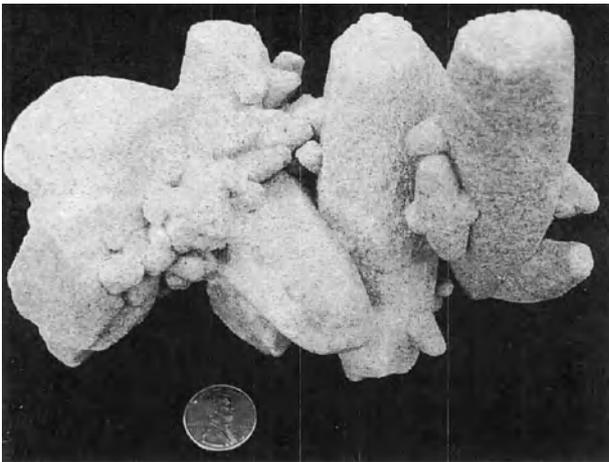

Figure D21 Calcite sand crystals. Coin for scale.

Figure D22 Cross-sectional view of several stylolites. Pencil for scale.

insoluble minerals from the host rock that underwent dissolution. Thus, as dissolution proceeds along the stylolite, this insoluble residue becomes thicker. One cannot simply assume that all the insoluble material along a given stylolite originated in this way, because in some cases much of the clay may have originated as a depositional clay seam, which subsequently became a stylolite. Some authors have proposed that clays promote pressure solution by providing a pathway for ion diffusion (Weyl, 1959). Andrews and Railsback (1997), however, demonstrated that stylolites can form in limestones with as little as 2.1 wt percent insoluble residue and concluded that abundant clay is not a necessary prerequisite for stylolite development. Meike and Wenk (1988) provided TEM evidence suggesting that some of the clay in these seams is authigenic.

There are two competing hypotheses for how pressure solution proceeds along the stylolite: the undercutting hypothesis and the solution film hypothesis. The undercutting hypothesis (Bathurst, 1975) proposes that dissolution occurs initially at point contacts resulting in preferential dissolution at the contact, which causes the grains to become closer to one another and transforms the point contact to a surface contact. This is followed by undercutting of the surface contact at the edges (water being absent along the surface contact), which results in undercutting and eventually in the formation of another point contact. The solution film hypothesis proposes that a contiguous film of liquid separates the two grains in a manner similar to that operative during displacive crystal growth (Weyl, 1959). This water is assumed to be under higher pressure at grain contacts and selective dissolution proceeds along the contact as a result. The second hypothesis (thin film) is currently in favor with most workers (Morse and Mackenzie, 1990).

As dissolution proceeds, ions migrate away from the site of dissolution either along the stylolite or away from the stylolite surface. Bathurst (1975) notes that much of the material must leave the stylolite, migrating into overlying or underlying host rock in order for dissolution to proceed. This material commonly reprecipitates near the stylolite (e.g., Wong and Oldershaw, 1981). The combination of cementation adjacent to stylolites, and the build-up of low-permeability clay-rich insoluble residue (discussed above) can produce a very low-permeability zone, that can act as a barrier to petroleum migration and groundwater flow.

Loss of material by dissolution along stylolites can have a significant impact on the sedimentary record. Bathurst (1975) indicates that reductions of vertical thickness due to stylolite growth of 20–35 percent is common, and that crustal shortening accomplished by tectonically generated stylolites can exceed that caused by folding and other deformation mechanisms.

Summary

Diagenetic structures are macroscopic features that are the result of diagenetic alteration of the host rock. The principal diagenetic structures are concretions, cone-in-cone structure, geodes, liesegang bands, reduction features, sand crystals, and stylolites.

Concretions are concentrations of authigenic minerals (mainly carbonate, silica, apatite, and iron oxides) that most commonly form in shales, sandstones, and limestones. They originate either by filling pores between framework grains or

by replacement of the host rock. Concretions form either concentrically, in which concretion growth initiates at the concretion core and material is progressively added to the exterior of the growing concretion; or in a complex manner, involving precipitation at multiple nucleation sites throughout the concretion body. Septarian concretions contain internal radial fracture networks that may result from internal shrinkage. Elongate concretions have been used to map out paleogroundwater flow orientations.

Cone-in-cone structures consist of nested cones of authigenic minerals, most commonly calcite, that are separated from one another by thin films of clay. They occur mainly in shales, but have also been reported in argillaceous sandstones. Numerous explanations have been put forth to explain these structures, with the most popular being formation through expansive crystal growth of the cones.

Geodes are subspherical concentrations of authigenic minerals (most commonly silica) that occur mainly in shales and limestones. They typically have a fine-grained external layer of chalcedony and an interior of coarser crystals that project into a cavity. Most appear to have formed by dissolution and silicification of evaporite nodules, though other origins are possible.

Liesegang bands are nested zones of authigenic minerals arranged in a regular repeating pattern. Their origin remains poorly understood, however, a commonly cited mechanism is precipitation in a Ostwald-Liesegang supersaturation–nucleation–depletion cycle.

Reduction features occur in redbeds as gray-green subspherical “spots” and elongate “zones” that are commonly associated with fractures. They form due to the presence of locally reducing pore waters.

Sand crystals are large, well-formed poikilotopic crystals in sandstone. They are most commonly composed of gypsum, barite, or calcite. Some grow passively, simply filling available pore space in the sand, whereas others grow displacively, excluding sand grains and disturbing the detrital fabric.

Stylolites are irregular, serrated surfaces that originate through pressure-induced dissolution of the host rock, most commonly a limestone. The surfaces typically contain a buildup of clay-rich material that is commonly assumed to represent an insoluble residue. The morphology of the surface is largely governed by the degree of heterogeneity of the host rock, with more heterogeneous lithologies having more serrated and irregular stylolites. Stylolites form perpendicular to the principal compressive stress axis, resulting in subhorizontal stylolite formation during normal burial and subvertical stylolites of tectonic origin. Stylolite formation accounts for the loss of considerable thicknesses of host rock by dissolution. The material removed by dissolution is precipitated adjacent to the stylolite in some cases, but can also migrate great distances before reprecipitating.

DIFFUSION, CHEMICAL

Diffusion of chemicals is one of the three main processes of solute movement in sedimentary porewaters, that is, diffusion, advection (flow) and biologically induced exchange near the sediment water interface (mainly irrigation). Chemical diffusion is the net transport that is caused by thermally generated random motions of particles in “solution”, may they be ions, molecules or colloids. The net result of this phenomenon is the transfer of a solute, that is, a flux, from regions of high concentration to those of low concentration. In a closed system, this flux leads to an eventual homogenization of the solute concentration, if no other processes act to maintain the gradients (Figure D23).

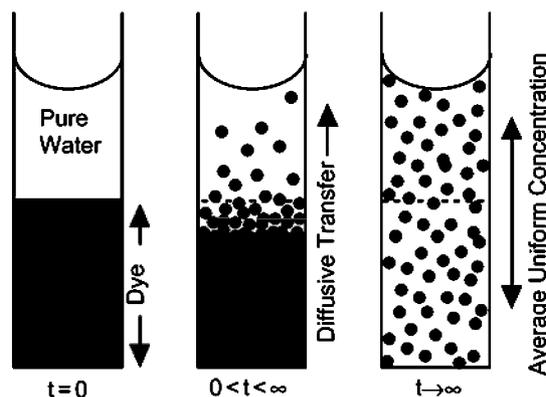

Figure D23 Illustration of diffusion in a tube containing pure water and water with dissolved dye particles (black circles).

The diffusive flux is governed by Fick's First Law of Diffusion, which in 1-dimension has the form

$$(F_D)_i = -D_i \frac{\partial C_i}{\partial x} \quad (\text{Eq. 1})$$

where $(F_D)_i$ is the diffusive flux of solute i , D_i is its diffusion coefficient, C_i is its concentration and $\partial C_i / \partial x$ is its vertical gradient. Values of D_i for various solutes of interest to diagenesis can be found in Boudreau (1997, chapter 4), and these typically fall in the range of $0.3\text{--}1.25 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$.

Diffusion in aqueous sediments is slower than in an equivalent volume of water because of the convoluted path(s) the diffusing particles must follow to circumvent the solid sediment particles (Figure D24); therefore, the effective solute diffusivity, D'_i , in sediments is smaller than D_i and given by

$$D'_i = \frac{D_i}{\theta^2} \quad (\text{Eq. 2})$$

where θ is the *tortuosity* (dimensionless). In diagenetic studies, θ is defined as the ratio of the average incremental distance, dL , that a diffusing particle must travel to cover a direct (vertical) distance, dx , that is, dL/dx (Berner, 1980).

The tortuosity can be related to a measured quantity called the “formation factor”, ff , which is obtained from electrical resistivity measurements,

$$f = \frac{\text{bulk sediment specific electrical resistivity}}{\text{resistivity of porewater alone}} \quad (\text{Eq. 3})$$

The relationship between tortuosity and resistivity is assumed to be of the form (Berner, 1980)

$$\theta^2 = \varphi f \quad (\text{Eq. 4})$$

where φ is the sediment porosity, that is, porewater volume fraction. When measurements of f are lacking, θ can be estimated by Archie's law in sands, that is,

$$\theta^2 \approx \varphi^{-2} \quad (\text{Eq. 5})$$

and, in fine-grained sediments (Boudreau, 1997, chapter 4),

$$\theta^2 \approx 1 - \ln(\varphi^2) \quad (\text{Eq. 6})$$

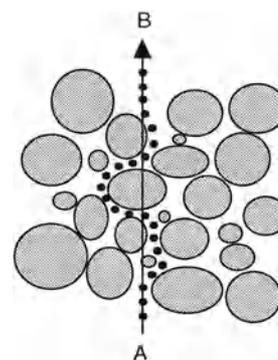

Figure D24 A particle trying to diffuse from point A to point B cannot pass through solid sediment particles (filled shapes); it must travel around these particles and so traverses the *tortuous* dotted path, rather than the direct solid-line path.

Molecular/ionic diffusion can be an effective transport process over “small” distances in sediments. Small in this context is defined by the so-called Peclet number

$$Pe = \frac{\varphi vL}{D_i} \quad (\text{Eq. 7})$$

where L is the distance of interest and v is the porewater flow speed. If $Pe \gg 1$, flow is the dominant transport process; conversely, if $Pe \ll 1$, diffusion is dominant, while both contribute significantly if $Pe \approx 1$.

An example of a situation where solute transport is strongly dominated by chemical diffusion is the penetration of oxygen into muddy organic-rich sediments. The scale of penetration is only a few tens of centimeters, at most, for example, Figure D25 where the Peclet number is of the order of 10^{-3} for $v \leq 0.1$ cm per year, $D_i = 10^2$ cm² per year, and $L = 1$ cm. In such situations, the oxygen mass balance is between the reaction that consumes it (decay) and the supply by diffusion. Because such oxygen profiles are essentially time invariant when observed from the sediment–water interface, that is, steady state, the mathematical statement of mass balance is given by the diagenetic equation (Bernier, 1980; Boudreau, 1997)

$$\underbrace{\frac{\partial}{\partial x} \left[D' \frac{\partial C_i}{\partial x_i} \right]}_{\text{Change of the diffusive flux with depth}} - \underbrace{R_o}_{\text{Rate of oxygen consumption}} = 0 \quad (\text{Eq. 8})$$

where R_o is generally assumed to be a constant. The solution to equation 8 with constant D'_i is of the form

$$C_i = C_0 + C_1x + C_2x^2 \quad (\text{Eq. 9})$$

where C_0, C_1, C_2 are constants. The excellent fit of equation 9 to data is also illustrated in Figure D25.

Outside of areas affected by groundwater flow, porewater velocities in recently deposited sediments are of the same order of magnitude as the accumulation velocity of the sediment,

that is, from about 10^{-1} cm per year in the nearshore to 10^{-3} cm per year in abyssal clays. With solute diffusion coefficients typically of the order of 10^2 cm² per year, the Peclet number for these porewaters will be less than unity for L ranging from tens to hundreds of meters. Thus, diffusion continues to act as a significant transport mechanism during latter diagenesis and even over fairly large distances, as illustrated by the modeling of Deep Sea Drilling Project data (Lerman, 1979; Bernier, 1980).

Other chemical transport processes that can occur in sediments are often modeled in analogy to chemical diffusion. Thus, dispersion of solutes that accompanies strong hydrological flow of porewater ($Pe > 1$) is almost universally represented in models as equation 1 with a new empirical diffusion coefficient, known as the dispersion coefficient. Likewise, mixing of porewaters by wave-induced water motions or by infaunal movement (not irrigation) is also conveniently represented as diffusion. An important point to remember in this respect is that molecular diffusion is always present, while these other “diffusions” may or may not occur in a given situation.

DIFFUSION, TURBULENT

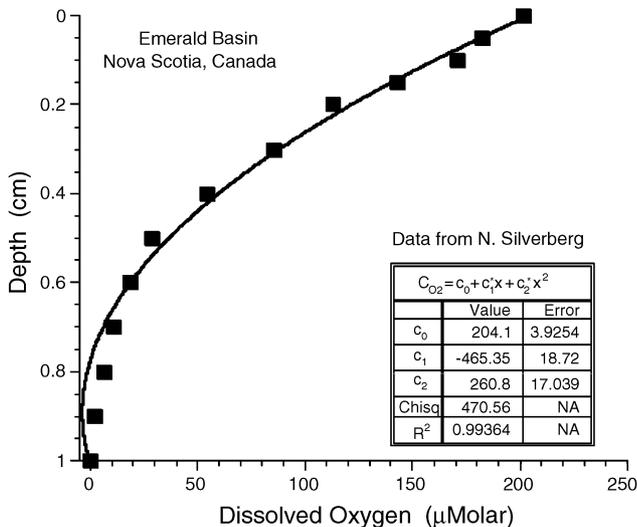

Figure D25 Dissolved oxygen profile (squares) from a muddy sediment, taken off the coast of Nova Scotia, Canada. The line through the data is equation 9.

A key feature of turbulent flows is that they are diffusive, so that the mean separation between initially adjacent fluid particles progressively increases in time. Sedimentary particles, suspended in a turbulent flow, move in response to fluid motions in addition to settling under gravity. The ratio of the settling velocity of the particles, w_s , to the magnitude of the turbulent fluid fluctuations, u_* , is therefore an important ratio for characterizing the motion and distribution of sediment. (This ratio, w_s/u_* , sometimes known as the *Rouse parameter*, is further discussed below.) In this article we present models for the diffusive motion of particles. We begin by reviewing the forces acting on individual particles and developing an equation of motion. We then consider how to model the evolution of a suspension of relatively heavy particles within a fluid by introducing a volumetric concentration, which varies both spatially and temporally. Even in a nonturbulent flow, suspended particles are subject to random fluid motion due to molecular movements (Brownian motion). This leads to a molecular diffusivity and we demonstrate how to develop a mathematical model of this process. In a turbulent flow, there are random fluid motions associated with unsteady eddies. We show how to form a mathematical description for the evolution of the average concentration and how, in analogy with molecular diffusive processes, it is possible to describe

these turbulent processes using a diffusion model. This model is empirical and we indicate some of the limits of its validity. We show how it can be used to model the vertical distribution of relatively heavy sediment suspended in a horizontal turbulent flow.

Particles suspended in fluids are subject to a number of forces, which means that they are not passively advected by the fluid motions. If the concentration of particles is high then these forces may arise from interactions between the suspended material (e.g., Bagnold, 1954), but even when the suspension is dilute, there are a range of possible effects. Maxey and Riley (1983) have formulated an expression for the forces on a single spherical particle in an unbounded fluid. These include the buoyancy force, which arises due to the density difference between the solid and fluid phases; the drag force, which is the force exerted by the fluid on the surface of the particle and is a function of the relative velocity between the phases; the added mass term, which is due to the displacement and acceleration of fluid surrounding the particle; the pressure gradient term which arises due to a nonuniform distribution of pressure within the fluid; and the Basset history term, which is associated with the acceleration of fluid surrounding the particle in response to the unsteady particle motion. In addition forces may arise due to the rotation of the particle, vorticity in the background fluid motion and the interaction with boundaries (see Clift *et al.*, 1978; Auton *et al.*, 1988). Thus, the calculation of the trajectory of a single particle is complicated even in an idealized, simple flow. However, the buoyancy and drag forces dominate the motion of most natural particles, with particle inertia playing a small role in some circumstances. Denoting the particle and fluid velocity by \mathbf{v} and \mathbf{u} , respectively, we find that when the drag force is linearly proportional to the relative velocity between the two phases, the equation of motion is then given by

$$\frac{d\mathbf{v}}{dt} = \frac{1}{\tau_p} (\mathbf{u} - \mathbf{v} - w_s \hat{\mathbf{Z}}), \quad (\text{Eq. 1})$$

where w_s is the Stokes settling velocity, $\tau_p = w_s/g$ is the particle relaxation time and $\hat{\mathbf{Z}}$ is a unit vector aligned with the vertical axis.

Given the complexity of this equation of motion, it is infeasible to calculate the trajectory of each constituent particle within a suspension. Rather, it is usual to introduce a volumetric concentration, $C(\mathbf{x}, t)$, which measures the volume of particles relative to the total volume of the suspension and which is a scalar function of time and space. (Some investigators employ a mass concentration which is the mass of particulate relative to the total mass of the suspension.) The dispersed particles are treated as a continuum and the evolution of the concentration field is calculated.

Whenever a quantity, such as temperature, salinity or the concentration of suspended particles, is nonuniformly distributed, random motions give rise to diffusion, whereby it is gradually spread throughout space. At a microscopic level, diffusive spreading is caused by the progressive increase of the mean separation between adjacent molecules, which is a consequence of Brownian motion. The botanist Robert Brown observed the motion of small pollen grains suspended in a fluid. Even though the system had come close to equilibrium and the pollen grains were uniformly distributed, he observed individual grains undergoing seemingly irregular motion which we now term Brownian motion. For a thorough

discussion of mathematical models of molecular interactions and the kinetic theory of gases see Chapman and Cowling (1970). The effects of diffusive spreading may be illustrated by considering a concentration distribution, $C(z, t)$, within a randomly moving fluid. Here, for simplicity, only one spatial dimension is considered although the analysis can be generalized to three dimensions. The random motion of the fluid may be modeled probabilistically so that $P(y, \delta t)$ denotes the probability that concentration field at position z is displaced to a new position $z+y$ after a time δt . The probability distribution has the following features: first, the probability of making a displacement is unity; and displacements are in either direction with equal probability, so that the first moment of the distribution vanishes. These properties may be written as

$$\int_{-\infty}^{\infty} P(y, \delta t) dy = 1 \quad \text{and} \quad \int_{-\infty}^{\infty} yP(y, \delta t) dy = 0. \quad (\text{Eq. 2})$$

Also the second moment is given by

$$\int_{-\infty}^{\infty} y^2 P(y, \delta t) dy = 2D \delta t. \quad (\text{Eq. 3})$$

Thus the mean square displacement grows linearly in time with rate $2D$. The concentration $C(z, t + \delta t)$, can be expressed as follows

$$C(z, t + \delta t) = \int_{-\infty}^{\infty} C(z - y, t) P(y, \delta t) dy. \quad (\text{Eq. 4})$$

Forming a Taylor series expansion for the concentration field, which is valid if the displacements are not large, yields

$$C(z - y, t) = C(z, t) - y \frac{\partial C}{\partial z} + \frac{y^2}{2} \frac{\partial^2 C}{\partial z^2} + \dots \quad (\text{Eq. 5})$$

Finally multiplying by the probability of a displacement and integrating gives an expression for the change in the concentration field during a time δt

$$C(z, t + \delta t) - C(z, t) = D \delta t \frac{\partial^2 C}{\partial z^2}. \quad (\text{Eq. 6})$$

In this expression D is termed the diffusivity and is the rate at which the random fluid motion leads to the increase of the mean-square separation of initially adjacent fluid particles. Diffusion leads to particle movement from regions of high to low concentration ("transport down the concentration gradient") and the diffusive flux is given by

$$-D \frac{\partial C}{\partial z}. \quad (\text{Eq. 7})$$

Note that individual particles are moving randomly and independently of the concentration gradient. However collectively their motion is such that there is net migration.

For small particles it is possible to estimate the diffusion coefficient due to Brownian motion, using arguments first presented by Langevin (1908) and Einstein (1905). Both of

these yield

$$D = \frac{kT}{6\pi\mu a}, \quad (\text{Eq. 8})$$

where T is the temperature, k the Boltzmann coefficient ($k = 1.38 \times 10^{-23} \text{ JK}^{-1}$), such that kT is a measure of the energy of the molecular vibrations, μ is the dynamic viscosity and a the particle radius.

We are now able to formulate the concentration transport equation on the assumption that the particles are advected with the fluid flow, have settling velocity w_s , and are diffused by random processes associated with Brownian motion. For a concentration field that is dependent on z and t , and a fluid flow denoted w , this gives

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial z} \left(D \frac{\partial C}{\partial z} - wC + w_s C \right). \quad (\text{Eq. 9})$$

The relative magnitude of the diffusion to the advection terms is UL/D , where U and L are the velocity and length scales of the flow, respectively, and this ratio is termed the *Peclet number*. For most naturally occurring flows with sediment, the Peclet number is much larger than unity, indicating that the diffusive transport of particles by Brownian motion is much smaller than advection with the fluid. Thus we may approximate the sediment motion to be advection with the fluid flow and settling under the action of gravity.

Many natural flows are turbulent and an essential characteristic of them is that the velocity fields are irregular and fluctuating. These apparently random fluid motions are able to induce diffusive migration, in an analogous manner to that generated by the random molecular motion described above (Hinze, 1959). A mathematical model of this turbulent diffusion is most simply developed by making the Reynolds decomposition in which the velocity and concentration fields are decomposed into mean and fluctuating parts. In what follows we treat only one-dimensional fields, which depend only on z and t . Thus we write

$$C(z, t) = \overline{C}(z) + c'(z, t) \quad \text{and} \quad w(z, t) = \overline{w}(z) + w'(z, t). \quad (\text{Eq. 10})$$

where an overbar denotes the mean quantity and the means of the fluctuating components vanish. In passing we note that this decomposition requires some care if the state around which the fluctuations are occurring is itself evolving in time. In such a situation it is still possible to make a Reynolds decomposition provided a typical timescale of the fluctuations is much shorter than the timescale over which the flow is evolving. In a similar vane, the Reynolds decomposition of flows which have a periodic variation requires the period of the oscillation to be much longer than the timescale of the fluctuations (Dyer and Soulsby, 1988). The mean evolution equation in the absence of molecular diffusion, is given by

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial z} \left(w_s \overline{C} - \overline{w} \overline{C} - \overline{w'c'} \right). \quad (\text{Eq. 11})$$

The terms on the RHS of this equation are the mean settling flux, $w_s \overline{C}$, the mean advective flux, $\overline{w} \overline{C}$, and the turbulent flux, $\overline{w'c'}$ (which is known as the *Reynolds flux*). If the fluctuations in the velocity and concentration fields are completely decorrelated then the Reynolds flux vanishes. However if the distribution of concentration is nonuniform, the correlation

between these fluctuating fields provides a mechanism for the transport of particles. A model of the Reynolds flux as a function of the flow field and the property of the particles awaits a complete description of two-phase turbulent flows. However a simple closure assumption is to draw an analogy between molecular diffusion and these turbulent motions and write the diffusive migration in terms of the gradient of the mean field,

$$\overline{w'c'} = -K_s \frac{\partial \overline{C}}{\partial z}, \quad (\text{Eq. 12})$$

where K_s is the *eddy diffusivity* (sometimes known as the sediment diffusivity). This relationship between the Reynolds flux and the eddy diffusivity is empirical and is justified by the apparently diffusive nature of turbulent flows in many situations. Here we reiterate that this diffusion is not associated with molecular fluctuations but is entirely due to the seemingly random turbulent fluid motion. One of the key weaknesses in the analogy between molecular and turbulent processes in some situations the scale of the turbulent eddies excursions, which comprise the “random” flow, can be quite large. In some boundary layer flows it is possible for the scale of these eddies to be comparable with the length scale over which there is significant variation within the concentration field. Thus the Taylor series approximation used to derive the dependence of the diffusive flux on the gradient of the concentration field may not be valid. However in many circumstances this eddy diffusion model has led to a good model of the distribution of sediment within a naturally occurring flow.

In addition to transporting particles, turbulent eddies also transport fluid and thus provide a means for interchanging fluid elements with different momenta. Their action, therefore, leads to an effective stress. By forming a Reynolds decomposition of the momentum equations it is possible to identify *Reynolds stresses* which are correlations between fluctuating velocity fields. These can then be related empirically to gradients of the mean velocity through the use of an eddy viscosity. For example for the two-dimensional, horizontally-aligned, shear flow $\mathbf{u} = (U(z), 0)$ with fluctuating velocity field $\mathbf{u}' = (u', w')$, the Reynolds stress can be written

$$\overline{u'w'} = -K \frac{\partial \overline{U}}{\partial z}, \quad (\text{Eq. 13})$$

where K is the eddy viscosity (Hinze, 1959).

In this context the *Schmidt number*, $\beta = K_s/K$, is the ratio between the sediment diffusivity and the eddy viscosity. Since both processes depend on the same turbulent eddies, it is natural to investigate whether the diffusion of sediment is more rapid than the diffusion of momentum or vice versa. Since a complete model of particle motion within a turbulent flow remains elusive, it is difficult to estimate the magnitude of β . This led Dyer and Soulsby (1988) to suggest that in most practical problems it is sufficient to set β equal to unity. There are, however, some physical processes in these flows which mean that the motion of the particles and the fluid are not identical and so β should be different from unity. This discussion is aided by identifying three timescales within the flow. The first is the particle relaxation timescale, τ_p , which is the time over which the relative velocity between the fluid and particle diminishes. This timescale is associated with the inertia of the particle. The other two timescales are associated with the turbulent flow and are the integral timescale of the

turbulence, T_L and a time scale L/u_0 , where L and u_0 are length and velocity scales of the flow. Note that the ratio $T_L u_0 / L$ is not necessarily of order unity (Hunt *et al.*, 1994).

We noted above that the gravitational force and the drag govern the motion of individual particles, which is a function of the relative velocity between the two phases. If the timescale over which the particle accelerates, τ_p , is much smaller than the timescale of the flow (either of the turbulent timescales) then the particle moves with the fluid motion and sediments under the action of gravity. However within a turbulent flow there are irregular motions with very rapid variations. Thus there will be periods in which the particle acceleration is non-negligible and thus the particle lags behind the fluid motion. Hence the particulate phase is not dispersed as widely as the fluid phase and the sediment diffusivity should be expected to be smaller than the eddy viscosity. Csanady (1963) discusses this phenomenon and proposes that β is a decreasing function of τ_p / T_L . However, for suspensions of dust in the atmosphere, this reduction is very small.

A second mechanism is the effect of crossing trajectories. Heavy particles, suspended in fluid, continuously change their fluid particle neighbors. Thus the velocity history of the particle is different from the surrounding fluid. For example, a heavy particle will sediment out of the eddy in which it is initially located. Thus the spatial decay of the correlation of the velocity field around it is more rapid than the decay of the coherent eddies. Hence the diffusivity of the particles should be expected to be smaller than the diffusivity of the fluid (Csanady, 1963; Hunt *et al.*, 1994).

One of the most fundamental problems in sediment transport is to establish the vertical distribution of suspended sediment within a turbulent flow over a horizontal, rigid boundary, such as a turbulent pipe flow or a free-surface flow such as a river. In these flows there can exist steady vertical distributions of sediment in which the weight of the suspended sediment is supported by the turbulent motions. (See the experimental data reported by Coleman, 1970; Vanoni, 1946). In terms of the diffusion equation, this balance is expressed by equating the settling flux and the vertical Reynolds flux. This balance is given by

$$\overline{w'c'} \equiv -K_s(z) \frac{d\bar{C}}{dz} = w_s \bar{C}. \quad (\text{Eq. 14})$$

In this expression the eddy diffusivity varies spatially which reflects the non-isotropic nature of the turbulent eddies. Close to the boundaries the size of the largest eddy is limited. Since these dominate the eddy-induced transport of sediment, it is to be expected that the eddy diffusivity should increase with distance from the boundary. Vanoni (1946) suggests that

$$K_s(z) = \beta \kappa u_* z (1 - z/H) \quad (\text{Eq. 15})$$

where β is the Schmidt number (assumed constant), $\kappa = 0.4$ is Von Karman's constant, H is the flow depth and the boundary shear stress $\tau_0 = \rho u_*^2$. Thus the vertical profile of sediment is given by

$$\frac{\bar{C}(z)}{\bar{C}(\delta)} = \left[\left(\frac{H-z}{z} \right) \left(\frac{\delta}{H-\delta} \right) \right]^{w_s / (\beta \kappa u_*)}, \quad (\text{Eq. 16})$$

where the concentration is known at a height δ . The key parameter in this distribution is the ratio of the settling velocity to a measure of magnitude of the turbulent velocity

fluctuations (w_s / u_*) and this determines the shape of the profile.

Some relatively recent observations of turbulent, boundary-layer flow have indicated that the notion of purely random fluid movement is inappropriate; rather there are coherent fluid motions which may dominate the dynamics close to the boundary (Kline *et al.*, 1967; Grass, 1971). Typically there is an inrush of relatively fast moving fluid toward the boundary and an ejection of slowly moving fluid away from the boundary. Collectively these are termed the turbulent bursting phenomenon. These types of fluid motion may have important consequences for the suspension of sediment, since the ejection events are a coherent means for lifting relatively heavy sediment upward from the boundary (Grass *et al.*, 1991). Furthermore since these events are coherent over relatively long length scales, it is doubtful whether a gradient-diffusion model is an appropriate framework for analyzing the effect of the turbulent motion. Further research is required to understand the dynamics of these coherent structures and to analyze their effects on the movement of particles

DISH STRUCTURE

Dish structures are thin, roughly horizontal, usually dark, flat to concave-upward laminations in sandstone and coarse siltstone beds (Figure D26). The dark color usually results from a local enrichment in mud, organic matter, micas, and other hydraulically fine or low-density grains. Dish structures were first described and named by Wentworth (1967) and Stauffer (1967) from thick-bedded deep-water sandstones of western California. Initially they were interpreted to be primary sedimentary structures related to the growth and breaking of antidunes during deposition from turbidity currents (Wentworth, 1967) or to inhomogeneous shearing

within grain flows (Stauffer, 1967). Lowe and LoPiccolo (1974) provided evidence that they are post-depositional structures formed during liquefaction and dewatering of rapidly deposited sediments. Experiments designed to reproduce dish structures reinforce this interpretation (Tsuji and Miyata, 1987; Nichols *et al.*, 1994).

Dish structures are most common in thick sandstone beds that are usually interpreted as deposits of high-density turbidity currents, although they have also been reported from alluvial sandstones. In general, each concave-up lamination or dish is underlain by a zone up to a few millimeters thick of lighter-colored sand representing the primary water flow path from which clays, organic particles, micas, and other hydraulically fine grains have been elutriated (Figure D27). Many dishes have upturned ends that define vertical water escape conduits called pillars or pillar structures (Figure D27). The width of individual dish structures ranges from about 1 cm to over 50 cm and their vertical spacing from 0.5 cm to over 30 cm. The bases of dish structures are sharp, whereas the tops tend to be gradational. The dishes range from relatively flat, continuous laminae with widely spaced interruptions (Figure D26) to more strongly curved dishes with frequent breaks (Figure D27). Rare bedding-plane views of dish-structures show a polygonal pattern of ridges separating shallow concave-upward depressions (Lowe and LoPiccolo, 1974).

Figure D26 Concave-upward dish structures cross-cut primary cross-laminations. The upturned ends of the dishes form peaks or pillar structures. Scale at top in millimeters. Turbidite from the Pennsylvanian Jackfork Group, Oklahoma.

Figure D27 Dish structures showing well-developed underlying light-colored water-flow paths from which dark clays, micas, and organic particles have been removed. Scale on right in millimeters. Turbidite from the Pennsylvanian Jackfork Group, Oklahoma.

Dish structures are interpreted to form through dewatering of rapidly deposited, cohesionless sand and silt. Rapid deposition results in loose packing of grains. Such sediments often undergo partial liquefaction in response to shocks associated with tectonic or sedimentological processes. The escaping water entrains hydraulically mobile grains, such as clays, organic materials, and micas. Semi-permeable laminations act as partial barriers to the upward flow of water within the liquefied sediment, forcing it to move laterally toward points where continued vertical escape is possible. Slow seepage through the bounding semi-permeable laminations results in filtering and concentration of the dark, hydraulically mobile grains to form the dark dish structures. Subsidence of the central parts of the dishes as the underlying water and sediment escape increases dish curvature. Primary semi-permeable laminae are not always present in dish-structured beds and might not be necessary for dish formation. Minor inhomogeneities in permeability, which are likely to be present even in apparently structureless beds, as well as the inhomogeneous development of flow paths due to hydrodynamic instabilities, can probably initiate dish-structure formation.

Allen (1982: 373–374) proposed that some or most dish structures can form through a process of stoping at the tops of water-filled cavities during dewatering of a loosely-packed, slightly cohesive water-saturated sediments. Tsuji and Miyata (1987) observed formation of dish structures as fine-grained sediment in water-filled cavities settled to the bottom, followed by the collapse of the roof. Some cavities had slowly subsiding roofs, and the water was filtered through the subsiding, relatively coherent sand mass. It is probable that dishes can form through both filtration along permeability barriers in liquefied sediments and stoping within water-filled cavities. The latter process is likely to result in dishes with more irregular shapes.

DOLOMITE TEXTURES

Rock texture is a composite characteristic determined by the size, shape, distribution and orientation of crystals, grains and pores. Texture carries genetic implications about kinetics of nucleation and growth of crystals and directly relates to porosity and permeability. Therefore, classification based on textural characteristics is appropriate when researchers are interested in the origin of dolomite or its petrophysical properties. The most useful textural characteristics for classifying dolomites are crystal shape (planar and nonplanar) and the degree to which textures of replaced allochems and cements are preserved (mimetic versus nonmimetic replacement).

Planar and nonplanar dolomite

Crystal shape is the most commonly used textural feature for classifying dolomite. Crystal shape may be categorized as planar or nonplanar (Sibley and Gregg, 1987). Planar dolomite crystals (Figure D28(A)) have straight dolomite-dolomite crystal boundaries. Nonplanar dolomites (Figure D28(B))

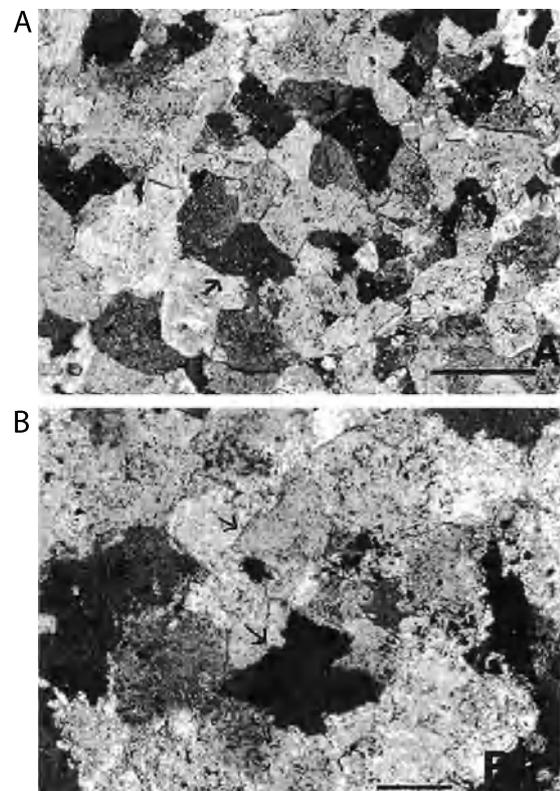

Figure D28 (A) Planar dolomite. Arrows point to straight enfacial junctions at a compromise growth boundary between adjacent crystals. Seroe Domi Fm., Pliocene, Bonaire, N.A. Cenozoic. Scale bar = 0.1 mm. (B) Nonplanar dolomites have both straight and irregular compromise boundaries (arrows). Trenton Fm., Ordovician, MI basin. Also notice the irregular extinction pattern in the dark crystal in the center and left-center of the field of view. Scale bar = 0.5 mm.

have curved, lobate or otherwise irregular dolomite-dolomite boundaries. Most petrographers use the terms planar and nonplanar to describe dolomite crystal shape, but the terms anhedral, euhedral, xenotopic and idiotopic are still commonly used (see *Classification of Sediments and Sedimentary Rocks*). Euhedral crystals are bounded by their faces, anhedral crystals are not. Idiotopic refers to a texture in which the majority of crystals are euhedral and xenotopic refers to a texture in which the majority of crystals are anhedral. Anhedral, euhedral, xenotopic and idiotopic are not appropriate descriptors of interlocking arrays of crystals observed in thin section because one cannot determine whether or not crystal-crystal boundaries represent crystal faces without using a universal stage. The terms planar and nonplanar are also flawed. These terms refer to three dimensions when, of course, thin section observations are two-dimensional. However, most dolomite crystal shapes are isotropic and, therefore, planar and nonplanar shapes are adequately represented in two dimensions. More importantly, segments of nonplanar dolomite-dolomite boundaries may be straight and straight boundaries may appear curved due to overlapping grains. As a result, qualitative distinction between planar and nonplanar dolomites may be very difficult even for experienced petrographers. Arbitrary criteria allow a quantitative distinction between planar and nonplanar (Gregg and Sibley, 1984) but the vast majority of published descriptions are based on qualitative analysis. Fortunately, it is usually easy to distinguish planar from nonplanar dolomite based on extinction characteristics. Planar dolomite has straight extinction and nonplanar dolomite usually has sweeping or segmented extinction (Figure D28).

Nonplanar dolomite cement, commonly referred to as saddle dolomite (Radke and Mathis, 1980) or baroque dolomite (Folk and Asserto, 1974), is volumetrically very minor but common. The distinguishing features are curved, saddle-shaped crystal faces (Figure D29) in open pore space and sweeping extinction. Dolomite-dolomite boundaries between saddle dolomite crystals are nonplanar. Saddle dolomite is a textural term that is commonly applied to dolomite

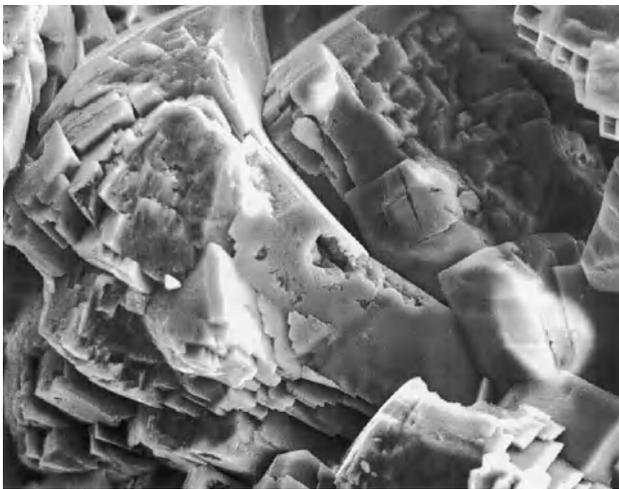

Figure D29 Synthetic saddle dolomite with characteristic curved faces produced in a hydrothermal bomb at 250°C (see Gregg, 1983). Field of view is 0.1 mm across.

$\text{CaMg}(\text{CO}_3)_2$, ferroan dolomite (<10 mole percent FeCO_3) and ankerite $\text{Ca}(\text{Fe, Mg})(\text{CO}_3)_2$.

Mimetic and nonmimetic replacement

Most dolomites are composed of equant rhombs tens to hundreds of micrometers in diameter. In these, it is generally impossible to determine whether the dolomite replaced a precursor calcium carbonate phase or precipitated directly from solution. When evidence of a precursor allochem (composite carbonate grain) or carbonate cement is present, the replacement dolomite is referred to as mimetic or nonmimetic (Kaldi and Gidman, 1982). Mimetic replacement of carbonate precursors occurs when micrometer to submicrometer-size dolomite crystals replace the carbonate in such a manner as to preserve the shape and internal texture of cements or allochems (Figure D30(A)). Poor preservation of allochems or cement texture is referred to as nonmimetic replacement. Nonmimetic textures often include “ghosts” which are inclusions of non-carbonate material which outline or show internal structure of pre-dolomitization allochems or cements (Figure D30 (B)).

Dolomite tends to nucleate epitaxially on calcite. Therefore, mimetic replacement may preserve the crystallographic orientation of calcite cements and allochems. When the host material is aragonite, dolomite tends to nucleate non-epitaxially. Therefore, mimetic replacement of aragonite will

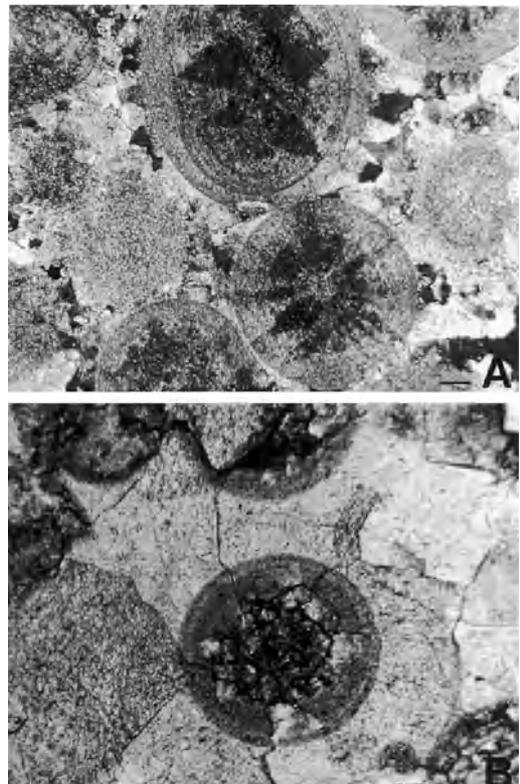

Figure D30 Mimetic (A) and nonmimetic (B) replacement of ooids. The mimetically replaced dolomite preserves the radial structure common in ooids. Nonmimetically replaced ooids are “ghosts” made visible by inclusions of organic material. Both samples from the Prairie du Chien Gp, Ordovician, MI Basin. Scale bars = 0.1mm.

preserve the structure of allochems or cements but not the original crystallographic orientation of aragonite crystals.

Crystal habit

Dolomites are not generally classified according to crystal habit because the only common form of dolomite crystals is the $\{10\bar{1}\}$ rhombohedron, although complex polyhedra occur (Naiman *et al.*, 1983; Gregg *et al.*, 1992). Spheroidal dolomites have been found associated with submarine hydrothermal vents (Pichler and Humphrey, 2001), hydrocarbons seeps (Gunatilaka, 1989) and possibly bacteria (Nielsen *et al.*, 1997).

Crystal size distribution

Dolomites crystal size distributions are lognormal to normal coarse skewed regardless of age or mean size (Gregg *et al.*, 1992; Sibley *et al.*, 1993). Similar crystal size distributions are found in other diagenetic minerals, as well as minerals in igneous and metamorphic rocks (Eberl *et al.*, 1998). Nonplanar dolomite tends to be coarser crystalline and more lognormal than planar dolomite (Sibley *et al.*, 1993; Woody *et al.*, 1996). Trends in crystal size and characterization of crystal size distributions have been of limited use in understanding dolomite petrogenesis because size distributions have not been directly linked to nucleation and growth theory.

Dolomite rock textures

Dolomite selectivity

Dolomite selectively replaces the fine crystalline portions of limestone. Therefore, the distribution of dolomite in a rock may reflect the original limestone texture rather than the chemistry or flow paths of dolomitizing solutions.

Fossil moldic porosity

Because dolomite selectively replaces fine crystalline components of a rock, coarse crystalline allochems such as brachiopod fragments often resist dolomitization. These resistant allochems may be subsequently leached. Fossil moldic porosity is also common in limestones but the fossils which make up the molds in limestones are typically not brachiopods or other coarse crystalline low Mg-calcite allochems.

Sucrosic dolomite

Porous, planar dolomites are generally equigranular giving the rock a sugary texture. The sugary texture is noticeable in hand specimen as light reflects off dolomite crystal faces. These rocks have attracted attention because they have relatively high permeability making them valuable hydrocarbon reservoir rocks.

Interpretations of dolomite textures

Interpretation of planar and nonplanar dolomite texture (Gregg and Sibley, 1984) is based on theoretical relationships between growth rate, supersaturation and/or temperature and crystal morphology (Sunagawa, 1984). Planar dolomite forms a smooth interface due to dislocation or 2-dimensional nucleation growth (Figure D31(A)). Nonplanar dolomite forms a rough interface by 2-dimensional nucleation and/or

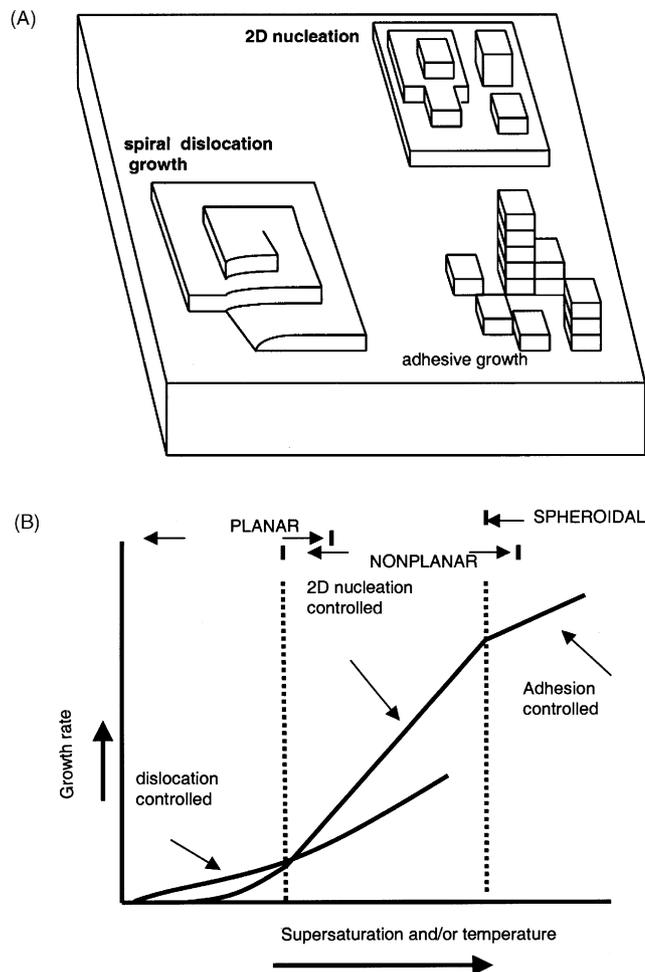

Figure D31 Models for crystal growth (A) and the associated geometry of crystal surface (B). Figure D31(B) is modified after Sunagawa (1984).

adhesive growth. Boundaries between dolomite types and crystal growth mechanism overlap because 2D nucleation can form plane crystal surfaces at relatively low temperature and/or degrees of supersaturation and irregular surfaces at higher temperature and/or supersaturation (Figure D31(B)). Spheroidal crystals are direct evidence that low temperature dolomites may form by adhesive growth but the majority of nonplanar dolomites have been attributed to growth at $>50^{\circ}\text{C}$ based on stable isotope and fluid inclusions (Spötl and Pitman, 1998).

Mimetic and nonmimetic textures reflect the density of nucleation sites present on the substrate being dolomitized. Mimetic texture requires a relatively high density of nucleation sites whereas nonmimetic texture reflects a low density of nucleation sites. The density of nucleation sites on a substrate is determined by the crystal size and mineralogy of the substrate as well as the degree of supersaturation and temperature of the solution. Mimetic replacement is favored in cryptocrystalline allochems. Coarse crystalline, low Mg-calcite allochems such as brachiopods are not mimetically replaced (Bullen and Sibley, 1984). Because the texture and

mineralogy of allochems can change during diagenesis, pre-dolomitization diagenesis can determine whether or not allochems are mimetically replaced.

In Paleozoic rocks, echinoderm fragments are commonly mimetically replaced whereas brachiopods are never mimetically replaced. In Cenozoic rocks, coralline algae and echinoderms are commonly mimetically replaced and generally the first allochems to be replaced (Sibley, 1982). Allochems that are normally mimetically replaced may be nonmimetically replaced if pre-dolomitization neomorphism results in significant crystal coarsening.

Lucia (1995) has shown correlations between porosity and permeability of dolomites, particularly when samples are grouped according to crystal size. Woody *et al.* (1996) have shown a correlation between porosity and permeability in planar and a lack of correlation in nonplanar dolomites. Therefore, improved correlations between porosity and permeability should be found if both crystal size and shape were considered.

DOLOMITES AND DOLOMITIZATION

The mineral *dolomite* is widely distributed in the Earth's crust, especially in sedimentary/diagenetic settings, in rocks that range in age from the Precambrian to the Recent. Ideal, ordered dolomite has a formula of $\text{CaMg}(\text{CO}_3)_2$ and consists of alternating layers of $\text{Ca}^{2+}\text{-CO}_3^{2-}\text{-Mg}^{2+}\text{-CO}_3^{2-}\text{-Ca}^{2+}$ etc. perpendicular to the crystallographic c-axis. Most natural dolomite has up to a few percent Ca-surplus (and corresponding Mg-deficit), as well as less than ideal ordering. *Protodolomite* has about 55 percent to 60 percent Ca and is partly to completely disordered, that is, the alternating layer structure is poorly developed to non-existing. Protodolomite or partially ordered dolomite with a few percent Ca-surplus are common as metastable precursors of well-ordered, nearly stoichiometric dolomite. *Dolostone* is a rock that consist of >75 percent dolomite. Dolostones are also called *dolomites*, especially in the literature prior to about 1990, but the term dolomites should be used only for different types of dolomite.

Two types of dolomite formation are common, that is, *dolomitization*, which is the replacement of CaCO_3 by $\text{CaMg}(\text{CO}_3)_2$, and *dolomite cementation*, which is the precipitation of dolomite from aqueous solution in primary or secondary pore spaces. The term dolomitization is also, yet incorrectly, applied to dolomite cementation. A third type of dolomite formation, where dolomite precipitates from aqueous solution to form sedimentary deposits ("primary dolomite"), appears to be rare and is restricted to some evaporitic lagoonal and/or lacustrine settings.

Despite intensive research for several decades, the origin of dolomites and dolostones is subject to considerable controversy. This is because some of the chemical and/or the hydrological conditions of dolomite formation are poorly understood, and because the available data permit more than one viable genetic interpretation in many case studies. One key

problem is that well-ordered, stoichiometric dolomite has never been successfully grown inorganically in laboratory experiments at near-surface conditions of 20–30°C and 1 atm pressure (to date, the lowest temperature/pressure at which (proto-) dolomite has been grown under well-controlled laboratory conditions is 60°C/1 atm: Usdowski 1994). Hence, geochemical parameters that are necessary for back-calculating the composition(s) of the dolomitizing fluid(s), such as the equilibrium oxygen isotope fractionation and trace element partitioning coefficients, have to be extrapolated from high-temperature experiments, which renders them notoriously inaccurate and often leads to ambiguous genetic interpretations in case studies of dolomitization. Furthermore, dolomite is fairly rare in Holocene environments and sediments, yet very abundant in older rocks. Collectively, these aspects make up the so-called “dolomite problem”, and they have led to a number of models for dolomitization.

Chemical constraints

Dolomite formation is chemically, that is, thermodynamically and/or kinetically, favored by (a) low $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ratios; (b) low $\text{Ca}^{2+}/\text{CO}_3^{2-}$ -ratios (= high carbonate alkalinity); (c) high temperatures; and (d) salinities substantially lower or higher than that of seawater (e.g., Machel and Mountjoy, 1986; Avidson and MacKenzie, 1999; Figures D32, D33). These constraints translate into three essential and common conditions and natural settings to form dolostones.

- (1) A sufficient supply of Mg^{2+} and CO_3^{2-} ; this condition favors marine settings and burial-diagenetic settings with

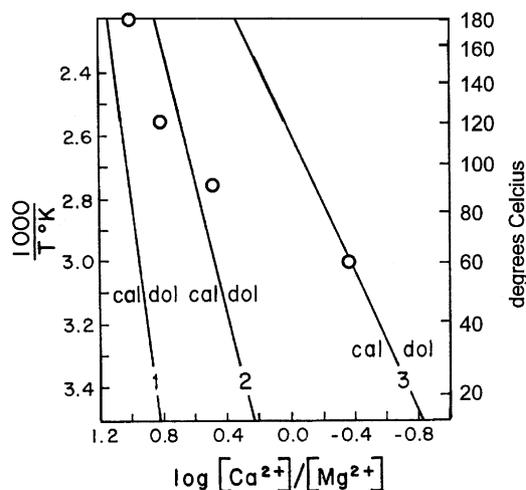

Figure D32 Bivariate thermodynamic stability diagram for the system calcite-dolomite-water. Square brackets denote activities. Lines are calculated from experimental data: line 1 = calcite + ideal, fully ordered dolomite; line 2 = calcite + ordered dolomite with slight Ca-surplus; line 3 = calcite + fully disordered protodolomite. The four open circles denote the results of Usdowski (1994), whose up to 7 year-long runs represent the lowest-temperature experimental dolomite formation performed to date. Usdowski's (1994) data for 90, 120 and 180°C plot close to line 2, but his data for 60°C plots on line 3, which probably reflects that protodolomite rather than dolomite formed at 60°C. Data from natural aquifers cluster close to line 2 (not shown), which can be considered representative of most natural dolomite. Diagram is modified from Carpenter (1980).

pore fluids of marine parentage because seawater is the only common Mg-rich natural fluid in sedimentary/diagenetic settings.

- (2) A long-lasting and efficient delivery system for Mg^{2+} and/or CO_3^{2-} (also exporting Ca^{2+} in the case of calcite replacement), which favors settings with an active and long-lasting hydrologic drive.
- (3) Carbonate depositional settings and/or limestones.

In addition, dolomite may form when rapidly rising formation fluids suddenly release CO_2 (Leach *et al.* 1991).

Considering that the above chemical constraints allow dolomite formation in almost the entire range of surface and subsurface diagenetic settings, the question arises why there are so many undolomitized limestones. The essential conditions for the common lack of dolomitization probably are: (d) ion pair formation, inactivating much of the Mg^{2+} and CO_3^{2-} in solution; (e) insufficient flow because of the lack of a persistent hydraulic head, too small a hydraulic head, or insufficient diffusion, resulting in insufficient magnesium and/or carbonate ion supply; (f) the limestones are cemented and not permeable enough; and (g) the diagenetic fluids are incapable of forming dolomite because of kinetic inhibition, for example, because the environment is too cold (most kinetic inhibitors of dolomite nucleation and growth are rather potent at temperatures below about 50°C, and the $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ratio of many cold diagenetic fluids is not low enough for dolomitization).

Mass balance constraints

Dolomitization is a diagenetic dissolution-replacement process for which many mass balance equations can be written. Dolomitization in its most simplistic form is represented by

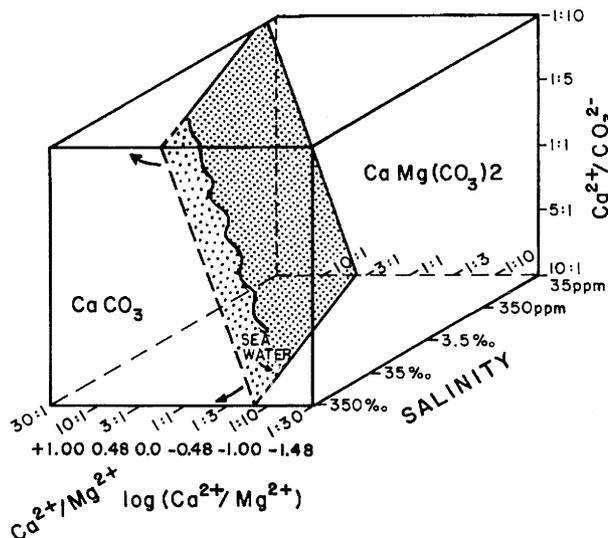

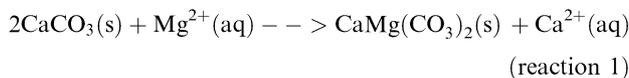

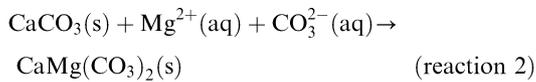

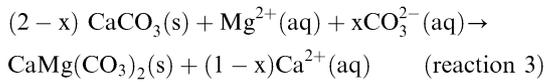

Figure D33 Trivariate kinetic stability diagram for the system calcite-dolomite-water. The ionic ratios are molar ratios. Seawater plots just in the calcite field. The stippled field boundary is bent towards higher Ca/Mg ratios at salinities greater than 35 permil. From Machel and Mountjoy (1986).

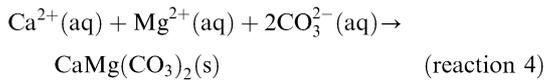

or by

Reactions 1 and 2 are end members of a range of possible stoichiometries, that is,

For $x=0$, reaction 3 becomes reaction 1, and for $x=1$ reaction 3 becomes reaction 2. Magnesium has to be imported to and calcium has to be exported from the reaction site in the case of reaction 1, whereas there is no export of calcium in the case of reaction 2. Intermediate cases are represented by values of x between zero and one. Dolomite cementation is most simplistically represented by

In any given case, the amount of the diagenetic fluid needed for dolomite formation depends on the stoichiometry of the reaction, temperature, and composition of the fluid. For example, if dolomitization proceeds via reaction 1, about 650 m^3 of normal seawater are needed to dolomitize 1 m^3 of limestone with 40 percent initial porosity at 25°C (Land, 1985). Dolomitization may not take place with 100 percent-efficiency, and larger water/rock ratios are required for complete dolomitization by seawater in a near-surface setting. If seawater is diluted to 10 percent of its original concentration, ten times as much water is needed. On the other hand, about 30 m^3 of brine are needed per m^3 of limestone at 100 percent-dolomitization efficiency in the case of a halite-saturated brine. The role of increasing temperature in the underlying thermodynamic calculations is to reduce the amount of magnesium necessary for dolomitization because the equilibrium constant (and hence the equilibrium Ca/Mg-ratio) is temperature-dependent (Figure D32). For example, at 50°C only about 450 m^3 of seawater are needed for complete dolomitization of 1 m^3 of limestone with 40 percent initial porosity at 100 percent-efficiency. The amounts of dilute and hypersaline waters change accordingly.

These calculations imply that, in all cases, large water/rock ratios are required for complete dolomitization. This necessitates the presence of active hydrologic flow systems for extensive, pervasive dolomitization. The exception are natural environments where carbonate muds or limestones can be dolomitized via diffusion of magnesium from seawater rather than by hydrologic flow.

Porosity and permeability

Dolomitization is important for petroleum and economic geology because most dolostones are more porous and permeable than limestones. However, it is not justified to presume that dolostones are always better hydrocarbon reservoir rocks than limestones. Schmoker and Halley (1982) have demonstrated with porosity/depth profiles of southern

Florida that many dolostones that have not been buried too deeply (less than about 1 km) have porosities equal to or less than those of adjacent limestones. A similar pattern has been found in Devonian dolostones of western Canada that were buried to more than 4 km (Amthor *et al.*, 1994). Furthermore, the shape and extent of dolostone reservoirs are determined by the process of dolomitization, that is, the direction and duration of the fluid flow regime(s). Therefore, and nevertheless, most dolomitized carbonates are better reservoirs than limestones, and dolostone reservoirs are diagenetic traps or combination traps with a diagenetic component. A related aspect is that dolostones often form aquifers and/or preferential migration pathways for hydrocarbons. For example, the dolomitized margin of the Devonian Cooking Lake platform is known as a migration pathway over a length of several hundred km (e.g., Amthor *et al.*, 1994).

Porosity may be retained, lost, or generated during dolomite formation. In the case of dolomite cementation, porosity (and permeability) loss is obvious and occurs in proportion to the amounts of dolomite cement formed. In contrast, about 13 percent of porosity is generated, such that a limestone with 40 percent porosity is replaced by a dolostone with about 45 percent porosity, in the so-called "mole-per-mole" replacement of calcite by dolomite according to reaction 1 (whereby two moles of calcite are replaced by one mole of dolomite). In such a case, the fabrics of the original limestone must be at least partially obliterated in order to account for the volume change during replacement.

More generally, porosity gains or losses can be represented by the values of x in reaction 3. In the special cases of $x=0.11$ and $x=0.25$ (for aragonite and calcite, respectively), there is no volume loss or gain (Morrow 1982). Hence, limestones dolomitized in a volume-per-volume replacement should not contain secondary pores or dolomite cements, and the primary textures may be partially or largely preserved. However, partial or complete obliteration of primary textures can occur even in a volume-per-volume replacement because of a marked change in crystal size (usually an increase, due to Ostwald ripening) and/or porosity redistribution.

All the above cases of dolomitization may, and many invariably do, involve reorganization of permeability pathways. Permeability modifications are a function of the textures and permeabilities of the precursor carbonates, as well as of reaction kinetics during dolomitization, that is, crystal nucleation and growth rates. While porosity changes can be estimated from the amounts of dolomite cement and/or intercrystalline secondary porosity, permeability changes during dolomitization are almost impossible to quantify.

Dolomite textures

The most widely used classification of dolomite/dolostone textures is the one by Sibley and Gregg (1987), based on Gregg and Sibley (1984). This classification is popular because it is simple and largely descriptive, although it carries genetic implications. Crystal size distributions are classified as "unimodal" and "polymodal", whereas crystal boundary shapes are classified as "planar-e" (euhedral), "planar-s" (subhedral), and "nonplanar" (anhedral). Where possible, a textural description includes recognizable allochems or biochems, matrix, and void fillings. Particles and cements may be unreplaced, partially replaced, or completely replaced. Replacement may be mimetic or nonmimetic. Unimodal size

distribution generally results from a single nucleation event and/or a unimodal primary (pre-dolomite) size distribution of the substrate. Polymodal size distributions indicate multiple nucleation events and/or a differential nucleation on an originally polymodal substrate. Planar crystal boundaries tend to develop at growth below about 50°C (the so-called “critical roughening temperature”), whereas nonplanar boundaries tend to develop at $T > 50^\circ\text{C}$ and/or high degrees of supersaturation. An exception are the planar yet curved crystal faces of saddle dolomite, which is known to form only at elevated temperatures of more than about 80°C (Radtke and Mathis, 1980; Machel, 1987). Saddle dolomite is different also in other respects, for example, it almost invariably is sparry and commonly milky-white, it has distinctively warped crystal lattices, undulose extinction, pearly luster, and abundant fluid inclusions.

Textures and reservoir characteristics of natural dolostones are highly variable. Where dolomitization is matrix-selective, significant porosity tends to be remnant primary porosity with relatively poor interconnection. Undolomitized calcite fossils commonly are dissolved during or after dolomitization, leaving a rock resembling Swiss cheese, that is, a relatively tight matrix with large holes. Various types of cement, often anhydrite, partially or completely occlude such secondary porosity. Where dolomitization is not matrix-selective, or where the matrix is relatively coarse-grained, sucrosic dolostones with intercrystalline porosity and excellent permeability tend to form.

Dolomite geochemistry

In addition to textures and their distribution relative to stratigraphy and structure, a wide range of geochemical methods may be used to characterize dolomites and dolostones, and to decipher their origin. The most widely used methods are stable isotopes (O, C), Sr-isotopes, trace elements, fluid inclusions, and paleomagnetism (e.g., various case studies in Purser *et al.*, 1994). Care must be taken to assess the degree of recrystallization, which may result in dolomite compositions that are characteristic of the environment(s) of recrystallization rather than the original environment(s) of dolomitization (e.g., Machel, 1997).

Natural environments and models of dolomitization

Dolomite occurs in many diagenetic environments that range from the surface to deep subsurface settings of several km burial depth. Most dolostones originate by the replacement of limestones that form(ed) in shallow-marine environments with normal seawater salinity, which is shown by relics of primary sedimentary features, such as ripple marks, reef fossils, burrows, etc., that have survived the replacement process. In the Recent, however, dolomite is almost absent from such carbonate depositional environments, despite the fact that seawater is many times supersaturated with respect to dolomite. Thus, various *models of dolomitization* have been devised to explain the origin of these types of replacement dolostones, and almost every time a new model has been proposed, it became a bandwagon until the next popular model arose. There also are dolostones that are devoid of primary sedimentary features, and where an origin without a limestone precursor appears possible. Dolomite is also

common, albeit generally not abundant, as a cement in limestones and clastic rocks.

The potential of natural environments to form dolomite and dolostone can be assessed on the basis of the above chemical considerations, and using hundreds of case studies that have been published over the last five decades (see compilations in Zenger *et al.*, 1980; Shukla and Baker, 1988; Purser *et al.*, 1994). Genetically, all natural dolomites can be grouped into two families (Budd, 1997). *Penecontemporaneous dolomites* form while the host sediments are in their original depositional setting. Most known penecontemporaneous dolomites are of Holocene age. However, there probably are many older examples in the geologic record, yet they are much more difficult to prove. *Postdepositional dolomites* form after deposition has ceased and the host carbonates have been removed from the zone of active sedimentation by progradation of the depositional interface, burial, uplift, eustatic sea-level change, or any combination of these factors. Almost all dolostones are postdepositional. Additionally, small amounts of dolomite may be formed syndepositionally or postdepositionally by the magnesium derived from within the dolomitized sediments, that is, originally contained in or adsorbed by Mg-calcites, organic matter, chlorophyll, biogenic silica, certain clay minerals, or older detrital dolomites, if present (e.g., Lyons *et al.*, 1984; Baker and Burns, 1985).

Penecontemporaneous dolomites and the microbial/organogenic model

There are two preferred settings of penecontemporaneous dolomite formation, that is, shallow-marine to supratidal, and hemipelagic to pelagic. In either case, and with few exceptions, the amounts of dolomite formed are small, and these dolomites are texturally as well as geochemically distinct.

Penecontemporaneous dolomites in shallow-marine to supratidal settings usually form in quantities of <5 vol-percent, mostly as Ca-rich and poorly ordered, fine-crystalline cements and/or directly from aqueous solution. One especially important type of penecontemporaneous (proto)dolomite forms lenses and layers of up to 100 percent in sabkhas, as discussed further below. The other occurrences are as lithified supratidal crusts (e.g., Andros Island; Sugarloaf Key; Ambergris Cay); as thin layers in salinas (e.g., Bonaire; West Caicos Island) and evaporative lagoons/lakes (e.g., Coorong); as fine-crystalline cements and replacements in peritidal sediments (e.g., Florida Bay; Andros Island); and as fine-crystalline supratidal weathering product of basic rocks (Capo *et al.*, 2000; this is the only known case to date where penecontemporaneous dolomite is ordered and stoichiometric). The dolomite-forming fluid is normal seawater and/or evaporated seawater, rarely with admixtures of evaporated groundwater.

Penecontemporaneous dolomite formation in hemipelagic to pelagic settings also form very small quantities of microcrystalline protodolomite, if any, that is, generally less than 1 weight-percent (Lumsden, 1988). However, under favorable circumstances the amount of dolomite can reach up to 100 percent locally. For example, Miocene hemipelagic carbonate sediments from the margin of the Great Bahama Bank are partially to completely dolomitized over a depth of range of about 50–500 m subsea. Dolomite occurs as a primary void-filling cement and by replacing micritic sediments, red algae, and echinoderm grains (Swart and Melim, 2000).

Both settings of penecontemporaneous dolomite formation appear to be linked to the “microbial model” or “organogenic model” of dolomitization (Vasconcelos and McKenzie, 1997; Burns *et al.*, 2000; Mazzullo, 2000). According to this model, dolomite may be formed syndepositionally or early-postdepositionally at depths of a few cm to a few hundred meters under the influence of or promoted by bacterial sulfate reduction and/or methanogenesis, as shown by $\delta^{13}\text{C}$ -values. The specific role of microbial activity in reducing the kinetic notorious barriers to dolomitization is presently uncertain, although reduction of Mg- and Ca-hydration barriers, an increase in alkalinity and changes in pH, seem to be involved. Most microbial/organogenic dolomites are cements, but some are replacive. They typically are fine-crystalline (less than $10\ \mu\text{m}$), calcic and poorly ordered protodolomites. The chief modes of Mg-supply are diffusion from the overlying seawater and/or release from Mg-calcites and clay minerals. Microbial/organogenic dolomites may act as nuclei for later, more pervasive dolomitization during burial.

Hyposaline environments and the mixing zone model

Hyposaline environments are those with salinities below that of normal seawater (35 mg/l). This includes coastal and inland freshwater/seawater mixing zones, marshes, rivers, lakes, and caves. Postdepositional dolomite has been found to form in all of these environments, but only in small amounts and commonly as cements.

One hyposaline environment, the coastal freshwater/seawater mixing zone (often simply called mixing zone) has given rise to one of the oldest and most popular models, that is, the “mixing zone model”. However, the mixing zone model has been consistently overrated since it was first proposed (Badiozamani, 1973; Land, 1973). For example, Humphrey and Quinn (1989) suggested that coastal mixing zones may form thick sections of dolomite in a platform-margin setting, and that such dolostones may be common in the geologic record. Other authors have proposed mixing zone dolomitization for entire carbonate platforms many hundreds of km^2 in size (e.g., Xun and Fairchild, 1987).

Dolomite may form in freshwater/seawater mixing zones. This is due to the fact that many freshwater/seawater mixing zones are thermodynamically undersaturated for calcium carbonate yet supersaturated with respect to dolomite in at least a part of the mixing spectrum (commonly in mixtures of about 10–50 percent seawater). However, not a single location in the world has been shown to be extensively dolomitized in a freshwater/seawater mixing zone, in recent or in ancient carbonates. Rather, dolomite formation appears to be kinetically inhibited in the vast majority of coastal mixing zones (Smart *et al.*, 1988; Machel and Mountjoy, 1990). Furthermore, calcite and aragonite dissolve at rates many times faster than dolomite is formed, thus, the most common result of mixing zone diagenesis is rocks riddled with secondary porosity up to the dimensions of caves, with or without small amounts of dolomite (e.g., Florida, Yucatan; Back *et al.*, 1986; confirmed by modeling: Sanford and Konikow, 1989). In addition, most coastal mixing zones are only a few hundreds of meters wide and pass relatively quickly through the rocks in response to eustatic sea level fluctuations and/or subsidence. Hence, even where mixing zones are capable of forming dolomite, the dolomitized rock volume is

relatively small and restricted to the platform margin(s) (Figure D34(A)).

Most mixing zone dolomite is petrologically and geochemically distinct. Most crystals are relatively clear, planar-e or planar-s, stoichiometric, well-ordered rhombs. However, some mixing zone dolomite is protodolomite. Crystal sizes commonly range from 1 micron to 100 microns but reach several millimeters in some cases. Most mixing zone dolomite occurs as cements in microscopic interstices and macroscopic voids, molds, vugs, and caverns. Alternating generations or growth zones of calcite/dolomite are common in coastal mixing zones with rapid and cyclical changes of salinity.

The main role of coastal mixing zones in dolomitization might be that of a hydrologic pump for seawater dolomitization, rather than that of a geochemical environment favorable for dolomitization (Machel and Mountjoy, 1990). At the seaward margin of a coastal mixing zone seawater is pumped

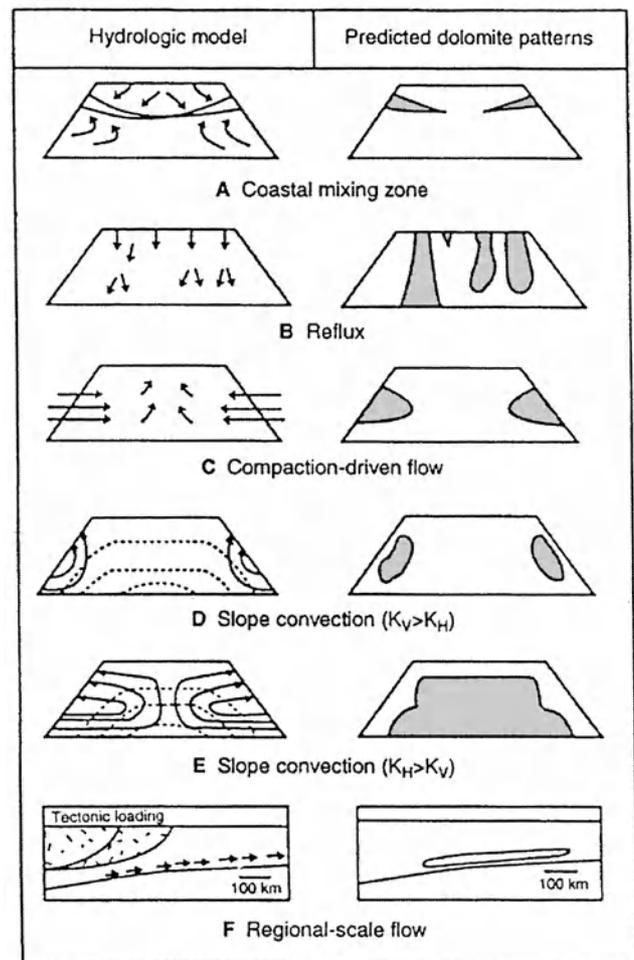

Figure D34 Selected models of dolomitization, illustrated as groundwater flow systems (left) and predicted dolomitization patterns (right). Examples are of incomplete dolomitization of carbonate platforms or reefs. Arrows denote flow directions; dashed lines show isotherms. Predicted dolomitization patterns are shaded. Models A–E are km scale; model F is basin-scale. Reproduced from Amthor *et al.* (1993).

through the sediments by the hydrologic action of freshwater–seawater mixing, whereby the water movement is influenced also by tidal pumping. Hence, substantial amounts of seawater may be pumped through the affected sediments by the hydrologic forces of freshwater–seawater mixing and the tides.

Hypersaline environments and the reflux model

Intertidal to supratidal environments with salinities greater than that of normal seawater occur throughout the world at latitudes of less than about 30°. Extensive, pervasive dolomitization of shallow water carbonates, up to the dimensions of huge and thick carbonate platforms, from density-driven flow (reflux) of the associated evaporitic brines has been suggested by many authors on the basis of case studies and modeling (e.g., Shields and Brady, 1995). This “reflux model” (Figure D34(B)) has been another very popular model of dolomitization throughout the last 30 years.

The sabkha of the Trucial Coast of Abu Dhabi, the probably best researched recent hypersaline intertidal to supratidal flat (Patterson and Kinsman, 1982; Baltzer *et al.*, 1994), is representative of prolific reflux dolomite formation. Fine-crystalline protodolomite is formed penecontemporaneously by evaporating floodwaters that are propelled periodically onto the lower supratidal zone and along remnant tidal channels by strong onshore winds. Dolomite formation takes place in a narrow (1–1.5 km) fringe next to the strandline and within the channels within the upper 1 m to 2 m of the sediments, and preferentially where the environment is chemically reducing (sulfate reduction, enhanced carbonate alkalinity). The distribution of protodolomite is uneven across the sabkha, and the best dolomitized parts contain 5 to about 65 weight percent protodolomite. Dolomite forms as a cement and aragonite is replaced, but lithification does not occur, or only partially. A variety of evaporite minerals, most notably multigenetic calcium sulfates, form within the dolomitized part of the sabkha.

In most respects, the Abu Dhabi sabkha appears to be a good recent analog for dolomitization in many ancient intertidal to supratidal flats, such as landward of the famous Permian carbonates of Texas and New Mexico. Rather than forming reservoir rocks, such dolostones—including the associated evaporites—generally form tight seals for underlying hydrocarbon reservoirs (e.g., Major *et al.*, 1988).

In general, sabkhas and ‘similar’ intertidal to supratidal environments in more humid climates typically form small quantities of fine crystalline protodolomite in thin beds, crusts, or nodules, either within the upper 1 m to 2 m of sediment, or at the sediment surface. Repeated transgressions and regressions may stack such sequences upon one another. Furthermore, it appears that the efficiency of reflux is different during transgression and regression. Mutti and Simo (1994) found in Permian carbonates that dolomitization occurred during transgressive cycles only in intertidal and supratidal facies, whereas dolomitization affected supra-, inter-, and subtidal facies during regression. They also speculated that tidal pumping and evaporative pumping may aid reflux in supplying Mg. In contrast, Montañez (1997) found in Ordovician carbonates that transgressive cycles were not dolomitized by reflux, whereas the facies within regressive cycles were almost completely replaced by tight fine-crystalline reflux dolomite. Be this as it may, deep penetration by refluxing evaporative

brines and/or platform-wide dolomitization has not been demonstrated anywhere in the world.

On the other hand, some the latest sophisticated modeling suggests that refluxing brines originating on ‘permanently’ flooded carbonate platforms may penetrate the platforms rather deeply, that is, 1–2 km (Jones *et al.*, 2002a,b). This situation differs from sabkhas and similar intertidal to supratidal flats, as the latter are flooded only intermittently. Even in flooded carbonate platforms, however, dolomitization is predominant and/or restricted to the upper few meters or tens of meters. Below these depths, the fluxes are too low and the brines, although still refluxing, have exhausted their dolomitization potential. Modeling the Devonian Grosmont platform in western Canada, based on extensive stratigraphic, lithologic, and geochemical data, Jones *et al.* (2002b) found that after 100 k years, during which brines concentrated up to 150 per mil (slightly beyond gypsum saturation) overlay the platform, reflux develops and shuts off geothermal circulation. The onset of reflux results in a reversal in groundwater flow direction as brines are transported from the platform interior basinwards. Refluxing brines enter the platform in a zone that extends approximately 150 km from the coast. As the platform evolves the brine plume, which is preferentially orientated in a horizontal direction, sinks into the platform subsurface and migrates basinwards. Computed distributions of fluid flux in conjunction with Mg mass-balance calculations permit the tracking of dolomite fronts as the Grosmont platform evolves. Within the range of parameter uncertainty, reflux could have delivered sufficient Mg in 1.6 m years to account for the pervasive dolomitization of the Grosmont Formation. However, even in these modeling results the amount of dolomite formed is not 100 percent, and dolomitization is restricted to layers and beds of dolomite that are interrupted by limestones, which results from repeated transgressions and regressions.

A previously unrecognized variant of reflux, proposed on the basis of numerical modeling by Jones *et al.* (2002a), is “latent reflux”. This type of reflux describes the phenomenon whereby brines of reflux origin continue to sink into a platform after the cessation of brine generation on the platform top. Hence, latent reflux could deliver magnesium to the platform carbonates after the cessation of evaporation, thereby forming additional dolomite. However, latent reflux, as active reflux during evaporation, would exit along or near the platform margin, and the brines would not lead to any dolomitization at greater depths. The efficacy of this process with respect to dolomitization remains to be proven.

Seawater dolomitization model

Postdepositional formation of massive dolostones has been attributed to the “seawater dolomitization model” (Purser *et al.*, 1994), with specific reference to the Cenozoic dolostones of the Bahama platform, which are often used as an analog for older dolomitized carbonate platforms elsewhere. Various hydrologic systems been invoked to drive large amounts of seawater through the Bahama platform, that is, thermal convection (Sanford *et al.*, 1998); a combination of thermal seawater convection and reflux of slightly evaporated seawater derived from above (Whitaker *et al.*, 1994); or seawater driven by an overlying freshwater/seawater mixing zone during partial platform exposure (Vahrenkamp and Swart, 1994), possibly layer-by-layer in several episodes (Vahrenkamp *et al.*, 1991). All these studies agree that the dolomitizing fluid was

essentially seawater that was, at best, only slightly altered by water-rock interaction.

It is noteworthy that the Bahama dolostones represent a hybrid regarding classification. This is because the dolomitizing solution probably was nearly normal seawater, yet thermal convection, as a hydrologic system and drive for dolomitization, is better classified under burial (subsurface) models. Similarly, Devonian dolostones in western Canada, which probably formed at depths of 300–1,500 m from slightly altered seawater, have been classified as burial dolostones (Amthor *et al.*, 1994), yet they could equally well be classified as seawater dolostones. This classification dilemma arose from the historical evolution of our understanding of these dolostones.

Burial (subsurface) environments and related models

Burial (subsurface) environments are those removed from active sedimentation by burial, and where the pore fluid chemistry is no longer entirely governed by surface processes, that is, where water–rock interaction has modified the original pore waters to a significantly degree (whereby ‘significant’ is ill defined). All burial (subsurface) models for dolomitization essentially are hydrologic models that differ mainly in the hydrologic drives and direction(s) of fluid flow (e.g., Morrow, 1999). Four main types of fluid flow take place in subsurface diagenetic settings: (1) compaction flow; (2) topography-driven flow; (3) thermal convection; and (4) tectonically-driven flow. Mixtures of these flow regimes and fluids are possible under certain circumstances.

The oldest burial model of dolomitization is the “compaction model” (Illing, 1959; Jodry, 1969). In this model (Figure D34(C)), seawater and/or its subsurface derivative is pumped through the rocks at several tens to several hundreds of meters. The model was never especially popular because it became clear that burial compaction can only generate fairly limited amounts of dolostone due to the limited amounts of compaction water.

Convection through carbonate platforms may be driven by heat from below or by density differences from above. One type of thermal convection originates from the horizontal density gradient caused by the regional temperature difference between the interior of uplifted platforms and the surrounding seawater. In this case, convection may take place in half-cells that are open to the adjacent and overlying ocean, with marked differences in the fluxes and heat transport as a function of the ratios of horizontal to vertical permeability (Figures D34(D), (E); Sanford *et al.*, 1998). The amounts of dolomite that can be formed in such convection half-cells are essentially unlimited, that is, dolomite can be formed as long as convection takes place. In contrast, the amounts of dolomite are much smaller where convection takes place in full-cells that are not open to the ocean. This may happen where convection is driven by a relatively weak regional heat gradient or by a local heat source, such as a magmatic intrusion. Thermal convection has been suggested for extensive, pervasive dolomitization in several carbonate platforms and/or regional carbonate aquifers (e.g., Morrow, 1999). In particular, thermal convection has been advocated as the chief mode of dolomitization for the Cenozoic carbonates of the Bahamas platform (here discussed under “Seawater dolomitization model”).

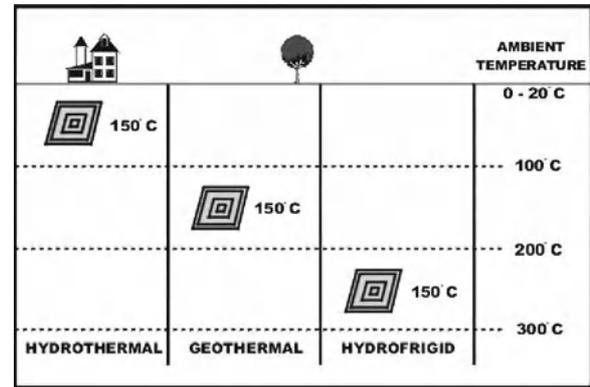

Figure D35 Hydrothermal, geothermal (formed in thermal equilibrium with the surrounding rocks), and hydrofrigid mineral formation. From Machel and Lonne (2002).

Convection cells invariably have rising limbs that penetrate the overlying and cooler strata, linking thermal convection to hydrothermal dolomitization. There are well-documented examples of hydrothermal dolomite, in local as well as in regional flow systems (e.g., Spencer-Cervato and Mullis, 1992; Qing and Mountjoy 1992, 1994; Duggan *et al.*, 2001). However, many dolomites that formed at elevated temperatures, especially but not exclusively saddle dolomites that formed at $T > 80^\circ\text{C}$, have mistakenly been called hydrothermal (e.g., Davies, 1997). The term “hydrothermal” is and should be used according to White’s (1957) time-honored definition as “aqueous solutions that are warm or hot relative to the surrounding environment”, with no genetic implications regarding the fluid source, including Stearns *et al.*’s (1935) rationale for a “significant” temperature difference of at least $5\text{--}10^\circ\text{C}$ (Figure D35). Hence, any mineral, including dolomite, should be called “hydrothermal” only if it can be demonstrated to have formed at a higher (by $>5\text{--}10^\circ\text{C}$) than ambient temperature, regardless of fluid source or drive (Figure D35, left). This definition does not carry a lower or upper temperature limit. A dolomite formed at only 40°C could be hydrothermal, if the surrounding rocks were significantly colder than that at the time of dolomite formation. If a mineral was formed at or near the same temperature as the surrounding rocks (within $5\text{--}10^\circ\text{C}$), it should be called “geothermal” (Figure D35, center), whatever the geothermal gradient. In keeping with common usage, the qualifier “geothermal” may simply be omitted, unless special emphasis needs to be placed on the geothermal nature of a particular mineralization event. Minerals formed at temperatures significantly lower than ambient (by $>5\text{--}10^\circ\text{C}$) may be called “hydrofrigid”, even if they formed at a rather high temperature (Figure D35, right). For example, seawater or freshwater may penetrate a rock sequence through highly permeable pathways, such that the water is heated to 150°C at a depth where the surrounding rock has a temperature of 250°C . If a mineral were formed at that time from the incompletely heated water, the mineral would be hydrofrigid.

Topography-driven flow takes place in uplifted sedimentary basins that are exposed to meteoric recharge. With time enormous quantities of meteoric water may be pumped through a basin, often concentrated by water-rock interaction (especially salt dissolution), and preferentially funnelled

through aquifers. Significant dolomitization can only take place, however, where the meteoric water dissolves enough Mg en route before encountering limestones. Gregg (1985) advocated topography-driven flow for regionally extensive dolomitization in Cambrian carbonates of Missouri.

Another type of flow that has been suggested to result in pervasive dolomitization is tectonically-driven, that is, metamorphic fluids expelled from crustal sections affected by tectonic loading that also drive basinal fluids toward the basin margin (Figure D34(F)). Such fluid flow could be injected into compactional and/or topography-driven flow, with attendant fluid mixing. Dorobek (1989), Drivet and Mountjoy (1997), and others have invoked tectonically-driven flow for dolomitization of the Siluro-Devonian Helderberg Group, USA, and for Devonian reefs in Canada, respectively. However, it is hypothetical at the present time whether tectonically induced flow, or the related fluid mixing, can form massive dolostones, because the fluxes of tectonically induced flow appear to be low (e.g., Machel *et al.*, 2000).

Textures and reservoir characteristics of dolostones formed in burial (subsurface) environments are variable. Where dolomitization is matrix-selective, significant porosity tends to be remnant primary porosity with relatively poor interconnection. Undolomitized calcite fossils may be dissolved during or after dolomitization, leaving molds and vugs. Where dolomitization is not matrix-selective, or where the matrix is relatively coarse-grained, sucrosic dolostones with intercrystalline porosity and excellent permeability tend to be formed. Unfortunately, these textures are not indicative of any of the genetic possibilities discussed above, with the exception of saddle dolomite, which appears to form only at $T > 80^{\circ}\text{C}$. This dolomite is texturally and geochemically distinct. Saddle dolomite occurs as cements in voids, as replacive masses (often as part of MVT-sulfide mineralization), or as so-called zebra dolomite in alternating layers with much finer-crystalline matrix dolomites. Zebra dolomite is much debated and may originate from repeated fracturing or some type of geochemical self-organization (Krug *et al.*, 1996).

Secular distribution of dolostones

The relative abundance of dolostones that originated from the replacement of marine limestones appears to have varied cyclically through time, with two discrete maxima of "significant early" dolomite formation (massive early diagenetic replacement of marine limestones) during the Phanerozoic, that is, the Early Ordovician/Middle Silurian and the Early Cretaceous (Given and Wilkinson, 1987). Various explanations have been proposed for this phenomenon, that is, that periods of enhanced early dolomite formation were related to or controlled by plate tectonics and related changes in the compositions of the atmosphere and seawater, such as an increased atmospheric CO_2 -level, high eustatic sea level, low saturation state of seawater with respect to calcite, changes in the marine Mg/Ca ratio, or low atmospheric O_2 -levels that coincided with enhanced rates of bacterial sulfate reduction (e.g., Stanley and Hardie, 1999; Burns *et al.*, 2000). At present, the reason(s) for the alleged or observed secular variations in dolostone abundance remain(s) uncertain.

Concluding remarks

There are many environments and possibilities to form dolomites and dolostones. However, the (paleo-) hydrologic

characteristics are rarely known well enough for an unambiguous interpretation of the dolomitizing fluid flow regime. Dolostones often consist of different generations of dolomite formed by different flow systems and mechanisms. Metastable (proto-) dolomites may be formed, especially in near-surface and shallow burial settings, which later and deeper recrystallize to more stable dolomites, either in one or in several recrystallization steps.

DUNES, EOLIAN

Introduction

Eolian dunes form part of a hierarchical system of bedforms developed in wind-transported sand which comprises: (i) wind ripples (spacing 0.1–1 m); (ii) individual simple dunes or superimposed dunes on compound and complex dunes (spacing 50–500 m); and (iii) compound and complex dunes (spacing >500 m). Dunes occur wherever there are sufficient supplies of sand-sized sediment, winds to transport that sediment, and conditions that promote deposition of the transported sediment. These requirements are satisfied in two main environments: (1) coastal areas with sandy beaches and onshore winds; and (2) desert areas. Most dunes occur in contiguous areas of eolian deposits called sand seas (>100 km²) or dune fields. Sand seas and dune fields are dynamic sedimentary bodies that form part of well-defined regional- and local-scale sediment transport systems in which sand is moved by wind from source areas (e.g., distal fluvial deposits, sandy beaches) via transport pathways to depositional sinks (Kocurek and Lancaster, 1999).

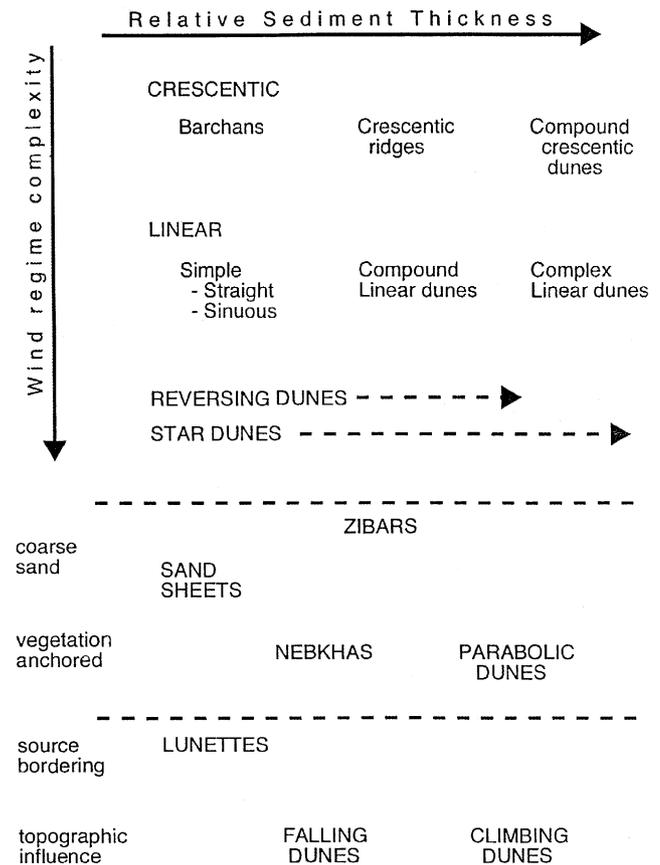

Dune types

Eolian dunes occur in five main morphologic types (Table D1). Although some authors have argued that coastal dunes have a distinct morphology, many recent workers argue that the only characteristic coastal dune form is the foredune because it is an integral part of the complex of nearshore processes forming the beach-dune system (Bauer and Sherman, 1999). Three varieties of each dune type can occur: simple (the basic form); compound (superimposition of small dunes of the same type on larger dunes); and complex (superimposition of different dune types on the primary form (e.g., crescentic dunes on linear dunes).

Eolian dunes occur in a self-organized pattern (Figure D36) that develops as the response of sand surfaces to the wind regime (especially its directional variability) and the supply of sand (Werner and Kocurek, 1997). Relations between dune types and wind regimes indicate that the main control of dune type is the directional variability of the wind regime (Figure D37). Grain size, vegetation cover, and sediment supply play subordinate roles.

Migration of crescentic dunes occurs as a result of erosion of the stoss slope and deposition on the lee. Rates of dune migration are inversely proportional to dune height. Linear

Table D1 A morphological classification of eolian sand dunes (after Lancaster 1995).

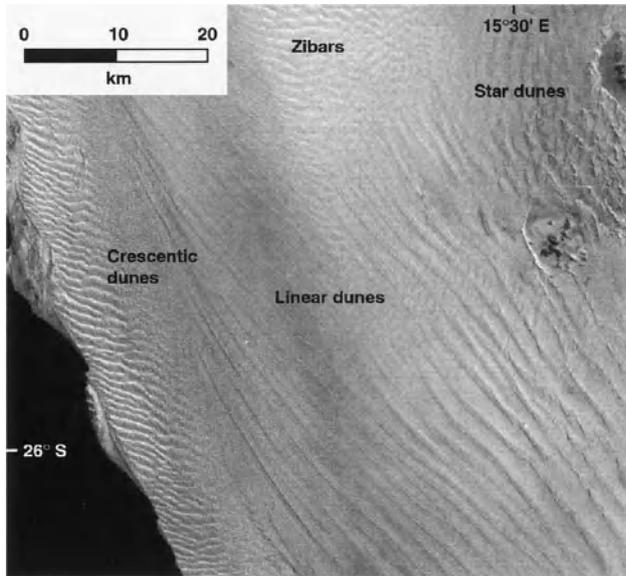

Figure D36 LANDSAT image of the southern part of the Namib Sand Sea, showing occurrence of different dune types as wind regime changes from coast to inland areas.

dunes do not migrate laterally, but extend downwind. Star dunes are essentially stationary forms.

The simplest dune types and patterns form in areas characterized by a narrow range of wind directions (unidirectional wind regime). In the absence of vegetation, crescentic dunes will be the dominant form. Parabolic dunes are the equivalent in partially vegetated areas. Isolated crescentic dunes or barchans occur in areas of limited sand supply, and coalesce laterally to form crescentic or barchanoid ridges that consist of a series of connected crescents in plan view as sand supply increases. Larger forms with superimposed dunes are termed compound crescentic dunes.

Linear dunes are characterized by their length (often more than 20 km), sinuous crestline, parallelism, and regular spacing, and high ratio of dune to interdune areas. They form in areas of bimodal or wide unimodal wind regimes. The essential mechanism for linear dune formation is the deflection of winds that approach at an oblique angle to the crest to flow parallel to the lee side and transport sand along the dune. Thus any winds from a 180° sector centered on the dune will be diverted in this manner and cause the dune to elongate downwind (Tsoar, 1983).

Star dunes have a pyramidal shape, with three or four sinuous sharp-crested arms radiating from a central peak and multiple avalanche faces. Star dunes occur in multi-directional or complex wind regimes and are the largest dunes in many sand seas, reaching heights of more than 300 m. The development of star dunes is strongly influenced by the high degree of form—flow interaction which occurs as a result of seasonal changes in wind direction, and the existence of a major lee-side secondary circulation. Most of the erosion and deposition involves the reworking of deposits deposited in the previous wind season. Sand, once transported to the dune, tends to stay there and add to its bulk (Lancaster, 1989).

Parabolic dunes are characterized by a U or V shape with a “nose” of active sand and two partly vegetated arms that trail

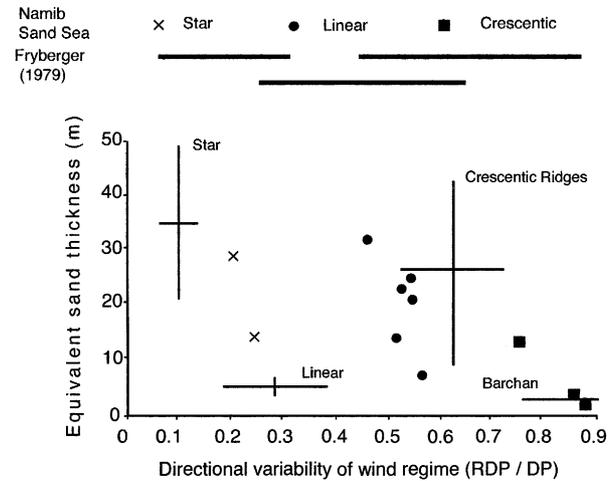

Figure D37 Relations between dune types and wind regimes. From Wasson and Hyde (1983) with Namib Sand Sea data superimposed (symbols) and range of wind regimes for three major dune types from Fryberger (1979). Equivalent sand thickness is a measure of the sand available for dune building and represents the thickness of sand if the dunes were levelled. The directional variability of the wind regime is characterized by the ratio between resultant (RDP) and total sand drift potential (DP).

up wind. They are common in many coastal dunefields and semi arid inland areas and often develop from localized blowouts in vegetated sand surfaces (Wolfe and David, 1997).

Other important dune types include nebkhas or hummock dunes (common in many coastal dunefields) anchored by vegetation; lunettes (often comprised of sand-sized clay pellets) that form downwind of small playas; and a variety of topographically controlled dunes (climbing and falling dunes, echo dunes).

Dune processes and dynamics

The development and morphology of all eolian dunes are determined by a complex series of interactions between dune morphology, airflow, vegetation cover, and sediment transport rates (Lancaster, 1995). As dunes grow, they project into the atmospheric boundary layer so that streamlines are compressed and winds accelerate up the stoss or windward slope. The degree of flow acceleration (the speed-up factor) is determined by the aspect ratio of the dune. Wind speed at the crest of the dune is typically 1.1 times to 2.5 times that measured immediately upwind of the dune (Figure D38(A)). Flow acceleration coupled with effects of stream line curvature on the windward slopes of dunes give rise to an exponential increase in sediment transport rates (Figure D38(B)) toward the dune crest (McKenna Neuman *et al.*, 1997), resulting in erosion of the stoss slope. In the lee of dunes, there is a complex pattern of flow separation, diversion, and re-attachment determined by the angle between the wind and the dune crest (angle of attack) and the dune aspect ratio (Sweet and Kocurek, 1990). On high aspect ratio (steep) dunes, high angles of attack result in flow separation, and lower angles of attack result in flow diversion. Low aspect ratio dunes are characterized by flow expansion. Flow separation (Figure D38(C)) results in the development of a back-flow

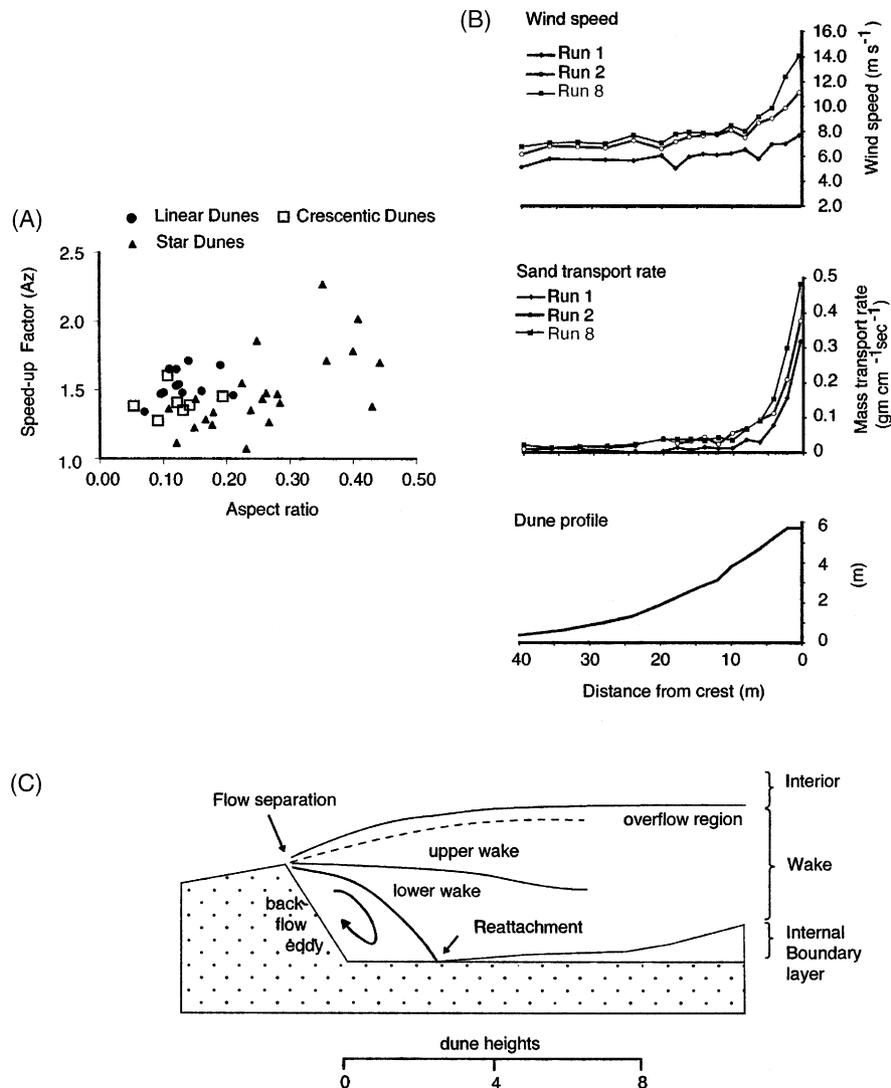

Figure D38 Elements of dune dynamics: (A): velocity speed-up (Lancaster, 1995); (B) winds and sediment transport rates on the stoss slope (McKenna Neuman et. al. 1997) (C) lee side flow separation and wake mixing (Frank and Kocurek, 1996).

eddy in the lee of the dune and a series of wakes that gradually diffuse and mix downwind (Frank and Kocurek, 1996). Flow separation also causes fallout of previously saltating sand grains and development of avalanche (slip) faces (Nickling *et al.*, 2002). Secondary flows, including lee-side flow diversion, are especially important where winds approach the dune obliquely, and are an important process on linear and many star dunes.

Dune sediments

Dunes are comprised of moderately- to well-sorted sands (1000–63 μm), with a mean grain size in the range 160 μm to 300 μm . Most dunes are composed of quartz, but may include significant quantities of feldspar (e.g., Kelso Dunes, California). Dunes composed of volcanoclastic materials occur in some areas (e.g., Great Sand Dunes, Colorado).

Carbonate-rich dune sands are found adjacent to many sub-tropical coastlines (e.g., Arabian Gulf) and gypsum dunes occur close to playas in Tunisia and at White Sands, New Mexico.

Three primary modes of deposition occur on dunes: (1) migration of wind ripples; (2) fallout from temporary suspension of grains in the flow separation zone (grainfall); and (3) avalanching of grains initially deposited by grainfall (grainflow). These create three basic types of eolian sedimentary structures: (1) wind ripple laminae; (2) grainfall laminae; and (3) grainflow cross-strata (Hunter, 1977). The primary sedimentary structures may be separated by a hierarchy of bounding surfaces representing episodes of reactivation, dune growth, and migration of dunes in conditions of bedform climb.

Crescentic dunes are dominated by grainfall and grainflow cross strata (Figure D39(A)) (Hunter, 1977; McKee, 1979).

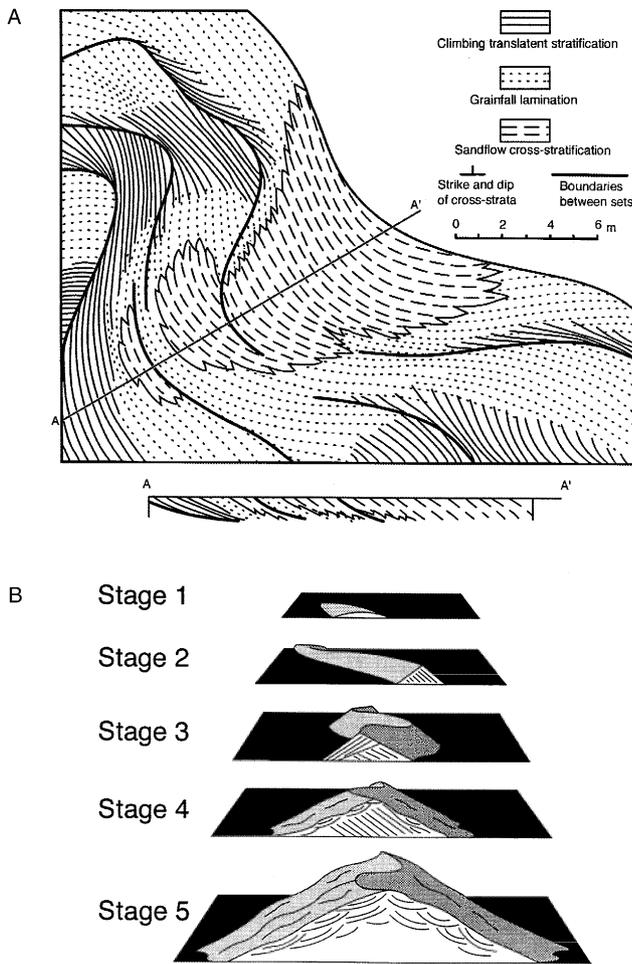

Figure D39 Sedimentary structures of dunes (A) crescentic dunes (Hunter, 1977); (B) linear dunes (from Bristow *et al.*, 2000).

Linear dune structures recently imaged using ground penetrating radar (Figure D39(B)) show a change in the dominant type of sedimentary structures as the dune grows (Bristow *et al.*, 2000). Small dunes are dominated by stacked sets of cross strata that dip in opposite directions and are formed by the migration of the elements of a sinuous crestline up the dune. The structures of larger dunes are dominated by trough cross-strata created by the migration of superimposed bedforms. Sedimentary structures of star dunes are not well-known, but likely complex.

Conclusions

Traditional field research, use of satellite image data, and some innovative modeling have provided a comprehensive picture of the basic elements of eolian dune forms and processes (Bauer and Sherman, 1999; Lancaster, 1995; Nickling and McKenna

Neuman, 1999; Pye and Tsoar, 1990). Significant areas for future research include the dynamics of lee face avalanching and numerical modeling of dunes and dunefields.

EARTH FLOWS

Earth flows are mass movements of fine-grained soils that range from rapid earth flows formed in highly sensitive clay deposits to relatively slower and drier earth flows common in plastic, fine-grained soils (Sharpe, 1938; Varnes, 1978; Cruden and Varnes, 1996). Common and widespread, earth flows can cause extensive damage to property and infrastructure; rapid earth flows have taken the lives of scores of people. Earth flows are a primary agent of erosion in many areas and contribute large amounts of sediment to streams and rivers. Scientists have recognized earth flows as a distinct type of mass movement from at least the early twentieth century; since then, many investigators have studied individual earth flows, their geology and underlying physical processes (e.g., Keefer and Johnson, 1983; Lefebvre, 1996). Earth flows as defined in older classifications, such as Sharpe's (1938), cross the divisions of modern landslide classification schemes to include earth flows, earth slides, composite earth slide-earth flows, as well as liquefaction spreads, and certain debris slides (Varnes, 1978; Cruden and Varnes, 1996).

Rapid earth flows

Most rapid earth flows occur in areas of highly sensitive clay deposits (quick clays). The largest known deposits of sensitive clay occur in Scandinavia and eastern Canada, but deposits also exist in Alaska, Japan, the former Soviet Union, and New Zealand (Lefebvre, 1996). Most sensitive clay deposits are young marine clays deposited in bodies of salt water that existed during retreat of the Wisconsin Ice Sheet. As a result of isostatic rebound, the formerly submerged deposits have since been uplifted, subjected to fresh-water leaching, and eroded. The marine clays typically contain 30–70 percent silt and their clay-sized fractions ($<2\mu$) typically contain more rock flour than clay minerals. The clay minerals are predominantly illite. Most workers have attributed the sensitivity to loss of salt from the pore water, an effect known to reduce the liquid

limits and remolded shear strength of clays (Lefebvre, 1996). Others have suggested that the high proportion of rock flour and resultant low plasticity of quick clays is a significant cause of their high sensitivity (Cabrerria and Smalley, 1973).

A rapid earth flow typically begins as a small landslide on a steep bank where a stream or river has eroded a valley into a sensitive clay deposit. Excess precipitation, elevated groundwater levels, earthquakes, pile driving and long-term erosion have triggered such earth flows (Sharpe, 1938; Lefebvre, 1996). Once the initial slide begins moving, it liquefies spontaneously and begins to flow. Consequently, the scarp is left unsupported and failure rapidly extends away from the bank as a series of rotational or translational slides. The overall movement is translational and retrogressive; as the basal quick clay liquefies and flows out of the scar, the relatively dry upper soil separates into blocks that may rotate or sink into the flowing quick clay. The entire failure process is usually completed within several minutes to several hours. Rates of movement as high as several meters per second have been observed (Cruden and Varnes, 1996). The retrogressive failure may result in either an arcuate scar that is elongate parallel to the bank or more commonly, a so-called "bottle-neck" landslide, in which the quick clay has flowed through a narrow notch in the bank from an irregular landslide area that may extend as much as 1 km from the original bank. The earth-flow deposit is hummocky, several meters to a few tens of meters lower than the original ground surface, and slopes gently toward the stream channel.

Slow earth flows

Slow earth flows are found in temperate and tropical climates across the globe, wherever clay or weathered, clay-bearing rocks occur in combination with moderate slopes and adequate moisture. Thus, earth flows are common in areas of clay-bearing sedimentary rocks and weathered volcanic rocks, as well as some areas of weathered metamorphic and plutonic rocks. Slow earth flows occur in fine-grained soils that consist dominantly of plastic silt or clay as well as rocky soils that are supported by a plastic silt-clay matrix. Atterberg limits of earth-flow material range widely between individual earth flows, but generally are consistent with moderate to high

plasticity. The materials also have low to moderate shear strength and low sensitivity.

Earth flows commonly have a teardrop or bulbous shape in map view, a sinusoidal profile, are elongate in the direction of downslope movement and several times wider than thick (Keefer and Johnson, 1983). Discrete lateral boundaries, characterized by shear zones that resemble strike-slip faults, are typical of slow earth flows. Depending on the rate of movement and amount of displacement, the lateral boundaries may be manifest as en echelon cracks or as continuous shear zones. Locally, flank ridges form inboard of the lateral boundaries (Fleming and Johnson, 1989). Such ridges form as a result of internal deformation as the earth-flow mass translates downslope.

The majority of slow earth flows move primarily by sliding on discrete basal and lateral slip surfaces. Distributed internal deformation accounts for a small fraction of the movement and contributes to the appearance of flowing movement. Numerous measurements and observations have confirmed however, that sliding is the dominant mode of movement and that internal deformation is consistent with the observed mechanism of sliding (Keefer and Johnson, 1983). In unusual cases, earth flow deposits absorb enough water and become sufficiently remolded that they actually flow; however, rapid earth flows of plastic, low-sensitivity clays are uncommon. Earth flows typically move at slow to moderate rates ranging from 10^{-10} m/s to 10^{-3} m/s; in a few instances, earth flows have surged briefly to rates ranging from 10^{-2} m/s to about 10^{-1} m/s (Keefer and Johnson, 1983).

The translational movement of earth flows makes them prone to persistent, long-term instability, thus earth flows commonly reactivate during periods of above-average precipitation or other disturbance, such as earthquakes, grading or irrigation (Keefer and Johnson, 1983; Skempton *et al.*, 1989). Long-term persistence of slip surfaces at residual strength contributes to earth-flow reactivation (Skempton, 1985). Mechanical and hydrologic isolation of earth flows by clay-rich layers at their boundaries also contribute to the persistent instability of earth flows (Baum and Reid, 2000).

Water is a significant factor in the movement and activity of slow earth flows. Increasing water content increases the unit weight, thereby increasing the driving stresses that tend to cause movement. Also, increasing pore-water pressure decreases the effective stress acting between soil particles, and thus the shear strength of the soil. Pore-pressure fluctuations, in combination with soil properties and shear-surface roughness, directly influence the rate of earth-flow movement (Keefer and Johnson, 1983; Iverson, 2000).

Summary

Earth flows are mass movements of fine-grained soils that result from composite modes of failure and movement. Most rapid earth flows form in highly sensitive clay deposits and progress by a rapid sequence of smaller failures that spontaneously liquefy and flow out of the source area. Slow earth flows form in deposits of plastic clay or silt and progress gradually by brief episodic movements or periods of sustained, relatively steady movement. Most slow earth flows move primarily by sliding on a distinct basal shear surface, accompanied by internal deformation of the earth-flow material.

ENCRINITES

Definition

Modern usage of encrinite was established by Bissell and Chilingar (1967: 156) as a crinoidal limestone with crinoidal ossicles in excess of 50 percent of the bulk of the rock. It could be either a crinoidal packstone or crinoidal grainstone (Dunham, 1962) or a crinoidal biomicrite, crinoidal biosparite, crinoidal biomicrudite, or crinoidal biosparudite (Folk, 1959).

In the first known reference to crinoids, Agricola (1546) used *Encrinos* to distinguish isolated pentagonal crinoid columnals. *Encrinos* or *Encrinus* was widely used, but interestingly, when this word was validly proposed in zoological nomenclature, it was used for a crinoid that has

circular columnals, i.e., *Encrinus liliiformis* Lamarck, 1801 (Lane, 1978). *Encrinus* is a common Triassic crinoid in western Europe (Hagdorn, 1993). The word encrinite is a derivative of Agricola's *Encrinos*, and through the centuries it has been used to generally refer a crinoidal limestone.

Abundance and diversity of encrinites

Encrinites are common fossiliferous limestones from the Ordovician through the Jurassic. The most common occurrence is thin ls to 10s of cm thick tabular to lenticular beds where crinoidal debris was concentrated either in a tempestite or a turbidite or in a lag due to winnowing of the matrix. Thicker encrinite deposits are common as flanking beds of reefs, mudmounds, and other carbonate buildups. The most extensive encrinite deposits are regional encrinites (Ausich, 1997). Regional encrinites are encrinite deposits that average more than 5 m to 10 m in stratigraphic thickness and have an areal extent in excess of 500 km². Although not exclusively, regional encrinites are most common on carbonate ramps during times when reefs did not form rimmed shelves. Examples include the Lower Silurian Brassfield Formation of Ohio; the Lower Mississippian Burlington Limestone of Missouri, Iowa, and Missouri; and the Triassic Muschelkalk of Germany. Regional encrinites are an "extinct" lithofacies.

EOLIAN TRANSPORT AND DEPOSITION

Eolian processes operate at a range of spatial and temporal scales, from the microscopic to the global and from microseconds to millennia. Sand and dust "storms", surface deflation and abrasion, as well as sand dune formation and migration are all part of the eolian process spectrum.

Landforms associated with eolian processes are conservatively estimated to cover 20 percent to 25 percent of the terrestrial land surface. Arid and semi-arid regions are primarily affected, but on a local scale, proglacial and periglacial settings, and surfaces disturbed by cultivation, mining and construction are also recognized for eolian transport. Annual global dust emissions are in the order of 2×10^9 tonnes (D'Almeida, 1989), with the Sahara alone producing up to 35 percent of this amount. Windblown silt and clay deposits (loess) cover as much as 10 percent of Earth's terrestrial surface in depths between 1 m and 100 m. These deposits form some of Earth's richest farmlands. Deep ocean sediments also are dominated by deposition of wind borne dust particles. At present, eolian transport is estimated to be roughly comparable on a global scale to the amount of sediment carried by rivers (Livingstone and Warren, 1996). Ancient sand seas, the massive Mesozoic and Permian (Colorado Plateau) sandstones, and the extensive Pleistocene eolian deposits throughout North America and Europe bear witness to an even greater role during varied periods of Earth's history.

It now has been 60 years since Bagnold produced his seminal work *The Physics of Blown Sand and Desert Dunes* in 1941. Since its first printing this text has been the benchmark reference for studies on eolian processes, and it remains on the reading list of many undergraduate and graduate courses even today. In the last two decades, the publication of papers addressing particle transport by wind has escalated. Five International Conferences on Eolian Research (at Aarhus, 1985 and 1991; at Zzyzx, 1994; and at Oxford, 1998 at Lubbock, 2002) have been organized and no fewer than ten comprehensive textbooks have been prepared, addressing all aspects of eolian transport and deposition. They include Brookfield and Ahlbrandt (1983), Greeley and Iversen (1985), Nickling (1986), Pye (1987), Thomas (1989), Pye and Tsoar (1990), Cooke *et al.* (1993), Lancaster (1995), Livingstone and Warren (1996), and Goudie *et al.* (1999).

The following sections attempt to introduce some of the central concepts and research questions surrounding sediment erosion and deposition by wind.

Initiation of motion

Surface shearing stress

One of the central concepts in eolian process geomorphology concerns the minimum force required to move particles of a given size. In practice, this force is very difficult to measure directly, and so, the threshold wind speed (u_t) is commonly determined. Where detailed wind speed profile data do exist for the inner constant stress region of a deep, fully adjusted boundary layer, it is possible to estimate the surface shear

stress (τ_0) at the threshold of motion from

$$\tau_0 = \rho u_*^2 \quad (\text{Eq. 1})$$

where u_* is the friction velocity as defined in the Karman-Prandtl log model:

$$\frac{u_z}{u_*} = \frac{1}{\kappa} \ln\left(\frac{z}{z_0}\right) \quad (\text{Eq. 2})$$

The fluid density is represented as ρ , von Karman's constant as κ , the reference height as z , and the roughness length as z_0 . Employment of this model has been the mainstay of shear stress estimation in a very great number of field and wind tunnel studies that depend upon robust and relatively inexpensive rotating cup and pitot anemometers for wind speed profiling. Extension of this model to strongly accelerated and decelerated flows (i.e., over dunes and surfaces of greatly varied roughness), especially those carrying sediment, has prompted much recent discussion concerning an acceptable range of application. Turbulent shear stresses, i.e., *Reynolds stresses* can also be measured via eddy correlation: this technique is witnessing increased usage in eolian process research, but constant temperature and sonic anemometers are expensive and not without their own particular set of limitations.

Grain entrainment models

The most widely employed relation describing the initiation of grain motion remains that of Bagnold (1941). In this simple model, the force moments associated with the particle weight and the drag of the airstream are balanced at the threshold of movement to give

$$u_{*t} = A \sqrt{\left(\frac{\sigma - \rho}{\rho}\right)gd} \quad (\text{Eq. 3})$$

where u_{*t} is the friction velocity at threshold, σ is the grain density, g is gravitational acceleration, d is the mean grain diameter, and A is a dimensionless coefficient (see also *Grain Threshold*). Since the grain and fluid densities are approximately constant at any given time and place, it is clear that the wind speed required for grain entrainment varies principally as the square root of the mean grain diameter. The most easily entrained sand particle has a diameter of approximately 80 μm . Coarser grains require a higher friction velocity for entrainment because of their greater weight ($A \sim 0.1$). Grains finer than 80 μm lie either partially or fully immersed within the viscous sublayer, so that the value of the entrainment coefficient A is found to increase with decreasing grain diameter. Small cohesive forces, associated with weak van der Waal effects and thin films of adsorbed water, further add to the resistance to motion (Iversen *et al.*, 1976).

Bagnold's model of the *static* or *fluid* threshold is based upon a number of simplifying assumptions that are important to identify. The force moments are derived for idealized spherical particles of uniform diameter. Lift and cohesive forces are omitted, as are turbulent fluctuations of shear stress on the bed.

A number of modellers have attempted to improve on Bagnold's entrainment function through developing a more explicit, physically-based specification for the entrainment

coefficient A (e.g., Iversen *et al.*, 1976). Wind tunnel simulation has played an important role in the development, validation and calibration of these model revisions. Even so, the direct measurement of threshold carries its own error of estimation. Specifically, there is no agreement as to the precise definition or identification of "threshold" for a natural sand containing a wide range of particle sizes. The uncertainty associated with the measurement of u_* is in the order of 10 percent in wind tunnel testing (Gillette and Stockton, 1989).

Once fluid entrainment has commenced, impact maintains the system through the grain-borne transfer of kinetic energy from the air to the bed. Consequently, it is estimated that the wind speed can drop to about 80 percent of the *static* threshold before saltation bombardment is no longer sufficient to initiate motion. This point is termed the *dynamic* or *impact* threshold. The partitioning of momentum among rebounding and ejected grains following collision is represented in numeric models of eolian saltation as the "splash function" (Anderson and Hallet, 1986; Anderson and Haff, 1988, 1991; Anderson and Willetts, 1991). It is measured directly in wind tunnel simulation using particle tracking velocimetry or PTV (Willetts and Rice, 1985, 1988, 1989; Rice *et al.*, 1995).

Eolian transport

Transport modes

In order of increasing velocity, wind transported grains travel in four principal modes: *creep*, *reptation*, *saltation* and *suspension*. The central process is *saltation* from the Latin *saltare*, to leap. Following their ejection into the air stream, saltating grains travel along smooth trajectories unaffected by turbulence. They gain momentum from the air stream during their ascent in association with the greater streamwise wind speeds above the surface, and eventually descend to collide with the surface several centimeters (on average) downwind of the point from which they emerged. The remaining transport modes all depend to varying degrees upon the momentum transfer between these saltators and other loose grains residing within the bed. *Creep* refers to grains that are rolled along the surface. These grains are generally coarser than the saltators. The creep:saltation ratio was found (by Willetts and Rice, 1985) to vary between 1 : 1 and 1 : 3. When a saltator strikes a surface, it also dislodges about 10 other grains which move at low velocity in short, low hops. Unlike saltating grains, these *reptating grains* have insufficient energy to eject other surface grains upon impact. Reptating grains constitute the majority of all grains in transport. Similar to saltators, their numbers are strongly dependent upon the speed of incoming grains and therefore, the friction velocity. *Suspended grains* follow the turbulent motion within the airstream. Over a relatively large range of friction velocity, the transition from saltation to suspension coincides roughly with a drop in grain diameter below 100 μm (Nalpanis, 1985). Pye (1987) also reports that sand sized grains rarely go into suspension. Since the entrainment of silt and clay sized particles requires relatively high wind speeds, the entrainment of these grains usually is dependent upon the impact of saltating grains. An intermediate transport mode, modified saltation, is sometimes identified wherein irregularities in the trajectories of saltating grains are introduced by turbulent eddies. The vertical velocity in turbulence is strongly affected by bed and saltation (Owen, 1964) roughness and by topography. As a result, some sand

grains do become suspended in the lee of transverse dunes, and dust particles may be found within the saltation layer where turbulence appears to be dampened.

Mass transport rate measurement

The transport rate (q) is defined by the mass of sediment moving through a unit width of surface per unit time (SI units: $\text{kg m}^{-1} \text{s}^{-1}$, or alternatively as the volume rate of transport: $\text{m}^3 \text{m}^{-1} \text{s}^{-1}$).

Accurate measurement of q in field settings is especially difficult because the sediment motion is: (1) omni-directional (unlike stream and wind tunnel flows); and (2) deflected by the presence of any given measurement device in the airstream. Mechanical trap designs fall broadly into 3 groups: horizontal, vertical passive, and vertical active (i.e., airflow is maintained by a pumping system). Sand traps designed to rotate into the wind require constant maintenance to keep them moving freely. The response time in gusty winds of highly variable direction is largely unknown, and is likely poor at best. No mechanical trap design has been successful as yet in monitoring omni-directional transport on sloping surfaces. Though flow acceleration around fixed traps does lead to scour at the base and under-collection, many workers have been successful in stabilizing the surface in the immediate area of the trap inlet with cementing agents and flat plates. Flow deflection within the saltation curtain is never completely avoidable, but samplers which are close to iso-kinetic can reduce under-collection considerably (Nickling and McKenna Neuman, 1997). Surface disturbance during trap installation and maintenance, as well as selectivity in particle size collection, further affect collection efficiency.

The last decade also has been witness to the development of several electronic devices for measurement of the mass transport rate and kinetic energy flux. The SensitTM outputs small electronic pulses at a rate dependent upon the kinetic energy of saltators striking a piezoelectric crystal while the SaltiphoneTM records the sound of saltating grains striking the device. Butterfield (1999) reports on a device that measures the extinction of light across a narrow width of surface as it is scattered by mobile grains. All of these electronic instruments are considerably more expensive than any given mechanical trap, and they require regular calibration.

Mass transport rate models

Given the many challenges and uncertainties associated with direct measurement of the mass transport rate, especially over an extended period of time, a very large effort has been expended in the development of predictive models. These models emanate from theoretical investigation, wind tunnel simulation and model calibration, and empirical field studies. The general form of the relation between Q and u_* is given as follows:

$$q \propto C \frac{\rho}{g} u_*^a (u_* - u_{*c})^b \quad (\text{Eq. 4})$$

where the exponents a and b sum to 3 (Livingstone and Warren, 1996). A detailed listing of these models is contained in table 3.5 in Greeley and Iversen (1985). A further review of their derivation and performance is provided in Sarre (1988).

As illustrated in Figure E1, very substantive differences exist in the predictions from these models, particularly at high

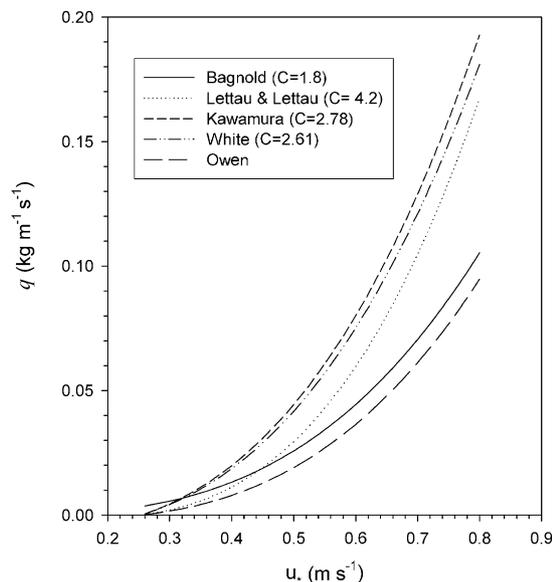

Figure E1 Comparison of mass transport rate model performance: Bagnold (1941), Kawamura (1951), Lettau and Lettau (1978), Owen (1964), White (1979).

friction velocities. Clearly no universal relationship between sediment transport and wind velocity has been established as yet. Even if it were to exist, its application would be limited to the simplest of field settings as represented by an extensive, horizontal surface of loose, well sorted sand. Herein, no restrictions on the sediment supply to the wind are assumed to exist, the boundary layer is deep and fully adjusted to the surface roughness, the wind is steady, the lower atmosphere is stable, and the velocity profile is semi-logarithmic.

Supply limited transport

Unfortunately for those wishing to fully model eolian transport, the idealized conditions described above rarely occur in nature. The presence of moisture, nonerodible roughness elements, crusting agents such as salts and microphytic organisms, organic matter, and macrophytic vegetation (i.e., grasses and shrubs) all play a role in limiting the supply of particles to the airstream. A good deal of current research on eolian processes is aimed at understanding, defining, and quantifying this role. Basically, all of these supply-limiting factors operate through one of more of the following effects: (1) introduction of interparticle force; (2) redistribution of momentum partitioning at the surface; and (3) alteration of the turbulence structure and intensity.

Moisture and crusting are most obviously associated with the introduction of interparticle force which opposes drag and lift to raise the (fluid) threshold friction velocity, often to levels exceeding those representative of most natural winds. However, moisture effects are characterized by strong temporal variability as the evaporation rate also depends on turbulent transfer, and therefore, wind speed. Little is known about this relationship at present. Particle impact also complicates modeling efforts considerably. It is well demonstrated that loose grains not only can saltate across damp and crusted

surfaces, but also, the bombardment will eject some exposed grains. This ejection contributes to further impacts, selective particle removal, and increased surface roughness and turbulence intensity (McKenna Neuman and Maljaars Scott, 1998; McKenna Neuman and Maxwell, 1999). Through this strong positive feedback, the ultimate destruction of the surface can take place relatively quickly, especially in the context of crusts.

Vegetation and other nonerodible roughness elements (NERE) in the form of gravel sized particles alter the partitioning of momentum to the sand bed, and the turbulence structure of the airstream. Grasses, shrubs, and protruding gravels shelter the surrounding sand surface from the drag of the wind, as described in the Raupach (1992) model:

$$\frac{\tau_s}{\tau} = \frac{1}{(1 - m\sigma\lambda)(1 + m\beta\lambda)} \quad (\text{Eq. 5})$$

where τ_s/τ represents the proportion of the total fluid stress which acts on the intervening fine grains, λ is the frontal area of the NERE per unit ground area (roughness density), β is the ratio of the surface drag coefficient to that of the NERE, σ is the ratio of the basal area of the NERE to its frontal area and m is an empirical coefficient. Grains in transport along intervening sand corridors can become trapped in the vicinity of vegetative elements, forming low sand shadow deposits and on a larger scale, coppice dunes. In the case of a developing gravel lag, the high momentum retention associated with grains ricocheting from the fixed elements can give rise to a temporary increase in the mass transport rate over a limited range of roughness density (McKenna Neuman, 1998).

Eolian deposition

Modes of deposition

There are three basic processes, and similarly three primary sedimentary structures, associated with the accumulation of wind blown sand (Hunter, 1977): (1) tractional or accretional deposition; (2) grainfall deposition; and (3) grainflow deposition or avalanching.

In tractional deposition (also termed accretion), a decline in the transport capacity of the wind causes grains moving by saltation, reptation and creep to come to rest in sheltered positions, typically on the lee slopes of sand ripples. This accumulation of excess sediment takes the form of wind ripple laminae. Pin-stripe bedding (Fryberger and Schenk, 1988) is also described for this mode of deposition with the concentration of relatively coarse grains on the upper part of ripple lee slopes forming the "stripes". Accretion deposits are tightly packed and firm to walk across. They are very widespread, occurring on dune stoss slopes, dune plinths or aprons, interdune areas and most sand sheets.

Grainfall deposition refers to particles that settle out of the air in the lee of dune crests as a result of a very rapid decrease in the transport capacity of the wind within the zone of flow separation. When saltating grains overshoot the dune brink, they can become temporarily suspended in strong updrafts within the wake flow so that they travel further than predicted by purely ballistic models (McDonald and Anderson, 1995). Measurement of the grainfall flux requires collection of the descending grains in small open cups spaced at regular intervals along a supporting horizontal boom. This flux (SI

units: $\text{kg m}^{-2} \text{s}^{-1}$) typically follows an exponential decline with horizontal distance, the value of the decay coefficient scaling with the dune height (Nickling *et al.*, 2002). Grainfall deposits are characterized by intermediate packing. Grainfall lamination is preserved only if no subsequent avalanching takes place, and it is most commonly observed on small dunes (Hunter, 1977).

Grainflow or avalanching occurs along the dune slip face (upper lee slope) as it is built to an angle greater than the angle of repose of the sediment. Very little is known about the frequency and point of origin of these localized mass failures. The grain flow cross-strata which result appear as a series of overlapping tongues of sediment with coarse grains concentrated on their upper surfaces and near the toe of the deposit. Most grainflow strata narrow toward to crest of the dune. In damp sand, slump structures and blocks may be preserved.

The sediment continuity equation

The kinematics of grain transport require that the mass or volume of sediment is preserved (Middleton and Southard, 1984) so that patterns of erosion and deposition can be modeled over a wide range in scale using the following continuity equation:

$$\frac{dz}{dt} + \frac{1}{\gamma} \left(\frac{dq}{dx} \right) = 0 \quad (\text{Eq. 6})$$

where z is the surface level, x is the horizontal distance, γ is the bulk density of the sediment, and t is the time. A local decrease in the mass transport rate with distance, for example, is interpreted to mean that sediment storage or accumulation is occurring with the influx of sediment to the area exceeding the outflux. The reverse also is true. Spatial changes in the mass transport rate are fundamental to understanding dune development and maintenance.

Eolian morphodynamic processes

There is a huge literature on eolian bedforms that includes reviews by Pye and Tsoar (1990) and Lancaster (1995; and see Dunes, Eolian).

Dune morphodynamics encompass the following processes: (1) initiation; (2) replication; (3) stoss side adjustments; and (4) grainfall and grainflow in the dune lee (addressed above).

Theories surrounding the origin of dunes focus on the inception of sediment accumulation around small obstacles such as plants, though more subtle features such as slight surface indentations or changes in roughness also may serve as nodes of accumulation (Kocurek *et al.*, 1992). Some field workers report calving of small dunes from larger ones, while others implicate the convergence of sand laden winds in association with secondary flow patterns. Very few sand patches formed by any of these means actually survive and grow into free moving dunes. The controls on protodune survival are not well understood. Very few direct observations have been made of dune initiation.

Eolian bedforms are dynamically similar to those formed in subaqueous shearing flows, and so, theories designed to explain their regular form and spacing bear many of the same features as those proposed for water (see *Surface Forms*). All require an initial disturbance on the bed, which may include development of the first protodune. This disturbance is

believed by some to fix in place underlying structured patterns in the turbulent flow, which ultimately control dune spacing. Evidence for this theory, though sparse, can be found in dune patterns that appear to be related to wave-like atmospheric motion in the lee of hills and mountain ranges. Other workers suggest that it is the initial, fully formed dune that produces the regular flow disturbance downstream. In this explanation, the sequential dune is thought to form beyond the point of flow reattachment associated with the upwind dune, as a new internal boundary layer develops. The reattachment point itself, which lies beyond the flow separation bubble or lee eddy, is noted for intense turbulence that prevents sand from accumulating (Frank and Kocurek, 1996).

Growth of a dune upward into the airflow causes a pressure drop in the outer flow over the dune crest, and therefore, flow acceleration along the direction of increasing elevation. High Reynolds stresses near the dune toe, as measured by Wiggs *et al.* (1996) in wind tunnel simulation, are believed to prevent sand accumulation within this zone of flow stagnation. The generalized pattern of increasing velocity and shear stress toward the dune crest should lead to an overall flattening out of the bedform through time. Clearly though, dunes do grow and so, this explanation must represent an oversimplification of stoss side transport processes. Detailed field measurements of stoss side transport and deposition on a reversing dune by McKenna Neuman *et al.* (2000) do suggest that in unsteady winds: (1) the proportion of the stoss slope length which is active is highly variable; (2) the local sand transport is rarely in full equilibrium with the air flow; and (3) spatial variations in stoss slope transport are influenced by outer wake flow shed from the upwind dune. The shape of the dune crest is also implicated in a number of studies. Rounded forms with a clear crest-brink separation are usually associated with shear stress reduction and deposition at the upper elevations, while erosion and dune lowering is observed to be more typical of sharp crested features. Wiggs *et al.* (1996) suggest that streamline curvature in the area of the dune crest is responsible for these patterns.

Summary

The last two decades have witnessed major advances in the identification and understanding of eolian transport mechanics. In parallel, technological developments have allowed eolian geomorphologists to explore in detail small scale, short term processes involved sediment entrainment and transport. Wind tunnel and numerical simulation has played a key role in these efforts. Grain scale processes are now relatively well understood and modeled. Still, great challenges lie ahead for the advancement of eolian process geomorphology, particularly in the content of fieldwork. Surprisingly few studies have attempted direct measurement of eolian dune morphodynamics. A high level of uncertainty still surrounds measurement of the mass transport rate and the surface shearing stress. Foremost, the bulk of model construction and experimental work has been predicated on the assumption that the airflow is uniform and steady, and that the sand transport is fully adjusted to this condition. In nature, this is perhaps rarely so. Future efforts also must work toward improved integration of the temporal and spatial scales over which eolian processes operate.

EROSION AND SEDIMENT YIELD

Erosion is the suite of processes that lower topography through the breakdown and transport of the substrate that forms the land surface. The substrate may either be bedrock

that must first be degraded chemically or physically to produce mobile solutes and loose particles that can be transported by water or wind, or the substrate may already be loose material, such as sand, loess, or volcanic ash. From a research perspective, the characterization of erosion depends on both spatial or temporal scales. Processes that are important on short timescales and small spatial scales average out as scales increase. Moreover, upon progressing to ever larger spatial scales depositional processes become more important, such that at the largest scale, the whole Earth over geologic time, uplift, erosion, and deposition appear to roughly balance.

Hillslope scale considerations

At the scale of a hillslope or a small plot of land, erosion appears relatively simple, a combination of chemical reactions, referred to as chemical weathering, and physical processes, referred to as physical weathering. The latter include phenomena such as freezing and thawing, salt crystallization, raindrop impactation, and wind abrasion, that degrade the substrate, loosening it and making it susceptible to transport processes. Dissolved weathering products are typically removed from the site of weathering, entering rivers and transported down to the ocean, unless these are incorporated into plants or reprecipitated within the soil profile or downslope because of drying or changes in oxidation state. The suite of dominant weathering processes changes with climate. Chemical weathering tends to dominate in warmer and wetter settings, while physical erosion tends to dominate in colder and drier settings (Garrels and Mackenzie, 1971; Stallard, 1995a,b).

The susceptibility of bedrock to erosion reflects both the chemical and bulk physical properties of the bedrock. Accordingly, susceptibility to erosion is a bulk property of bedrock. Rocks of identical geologic classification may erode at different rates. For example, very old granodiorites of Precambrian age appear to weather at about half the rate of much younger granodiorites. This may be due to the loss of or translocation volatiles—water, halides, and sulfides—over billions of years, making the bedrock more resistant to weathering. Likewise, densely jointed or sheared granodiorites are more susceptible than massive granodiorites. Certain classes of rocks, such as massive evaporites, carbonates, and quartzites are eroded almost exclusively by chemical weathering. The interaction between bedrock, tectonic regime, and erosion produces characteristic landscapes (Stallard, 1988, 2000).

The mobilization and transport of solid erosion products off of a hillslope is decidedly more complex than for solutes. The energy available for transport processes depends on the steepness and length of the slope. Loose material tends to migrate down the slope gradient, and water flows down gradient as well. The balance between the supply of loose material and the ability of physical transport processes to move that material defines two types of erosion regimes (Carson and Kirkby, 1972; Stallard, 1985). One is a weathering- or supply-limited regime, where the capacity of transport processes to move loose material, averaged over time, exceeds the rate at which loose material is supplied through weathering. Weathering limited settings typically have steep slopes. The other regime is transport limited, where the weathering processes generates more loose material than can be moved by transport processes. The thickening layer of loose

material develops into a soil. Transport limited settings typically have flat to gentle topography. If soils are deep and permeable such that even intense rains generate little surface runoff, even steeper slopes may be transport limited. If erosion is weathering limited and if the rate limiting step is chemical weathering, then the rates and chemistry of chemical and physical erosion products can be linked in models (Stallard 1995a,b).

Several rules of thumb can be applied to sediments produced during this more classical erosion. Where physical erosion and transport predominate, sediments are rich in primary minerals with only a small contribution from weathering products. The greater the role of chemical weathering the more depleted the sediments are in alkalis (sodium, potassium, etc.) and alkali-earth (magnesium, calcium, etc.). The most intense chemical weathering leaves quartz, kaolinite, and aluminum and iron sesquioxides. Chemical weathering is greatest under a warm, wet climate and transport-limited erosion.

Episodic erosion and the role of organisms

Many aspects of the breakdown of parent material, its processing within soil and its protection from immediate erosion are influenced by a huge suite of organisms (Stallard, 2000). The supply of loose material to physical transport is often strongly mediated by biological processes. The top of the soil profile is often reworked and churned by an ensemble of biological processes. Included are the actions of soil fauna, the growth and decay of roots, the toppling of trees, and in agricultural lands, plowing. Depths of this zone range from a few centimeters to a few meters. Moreover, animal burrowing and the formation and decay of roots increases the permeability of this zone, increasing infiltration of intense rain and reducing surficial runoff and physical transport. Surficial erosion processes, such as, raindrop impact, sheet wash, and rilling detach material not anchored by vegetation (roots and fungal mycorrhizae) and biotic crusts (lichens, mosses, liverworts) and coverings (litter, duff), moving it downslope. Roots and fallen trunks can dam surficial runoff promoting its infiltration and reducing its erosiveness.

Major, often catastrophic erosional events are often associated with the development and collapse of plant and animal communities, often defining what is often referred to as a "disturbance regime." The growth and failure of vegetation as a soil anchor is related to dramatic episodic erosion when the anchoring fails for a variety of reasons. Two types of episodic erosion stand out: post-fire erosion (fire/flood events) and soil avalanches (landslides). Of these, post-fire erosion appears to have the shortest repeat times. Post-fire erosion requires an intense forest fire that is capable of burning away the organic duff or litter and the root network that protects the soil. The intense heat of the fire may also drive hydrophobic organic compounds into the soil as these materials burn. The heat also dries the soil making it hydrophobic. Whatever the immediate cause of this hydrophobicity, the frequent observation is that if an intense rain follows a major fire by a year or two, typically the soil fails to soak up the rain, which instead flows overland producing dramatic sheet erosion, rilling, and channel excavation (McNabb and Swanson, 1990). So much erosion occurs that major debris flows form. Much of the eroded material is temporarily stored in alluvial fans and within low gradient streams (Meyer *et al.*, 1995). Regrowing vegetation eventually anchors material on the hillslope, but

it often takes several hundred years before enough burnable plant material (fuels) accumulates for a fire to be sufficiently hot to repeat the process. During the time between fires, chemical and physical breakdown of bedrock produces the soils and other loose material that will erode in a subsequent fire.

Soil avalanching is remarkably similar in its requirement that vegetation anchor a developing soil. In contrast to fire erosion, soil avalanching requires a prolonged and continuous protection of soil such that surficial erosion does not balance the production of loose material, and the soil profile thickens. During this time, the erosion regime appears to be transport limited. Rooting depths are limited, and eventually roots are predominately in less cohesive parts of the soil profile. If the slope is sufficiently steep, and if there is a triggering event that cause the soil to shear internally, such as a major rainfall or an earthquake, then a soil avalanche forms, and a mass of hillslope is hurtles toward the valley bottom, where it is in turn, eroded by fluvial processes. Subsequently, for a number of years, surficial erosion removes more loose material from the scar. The slide scar eventually revegetates and soil profiles develop and thicken once more (Scott, 1975; Stallard, 1985). Because a critical accumulation of soil is require, typically a meter or more, the repeat time for landslides is much longer than for major fires.

In setting where episodic erosion operates, it contributes much of the sediment delivered to rivers, often well in excess of surficial physical erosion by sheet wash and rilling. In protected forests of eastern Puerto Rico, landslides may contribute 80 percent to 90 percent of the sediment in rivers. In parts of Yellowstone National Park, fire-related erosion may contribute half of the sediment. Sediments generated by episodic erosion are derived from the entire loose soil profile. Typically, this material has lost a larger proportion of sodium and calcium-bearing minerals than potassium and magnesium bearing minerals.

Human activities

Human activities are responsible for mobilizing vast quantities of material for physical erosion. Humans accelerate erosion by removing plant cover and altering hillslope profiles. A feature that distinguishes this erosion from fire-related erosion or soil avalanching is the human erosion is almost never in equilibrium with the processes that generate loose material, and the erosion proceeds by degrading soils or exposing to transport processes vulnerable substrates that had long been protected by vegetation. Many rural land-use practices promote or accelerate erosional processes that already operate on a landscape. In the case of landslides and debris flow, this phenomena has cause great loss of life and property. In 1998 more than 10,000 people died during Hurricane Mitch and in 1999, 15,000 to 30,000 people died following rains along the north coast of Venezuela. Many have argued that fire related erosion has accelerated in the American West because a century of fire suppression has allowed for sufficient buildup of fuels that eventual fires are so intense that all biomass burns leaving especially unprotected and vulnerable hydrophobic soils. Stratigraphic data from deposits in parts of the American West indicate that fire-related erosion was operating at similar rates long before European settlement. In terms of eroded mass, the most intense human-related erosion appears to result from the destruction of natural ground cover on vulnerable

substrates such as loess terrains (Yellow River, central Mississippi Valley) and deeply weathered tropical soils.

The accelerated erosion of uplands by human activities has not translated to a major export of sediment to the ocean (Milliman and Mead, 1983). Instead much of the sediment appears to be trapped as colluvium, alluvium, and lacustrine deposits. The construction of dams worldwide, about 70,000 in the United States alone has promoted lacustrine deposition. The storage of carbon in these deposits may be a significant component in today's carbon cycles (Stallard, 1998).

Role of storage and remobilization

The highest rates of physical erosion typically are measured on hillslopes in steep upland catchments. Frequently, because flows are less energetic on less steep slopes near valley bottoms, loose material is deposited as colluvium. Then, as streams leave uplands and gradients become less steep and flows less flashy, sediment is deposited in channel systems as alluvium. Colluvial, alluvial, and lacustrine sedimentation can intercept and store sediment coming from upland regions over long, even geologic, timescales. For example, vast quantities of sediment is stored in alluvial fans and foreland basins. A large fraction of the sediment generated by human-induced physical erosion is stored as colluvium, alluvium, and lacustrine sediment in lakes and reservoirs.

Chemical weathering in alluvium can completely change the composition of sediment migrating downriver. For example, sands crossing the Llanos alluvial plane in Venezuela change from lithic arenites to quartz arenites (Stallard, *et al.*, 1991).

Glacial erosion

During the past approximately two million years, the Earth has experienced episodic glaciations with repeat times of a bit more than 100,000 years. Associated with these ice ages has been the development of large continental glaciers, the largest being the Laurentide Ice Sheet, along with global cooling and drying. The flow of glacial ice is often associated with profound physical erosion, particularly where glaciers have warm bases, where liquid water exists at the glacial bed. While exact mechanisms are uncertain, freezing and thawing near the glacial bed and perhaps more narrow shear zones appear to enhance the breakdown of bedrock. Cold-based glaciers, where the base is frozen, can be remarkably nonerosive, sometimes preserving pre-glacial soils. Marine cores indicate that the continental ice sheets were quite erosive, lowering the Canadian Shield, for example, more than would chemical and physical weathering operating over the same period of time. The chemical weathering associated with glaciation is quite distinctive, reflecting a high ratio of fresh rock to water. Of note is the large contribution from easily weathered minerals that are disseminated through most siliceous rocks. These include carbonates (dissolved calcium), sulfides (dissolved sulfate), and micas (dissolved potassium). The exposure of large amounts of biotite to water and oxidative breakdown produces and releases large amounts of vermiculites to soils and sediments (Stallard, 2000).

Ice ages are times of exceptional wind erosion and deposition. The wind-borne dust forms great deposits of loess around the peripheries of the glacierized landscapes. Ice Age samples from deep ice cores from Greenland show far more dust than was deposited after the Ice Ages ended.

The study of erosion and sediment production is one of the most interdisciplinary fields of investigation in the Earth sciences. As such it still presents many barely-explored frontiers for researchers. Of particular note is: (1) the role of organisms, especially plants, in the erosion process; (2) the chemical and physical changes of sediments deposited on land; and (3) the details of erosion under continental ice sheets. An understanding of these issues is critical for the reconstructing sedimentary record of the history of the Earth.

EVAPORITES

Introduction

Evaporites are sedimentary deposits chemically precipitated from standing bodies of seawater (marine evaporites) or lakewaters (nonmarine evaporites) as a result of evaporative concentration. The major minerals of evaporites are salts of sodium, potassium, calcium, magnesium, chloride, sulfate, bicarbonate and carbonate ions (Table E1). Evaporite deposits are found in stratigraphic units of all ages back to the Late Precambrian. Indirect evidence of evaporite deposition is found in the form of molds and casts of saline minerals such as halite and gypsum in rocks as old as Archean. The scientific importance of evaporites lies mainly in the information they carry about: (1) the chemistry of ancient seawaters and lakewaters; (2) the distribution in space and time of hydrologically-restricted sedimentary basins with arid climates; and (3) the early stages of continental breakup and the formation of "proto-oceans" when thick and extensive saline deposits accumulated (e.g., the huge thicknesses of Jurassic and Cretaceous salt deposits preserved in initial rift valleys beneath the continental margins of both the North and South Atlantic Oceans).

Evaporite deposits are of major economic importance, mined on all continents as basic materials for the manufacture of inorganic chemicals used extensively in the chemical, agricultural and construction industries. Principal mining targets are halite (NaCl, common table salt), gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, used to make "drywall"), potash salts (such as sylvite, KCl, known as "muriate of potash" in industry), sodium carbonate salts (such as trona, $\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$ from which "soda ash" used in the glass, paper and pulp industries is made), and sodium sulfate salts (such as mirabilite, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ from which "salt cake" or "Glauber's salt" is made). Modern surface and subsurface saline brines (the latter are known as basinal brines or oilfield brines), both primary and secondary (the latter formed by dissolution of buried evaporites), are major sources of important minor chemical elements such as bromine, iodine, lithium, etc. Evaporite deposits also play a significant role as impermeable seals of petroleum reservoirs. Despite the fact that evaporites constitute less than 5 percent of the volume of sedimentary rocks in the geologic record, they cap about half the world's known oil and gas resources.

Common table salt has been a critical trading commodity for millennia. Roman soldiers were given money to buy salt, a payment that became known as a *salarium*, from which the English word "salary" was derived. As early as 500 B.C. the Roman government took over control of salt works near the River Tiber. Three hundred years later the Roman government imposed taxes on salt to raise money to finance the Second Punic War. Medieval France copied this old Roman practice of salt monopolies and taxes. The leaders of the French Revolution made the repeal of the salt tax a major objective, which they achieved in 1790 (Multhauf, R.P., 1978).

Environmental conditions required for the formation of evaporite deposits

First and foremost, evaporites require for their formation: (1) an *arid climate*, that is, annual rate of evaporation > annual rate of inflow of water, where inflow = surface sources (seawater and/or river water + rainfall + surface spring inflow) + subsurface input of groundwater; and (2) a *hydrologically closed or restricted basin* (outflow < inflow). These two basic conditions will ensure that any standing water on the floor of the depositional basin will undergo the evaporative concentration necessary to induce evaporite minerals to precipitate. However, for accumulation of any measurable thicknesses of evaporites there are two additional requirements; (3) the closed arid basin must be either a deep receptacle before evaporite accumulation or must actively subside during evaporite accumulation; and (4) the inflow of solutes into the basin must be substantial over a long period of time.

If seawater is the primary inflow water then the evaporating basin must be a coastal depression (shallow or deep) with a constricted, very shallow inlet channel or a "leaky" sill of some kind. Such a hydrologic system must be fundamentally dependent on the position of sea level. The absence of any major marine evaporite depocenters today is testimony to this particular constraint. The rising Holocene sea level has overrun all the preexisting restricted marine basins in arid settings, such as the Red Sea and the Mediterranean Sea. During the Miocene these two basins were essentially isolated from direct surface inflow of seawater as sea level dropped to or below the shallow sills at their "mouths". During this period of basin restriction, very thick (km-scale) deposits of marine evaporites accumulated on the floors of the Red and Mediterranean Seas, as has been revealed by drilling.

Table E1 Chemical composition of some of the common saline minerals of evaporites

Anhydrite	CaSO_4	kainite	$\text{MgSO}_4 \cdot \text{KCl} \cdot 11/4\text{H}_2\text{O}$
Antarcticite	$\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$	kieserite	$\text{MgSO}_4 \cdot \text{H}_2\text{O}$
Aragonite	CaCO_3	langbeinite	$2\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot$
Bassanite	$\text{CaSO}_4 \cdot 1/2\text{H}_2\text{O}$	mirabilite	$\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$
Bischofite	$\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$	nahcolite	NaHCO_3
Bloedite	$\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 6\text{H}_2\text{O}$	natron	$\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$
Calcite	CaCO_3	polyhalite	$2\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$
Carnallite	$\text{MgCl}_2 \cdot \text{KCl} \cdot 6\text{H}_2\text{O}$	rinneite	$\text{FeCl}_2 \cdot \text{NaCl} \cdot 3\text{KCl} \cdot$
Dolomite	$\text{MgCO}_3 \cdot \text{CaCO}_3$	shortite	$2\text{CaCO}_3 \cdot \text{Na}_2\text{CO}_3$
Epsomite	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	sylvite	KCl
Glauberite	$\text{CaSO}_4 \cdot \text{Na}_2\text{SO}_4$	tachyhydrite	$\text{CaCl}_2 \cdot 2\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$
Gypsum	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	thenardite	Na_2SO_4
Halite	NaCl	thermonatrite	$\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$
Hexahydrite	$\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$	trona	$\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$

For nonmarine basins, the inflow waters may be meteoric waters (dilute river waters or groundwaters), upwelling basinal brines, upwelling hydrothermal brines, upwelling acid volcanogenic waters, or any combination of these source waters. Of particular significance is that many modern nonmarine evaporite deposits are accumulating in active continental rift and strike-slip basins. The floors of these tectonic basins are fed by groundwaters convected upward along fault and fracture zones by thermally-induced density instabilities (e.g., generated by magmatic heat sources beneath the rifts) or forced to the surface by large topographic gradients resulting from the high relief between the basin floor and the surrounding uplifted fault-block mountains.

Types of evaporite deposits

Marine evaporites (formed by evaporation of seawater).

There are two major groups, related to their tectonic setting: (1) *Shallow shelf marine evaporites* deposited along the coasts of continental shelves (e.g., modern Lake MacLeod, Western Australia) or foreland basin ramps (e.g., modern Persian Gulf) in arid settings. Stratigraphically, these evaporites are typically made up of stacks of thin (meter scale), sheet-like bodies deposited in back-barrier tidal flats and shallow lagoons.

The tidal flat (or sabkha, an Arabic term for salt flat) marine evaporites are supratidal deposits that cap subtidal-intertidal marine detrital deposits (siliciclastic or carbonate composition), producing a classic “shallowing-upward cycle”. Each cycle is formed by seaward progradation of the shoreline, with the vertical thickness dictated by the tidal range and the depth of the subtidal lagoon (typically a few meters).

The lagoonal evaporites are subtidal deposits that consist principally of layers of subaqueous gypsum and halite crystal accumulations of: (1) “pelagic” crystals which nucleated at the brine-air interface then settled gravitationally to the lagoon floor; and (2) arrays of vertically-oriented crystals grown on the lagoon floor. These gypsum-halite units may be punctuated by thin interbeds of marine detrital sediment that record “freshening” events when new seawater entered the lagoon.

(2) *Rift basin marine evaporites* deposited in active tectonic pull-apart basins formed during the early stages of continental breakup and development of ocean basins by seafloor spreading (e.g., Cretaceous of Brazil and Gabon, proto-Atlantic

Ocean; Miocene beneath the Red Sea). These evaporites are commonly very thick (10^2 m to 10^3 m) deposits, fringed by alluvial fan deposits. The type of evaporite depositional environment can vary from tidal flat to lagoonal to deep perennial basin. This latter setting is characterized by the deposition of “pelagic” gypsum and halite precipitated from the evaporating surface brines and by incursions of gypsiferous turbidity flows derived from the “gypsum factories” on the shallow fringing shelves.

Nonmarine evaporites (formed by evaporation of continental waters)

Ancient nonmarine evaporite deposits are uncommon. The Eocene Green River Formation of Wyoming, a major source of sodium carbonate and oil shale, is one of the best known of the nonmarine type of evaporite deposit, renowned for its huge inventory of unusual minerals and spectacular specimens of fossil plants, fish, insects, birds, turtles, crocodylians, lizards, snakes, bats, and a host of invertebrates.

Much of what we know about deposition of nonmarine evaporites comes from the study of active modern systems. The vast majority of such depositional settings are hydrologically closed basins formed by continental rifting (e.g., Lake Magadi, East African rift) or strike-slip faulting (e.g., Dead Sea). Importantly, the high relief of the upfaulted mountains enclosing these two types of continental tectonic basins can act as rainfall–snowfall traps and barriers, making the basin floors local rain–shadow deserts independent of latitude (“orographic deserts”, e.g., the modern Basque Lakes evaporites are located in western Canada at latitude 50° N). For those tectonic basins outside of the dry “horse-latitudes” the atmospheric precipitation trapped by the enclosing high mountains provides a significant source of inflow waters (e.g., modern Death Valley, California; modern Great Salt Lake, Utah). Such basins are capable of accumulating very thick nonmarine evaporite deposits.

Chemically and mineralogically, non-marine evaporites are far more varied than marine evaporites because of the very wide range of chemical compositions displayed by continental waters (Table E2). Nonetheless, non-marine evaporites can be separated into two major chemical groups, an alkaline group and a neutral group.

The *alkaline group* of composition Na-K-CO₃-SO₄-Cl are characterized by sodium carbonate minerals such as trona,

Table E2 Representative chemical compositions of inflow waters to modern evaporite basins (concentrations in parts per million)

	1	2	3	4	5	6	7	8	9

1. Groundwater (granite, White *et al.*, Table 1, #7); 2. Groundwater (basalt, White *et al.*, Table 2, #8); 3. Groundwater (limestone, White *et al.*, Table 6, #2); 4. “Average” modern river water (Spencer and Hardie, 1990, Table 1, #9); 5. Acid volcanic hot spring (White *et al.*, Table 19, #1); 6. Basinal brine (White *et al.*, Table 13, #7); 7. Continental hydrothermal brine (Salton Sea, Calif., Hardie, 1991, Table 6); 8. Mid-ocean ridge hydrothermal brine (Spencer and Hardie, 1990, Table 1, #4); 9 = Modern seawater (Spencer and Hardie, 1990, Table 1, #1).

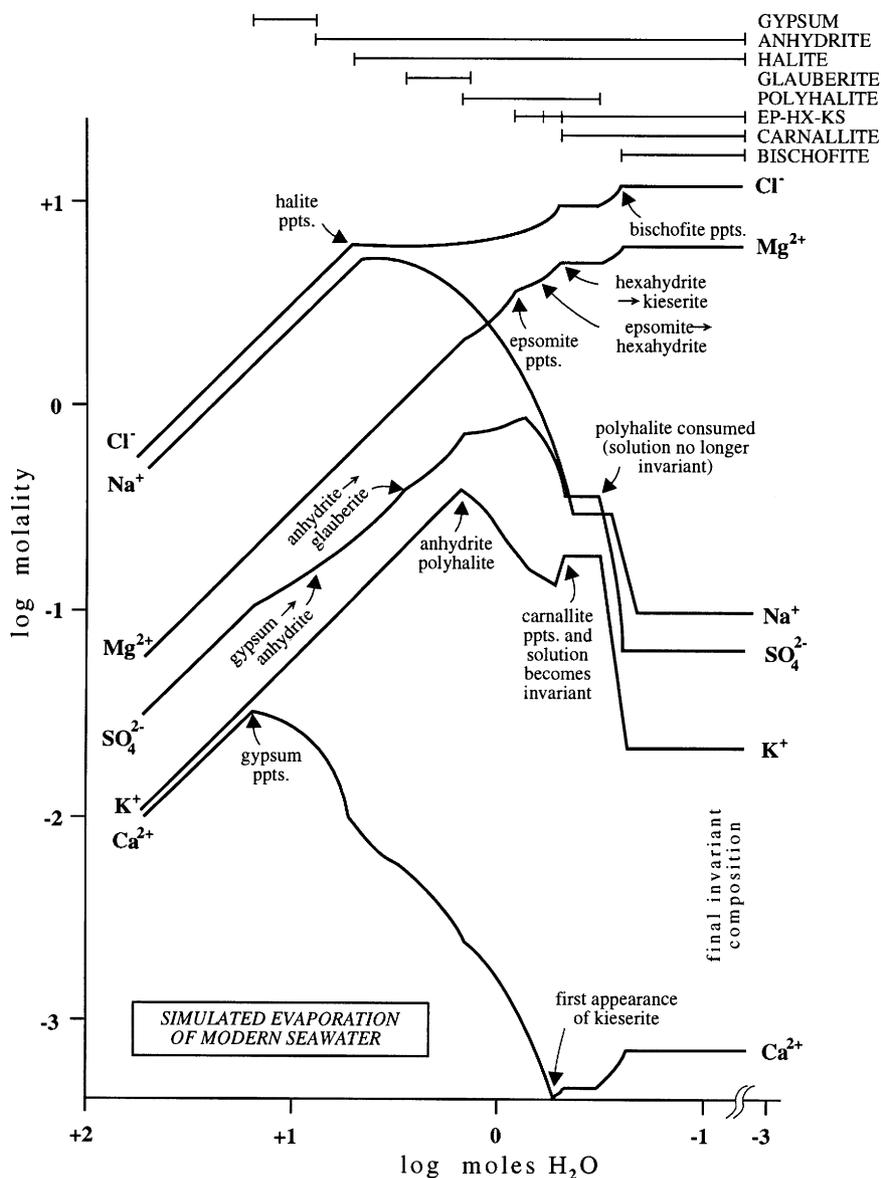

Figure E2 Evaporative concentration of modern seawater at 25°C and 1 atm. pressure simulated using the computer program of Harvie *et al.* (1980). The curves show the progressive changes in major ion concentrations in the seawater brine as evaporation and mineral precipitation and resorption proceed (initial mass of seawater contained 1 kg of H₂O) (from Hardie, 1990).

nahcolite and natron (Table E1) precipitated from high pH alkaline brines. The parent waters of this alkaline group are river waters and shallow continental groundwaters, which are classic bicarbonate-rich meteoric waters formed by chemical weathering of continental bedrocks by CO₂-charged rainwater. Evaporative concentration of these bicarbonate-rich meteoric waters produces alkaline brines rich in sodium and carbonate ions and poor in calcium and magnesium ions (see next section on brine evolution).

The *neutral group* of composition Na-K-Ca-Mg-SO₄-Cl are characterized by gypsum, halite, and a variety of sodium and magnesium sulfate minerals, among others (Table E1), precipitated from near-neutral pH sulfate-chloride brines.

The chemical evolution of these bicarbonate/carbonate-poor brines during evaporative concentration pivots around the early precipitation of gypsum, which determines whether the brines will become sulfate-poor or calcium-poor (the so-called gypsum “chemical divide”, see next section on brine evolution). This leads to two main chemical subgroups, an Na-K-Mg-Ca-Cl subgroup (“CaCl₂ evaporites”, characterized by potash minerals such as sylvite and rare CaCl₂ minerals such as tachyhydrite, Table E1) and an Na-K-Mg-SO₄-Cl subgroup (“MgSO₄-NaSO₄ evaporites”, characterized by minerals such as epsomite, thenardite and glauberite, Table E1). These subgroups owe their chemical signatures to the influence of unusual bicarbonate-poor inflow waters, such as SO₄-rich acid

volcanogenic waters, SO_4 -rich meteoric waters derived by weathering of sulfide ore-bearing bedrocks, or CaCl_2 -rich basinal brines and hydrothermal brines (Table E2).

Brine evolution and evaporite mineral sequences: geochemical principles

The reluctance of sparsely soluble minerals to precipitate from aqueous solutions at Earth surface temperatures is well-known. Marine carbonates, so common in the sedimentary record, are classic examples of non-equilibrium precipitation of such sparsely soluble minerals. Modern marine cements are typically aragonite and high-magnesian calcite (HMC), minerals that are theoretically metastable at Earth surface temperatures and pressures with respect to calcite and mixtures of dolomite + calcite respectively. Experimental work has shown that the Mg/Ca ratio, the temperature and the salinity of the parent water determines whether calcite, HMC + aragonite, or aragonite will precipitate, in agreement with the observation that metastable aragonite + HMC are the phases that preferentially nucleate from modern seawater with its high Mg/Ca mole ratio of 5.1. In contrast to all this, thermodynamics predicts that the only stable carbonate phase in equilibrium with modern seawater should be ordered stoichiometric dolomite. However, experimental work has failed to nucleate ordered stoichiometric dolomite in typical surface waters such as modern seawater at Earth surface temperatures, supporting the long recognized absence of ordered dolomite as the primary sedimentary precipitate in both modern and ancient carbonate deposits (the “dolomite problem”). Clearly, kinetics rather than equilibrium thermodynamics controls the important alkaline earth carbonate system in modern and ancient sedimentary systems, including evaporites.

While the kinetically-controlled alkaline earth carbonates are the typical minerals that precipitate during the early stages of evaporative concentration of natural waters, evaporite deposits are characterized by the more soluble salts such as gypsum and halite that for the most part behave in accordance with thermodynamic predictions. Using a combination of equilibrium thermodynamics and experimentally determined solubilities of evaporite minerals, it is possible to predict quantitatively: (1) the chemical evolution of waters undergoing evaporative concentration at a given temperature and 1 atm. pressure; and (2) the sequence of minerals (and their masses) precipitated during this evolution (Harvie and Weare, 1980; Harvie *et al.*, 1980). Figure E2 illustrates this approach as applied to evaporative concentration of modern seawater (see Table E2 for composition of modern seawater). Figure E2 clearly highlights the critical steps in the chemical evolution of modern seawater as it undergoes progressive evaporative concentration. These critical steps occur at those points where new minerals first precipitate. The progressive crystallization of a new mineral causes drastic changes in the concentrations in the brine of those ionic species making up that mineral. Halite provides a simple but powerful example (Figure E2). As the evaporating brine first reaches saturation with halite, the equilibrium between halite and brine is defined by the chemical reaction:

At equilibrium between halite and the brine, the activities (“thermodynamic concentrations” = molality \times activity coef-

ficient) of the components are related as follows:

$$K_a = a_{\text{NaCl}}/a_{\text{Na}} \cdot a_{\text{Cl}} \quad (\text{Eq. 2})$$

where K_a is the equilibrium constant for the T and P of interest. Since halite is a pure crystalline phase the activity of the component NaCl in halite is unity by definition. Thus, as long as equilibrium is maintained between halite and the brine during evaporative concentration, the product of the activities of Na and Cl ions in the brine is fixed even though these ions are being extracted from the brine to produce halite crystals. It follows, then, that during halite precipitation, as Na and Cl ions are *removed in equal molar proportions* while the ion activity product ($a_{\text{Na}} \cdot a_{\text{Cl}}$) remains constant, the concentrations of Na and Cl ions *must change antipathetically*. Typically, as evaporative concentration proceeds the ion with the lower concentration at the initial point of mineral precipitation will progressively decrease in concentration while that of the other ion will progressively increase (but at a much reduced rate). This type of critical step in brine evolution driven by evaporative concentration (see Hardie and Eugster, 1970) has been dubbed a “chemical divide” by Drever (1982, pp. 201–209). This behavior is clearly illustrated in Figure E2 for both halite and gypsum. Experimental work and observations of natural saline lakes and commercial salt pans have verified this predicted behavior.

The significance of the principle of “chemical divides” is that it explains the origin of the following three major compositional types of brines (Hardie and Eugster, 1970):

- (1) Na-K-Ca-Mg-Cl brines (“calcium chloride brines”, e.g., hydrothermal brines, basinal brines)
- (2) Na-K-Mg- SO_4 -Cl brines (“magnesium sulfate brines”, e.g., modern seawater bitterns)
- (3) Na-K- CO_3 - SO_4 -Cl brines (“alkaline brines”, e.g., soda lake brines).

As illustrated in Figure E3, the initial precipitation of CaCO_3 (as either calcite or aragonite) during the very early stages of evaporative concentration of either seawater or lakewaters determines whether the resulting brine will become

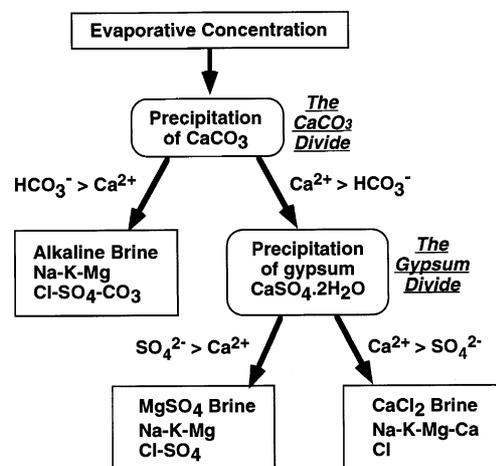

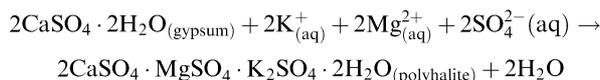

Figure E3 “Chemical divides” and the chemical evolution of the three major types of brines during evaporative concentration of surface waters (after Hardie and Eugster, 1970).

an “alkaline brine” (rich in $\text{HCO}_3 + \text{CO}_3$ ions, poor in Ca ions) or a “neutral brine” (poor in $\text{HCO}_3 + \text{CO}_3$ ions, rich in Ca ions). The outcome is determined by the relative concentrations of Ca and HCO_3 ions at the initial point of precipitation of CaCO_3 : if $\text{Ca} > \text{HCO}_3$ then the resulting brine will be a “neutral brine”, if $\text{HCO}_3 > \text{Ca}$ then the brine will be an “alkaline brine” (Step 1 in Figure E3). Further evaporation of the alkaline brine will lead to removal of essentially all the Ca ions while the CO_3 ion concentration and the pH of the brine both increase, ultimately producing an Na-K- CO_3 - SO_4 -Cl type brine. For those waters initially richer in Ca than HCO_3 ions (Table E2), evaporation beyond the “ CaCO_3 divide” leads to a second evolutionary step, the “gypsum divide” (Step 2 in Figure E3). The outcome at this “gypsum divide” is determined by the relative concentrations of Ca and SO_4 ions: if $\text{Ca} > \text{SO}_4$ then the resulting brine will be a “ CaCl_2 brine” (Na-K-Ca-Mg-Cl type), if $\text{SO}_4 > \text{Ca}$ then the brine will be an “ MgSO_4 brine” (Na-K-Mg- SO_4 -Cl type) (Figure E3).

The exact pathways followed on evaporative concentration of a given water belonging to any one of the three main types depends mainly on the particular ion ratios at each chemical divide but other factors that can alter the chemical evolution of the evaporating brine may come into play. In this latter regard, two of the more important factors are: (1) nucleation of metastable instead of stable minerals, e.g., precipitation of magnesian calcite instead of calcite will influence the ultimate Mg/Ca ratio of the brine; (2) equilibrium brine evolution may depend on certain early formed minerals that *back-react* with the chemically evolving brine, i.e., the reaction

predicted for modern seawater. In this example, if the early formed gypsum becomes separated from the mother-liquor by settle-out or by brine migration then both the chemical evolution of the brine and the mineral succession will be significantly different from those involving back-reaction (Hardie, 1984, figure E4).

Evaporites and the chemistry of phanerozoic seawater

Ancient “potash evaporites”, rich in economically important potassium minerals, have for more than a century been assumed to be of marine origin, formed by evaporation of seawater with the chemistry of modern ocean water. Indeed, J.H. van't Hoff, the first Noble Prize winner for Chemistry spent the later years of his career (1896–1908) experimentally investigating the phase relations among the saline minerals in the system Na-K-Ca-Mg- SO_4 -Cl- H_2O at temperatures from 0 to 110°C at atmospheric pressure. His objective was to better understand the origin of the economically important Stassfurt potash evaporites of Germany. His extensive series of studies (carried out with the aid of 33 collaborators) constitutes the first systematic application of chemical experiments to the solution of a geological problem, and gave birth to modern experimental geochemistry (Eugster, 1971).

Unfortunately, van't Hoff's pioneering experimental efforts were unable to resolve the fundamental dilemma presented by the stratigraphic record of evaporite deposits, namely, that the majority of ancient potash evaporites thought to be of marine

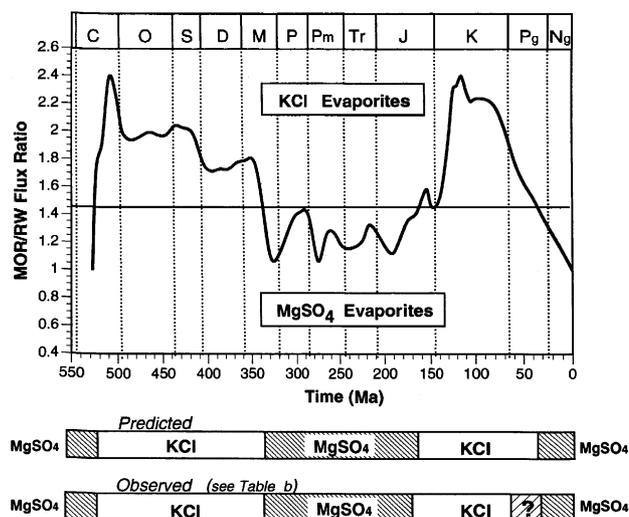

Figure E4 Plot of MOR/RW flux ratio versus geologic time over the past 550 m.y. using the new calculation method of Hardie (2000). The horizontal line at $\text{MOR/RW} = 1.45$ is the chemical divide that separates paleoseawaters from which either KCl or MgSO_4 evaporites will form on evaporative concentration. Comparison of the predicted and observed potash evaporite types is shown in the bars below the graph.

origin are of the “KCl-type” (formed from CaCl_2 brines of the system Na-K-Ca-Mg-Cl, see above) rather than the “ MgSO_4 -type” (formed from brines of the system Na-K-Mg- SO_4 -Cl, to which modern seawater belongs) (Hardie, 1990, Tables 1 and 2). If the major ion chemistry of seawater has remained close to its present composition for the last 1–2 billion years, as has been assumed by almost all 20th Century geologists and paleontologists as well as aqueous geochemists (e.g., Rubey, 1951; Mackenzie and Garrels, 1966; Sillen, 1967; Holland, 1972), then how are we to explain the preponderance of KCl over MgSO_4 marine potash evaporites in the Phanerozoic record? A variety of explanations have been proposed, mainly involving penecontemporaneous or later burial diagenesis of primary MgSO_4 potash evaporites, contemporaneous alteration of seawater entering a marginal marine basin by dolomitization of early formed CaCO_3 deposits, by the activity of sulfate-reducing bacteria, or by mixing of seawater with Ca- HCO_3 -rich river waters. A radical solution to this dilemma has been suggested by Spencer and Hardie (1990). They proposed that the chemistry of global seawater over much of geologic time has been controlled principally by simple mixing of the two principal sources of major ions to the ocean, namely, river water (RW) and mid-ocean ridge (MOR) hydrothermal brine. They presented quantitative predictions of secular variations in the major ion chemistry of seawater as a function of hypothetical secular variations in the ratio of the input fluxes of MOR brine and river water. Their calculations indicated that relatively small changes in the MOR/RW flux ratio would result in seawater chemistry switching from the Na-K-Mg- SO_4 -Cl type (the modern seawater type, from which MgSO_4 potash evaporites would precipitate) to the Na-K-Ca-Mg-Cl type (from which KCl potash evaporites would precipitate). Hardie (1996, 2000),

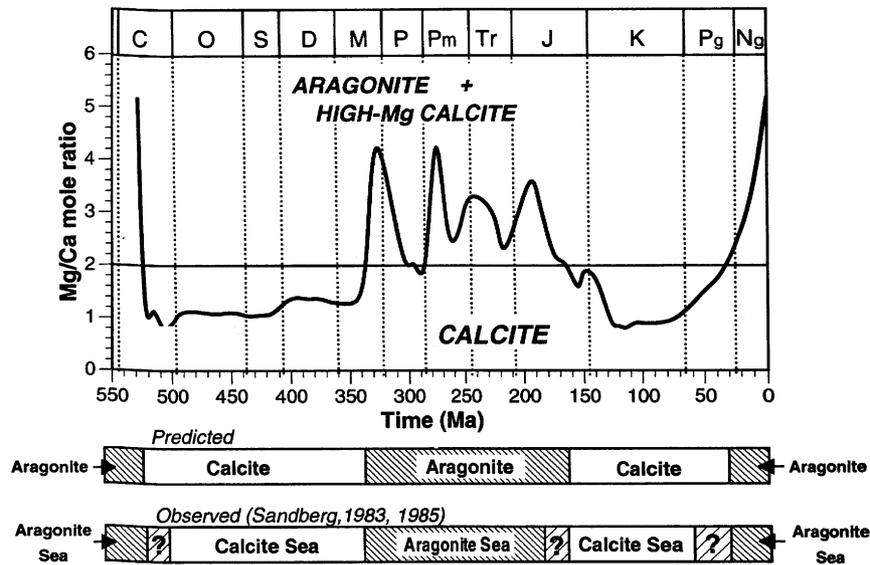

Figure E5 Plot of predicted oscillations in Mg/Ca mole ratio in seawater over the past 550 m.y. using the new calculation method of Hardie (2000). The horizontal line at Mg/Ca = 2.00 is the divide that separates waters from which either calcite or aragonite (\pm high-Mg) are predicted to precipitate (Stanley and Hardie, 1998, 1999). Comparison of the predicted and observed mineralogies of nonskeletal limestones is shown in the bars below the graph.

using the Spencer–Hardie seawater approach and the assumption that secular variations in the MOR brine flux were proportional to secular variations in ocean floor production, showed that the temporal records of oscillations during the Phanerozoic in KCl versus MgSO_4 marine potash evaporites, and in “aragonite seas” versus “calcite seas” determined by Sandberg (1983, 1985) are in very good agreement with those predicted by this simple “mixing model” (see Figures E4 and E5, which are based on the improved mixing model of Hardie, 2000). Furthermore, the predictions are in full accord with the observed synchronicity of KCl potash evaporites with calcite seas and MgSO_4 potash evaporites with aragonite seas. Chemical analyzes of fluid inclusions in ancient halite crystals from evaporite deposits ranging in age from Late Precambrian to Late Miocene carried out by a number of workers using several different techniques are also in very good agreement with the predicted oscillations in global seawater chemistry based on the MOR brine–river water mixing model (e.g., Lowenstein *et al.*, 2001). Finally, Stanley and Hardie (1998, 1999) have drawn attention to the possible consequences of oscillations in the Mg/Ca ratio and the Ca concentrations of Phanerozoic seawaters on the carbonate mineralogies of invertebrate skeletons. For example, the very low Mg/Ca ratio and very high Ca concentration predicted for Cretaceous seawater (compared to modern seawater) provide a plausible explanation for the spectacular production of coccolith chalk during this period. The progressive increase in Mg/Ca ratio and decrease in Ca concentration predicted for the period Paleocene to Quaternary can explain the observed progressive loss of coccolith mass and the final demise of the *Discoaster* coccolithophorids during this period (Stanley and Hardie, 1998, 1999). The combined weight of all these results provides strong support for the hypothesis that seawater chemistry has oscillated significantly during the Phanerozoic Eon as a result

of oscillations in the MOR/RW flux ratio driven mainly by secular variations in rates of seafloor spreading.

EXTRATERRESTRIAL MATERIAL IN SEDIMENTS

Ultimately, the entire Earth is composed of “extraterrestrial” material, which accreted (mostly in the form of kilometer-sized and larger bodies) about 4.56 billion years ago to form our planet. But even today, the Earth continues to accrete large amounts of extraterrestrial matter, about 40,000 tons per year of mostly fine dust (within the mass range 10⁻¹⁶ kg to 10⁻⁴ kg), which is derived from asteroids, comets, and even from the Moon, Mars (as rare meteorites), and the interstellar medium, although proportions vary widely. This extraterrestrial matter settles through the atmosphere and accumulates, much diluted, in terrestrial and marine sediments, comprising one class of extraterrestrial material in sediments. On occasion, larger bodies (cm- to m-size) fall as meteorites, which mostly weather away in geologically short time periods, although a few fossil meteorites have been found in Ordovician rocks (Peucker-Ehrenbrink and Schmitz, 2001). Even less frequent, but still often in geological terms, asteroid- and comet-nucleus-sized bodies impact the Earth with cosmic velocity, leading to the formation of an impact crater, and, depending on the size of the impactor, a regional to global distribution of impact ejecta, being the other class of extraterrestrial material in sediments.

Extraterrestrial dust is mainly derived from the collision of asteroids in the asteroid belt and the subsequent migration of the dust due to the Poynting-Robertson effect toward the Earth and Sun. The other main source is the disintegration of comets (“dusty snowballs”), which release dust into the inner solar system when they get close to the sun and the ice, which makes up the bulk of their mass, evaporates. The flux from both sources varies considerably over time (Peucker-Ehrenbrink and Schmitz, 2001). An excellent tracer for extraterrestrial material in marine sediments is the presence of ³He, which is carried to the seafloor in the finest fraction of interplanetary dust and is retained in some sediments for up to several hundred million years (Farley, 2001). Such isotopic studies of oceanic sediments provided evidence for a shower of long-period comets at around 35 Ma.

Ejecta from large impact events on Earth comprise a mixture of uniquely shocked and melted terrestrial material and remnants of the extraterrestrial impactor (Montanari and Koeberl, 2000; Koeberl, 2001). The discovery of shock-metamorphosed mineral grains (e.g., quartz, feldspar) in sediments of Cretaceous-Tertiary (K-T) boundary age (65 Ma) from locations around the world (Bohor *et al.*, 1987) provided confirming evidence for the hypothesis that a large impact event marked the end of the Cretaceous and was responsible for the mass extinction at that time (Koeberl and MacLeod, 2002). Impact craters with diameters of about ≥80 km may be associated with globally distributed impact ejecta; the Chicxulub impact structure, which is buried beneath Tertiary sediments in Yucatan, Mexico, and which is the source of the K-T boundary ejecta, has a diameter of almost 200 km.

Geochemical methods can be employed to detect the chemical signature of the remnant of the impactor in sediments (Koeberl, 1998). This is mainly done by searching for anomalously high concentrations of siderophile elements, especially the platinum-group elements (PGEs—e.g., Ir, Os), because these elements typically show low concentrations in crustal rocks and sediments, and much higher abundances (by several orders of magnitude) in most meteorites. Most often contents of the element Ir are reported, because it is the easiest of all PGEs to measure. Crustal Ir contents are about 0.02 ppb, whereas impact ejecta commonly have 0.2 ppb to 10 ppb. Also, the isotopic compositions of the elements Os (Koeberl, 1998) and Cr (Shukolyukov *et al.*, 2000) show significant differences between terrestrial crustal rocks and meteorites, providing very sensitive and selective tracers for meteoritic matter. Impact ejecta are found from the beginning of the geological history of the Earth as recorded in sedimentary rocks, although the evidence for traces of the so-called late heavy bombardment at 3.85 Ga is still contradictory (Ryder *et al.*, 2000). Rather unusual impact ejecta are found in 3.4 Ga rocks from Barberton, South Africa (Shukolyukov *et al.*, 2000). Geochemical evidence for an extraterrestrial component was found in 2 Ga spherule layers from the Transvaal Supergroup, South Africa (Simonson *et al.*, 2000), which are similar to approximately coeval spherule layers in Australia.

Sediments Produced by Impact

F

FABRIC, POROSITY, AND PERMEABILITY

Introduction

Rocks are generally classified by their *texture* and *composition*. Texture includes the size and shape of the various solid particles, and their arrangement in space: it therefore also includes the geometry of the pore spaces included within the rock (or sediment). There is no generally accepted term to include all the types of solid particles, but in this article we follow Lucia (1995) in using the term *particle* to include both chemically precipitated *crystals*, and clastic *grains*, which may themselves be composed of one or more crystals. Unlithified sediments are generally composed exclusively of grains which originated either outside the basin of deposition (so are *allogenic*) or within the basin of deposition (so are *autogenic*), but a few sediments or sedimentary rocks may be composed of crystals precipitated directly on the sediment surface. The size and shape of sediment particles is an important part of texture (see *Grain Size and Shape*) but it is not the whole story: it is very important how the particles are arranged in space, because this determines some of the bulk (geophysical) properties, including the size, shape, and orientation of the pore spaces. These in turn determine two of the most economically important bulk properties of a sediment: (1) The percentage volume of pore space, or *porosity*; and (2) The ease with which fluids can flow through a rock, which is generally quantified as its *permeability*.

Fabric

The arrangement of particles in space is described as the *fabric*. Early workers (for a review, see Martini, 1978) described fabric in terms of two main properties: (1) The *orientation* of the particles: either the actual orientation of the grains themselves (*dimensional orientation*), or the orientation of the crystals composing the particles (*crystallographic orientation*); and (2) The *packing* of the particles. Packing can be described using theoretical models for regular packings of sphere, or (somewhat more realistically) for random packings. For real

particles, the *packing density* (see Kahn, 1956; or Martini, 1978, for quantitative definitions) is a measure of the porosity, and the *packing proximity* describes the number of contacts between particles. The types of contacts are also very important: for grains, Taylor (1950) introduced the terms tangential, long (essentially planar), concavo-convex, and sutured to describe increasing close contact between grain in sandstones, and showed that only tangential and a few long contacts are present in uncompacted sands, but concavo-convex and sutured contacts become more significant as sands are compacted by deep burial. Later studies have stressed the importance of using techniques such as cathodoluminescence (*q.v.*) to distinguish original clastic grains from chemically deposited (diagenetic) cements in assessing the nature of grain contacts. Many apparently concavo-convex and sutured contacts are not produced by pressure solution (*q.v.*) but by deposition of cement (see *Cements and Cementation*). For more recent approaches to packing see Allen (1982, Chapter 4), Bideau and Dodds (1991) and Rogers *et al.* (1994).

Grain orientation

The way that grains become oriented is an interesting part of the depositional process. It has also been studied as an indicator of the depositional process itself, particularly for deposits that do not show obvious internal stratification, such as tills, debris flow deposits, and some turbidites (for a review see Allen, 1982, Chapter 5). Most types of deposits show elongate grains oriented in the direction of the flow, but transverse and bimodal orientations are also known, particularly for roller-shaped pebbles (see *Size and Shape of Grains*). Flat pebbles in fluvial deposits commonly dip in the up-flow direction, but dip directions on beaches are more variable (see *Imbrication and Flow-Oriented Clasts*).

Most investigations, of grain orientation have been motivated by the need to obtain paleocurrents from such deposits (see *Paleocurrent Analysis*). The statistical techniques required to establish the fabric type and the preferred orientation (if any) have been reviewed by Fisher (1993) and Fisher *et al.* (1987): see Middleton (2000, Chapter 9) for references. Particle orientation may be produced or modified by compaction (*q.v.*)

or diagenesis (*q.v.*), particularly in fine grained, clay rich sediments (see *Depositional Fabric of Mudrocks*). Most sedimentary rocks have anisotropic fabrics, i.e., the grains and pore spaces show a preferred orientation, with the result that bulk properties, especially permeability, are also markedly anisotropic. Permeability is almost always much larger in the plane of stratification than normal to that plane. Fabrics generated by physical depositional processes are frequently modified by biological processes (see *Biogenic Structures*, and the symposium organized by Kemp, 1995).

Porosity

Techniques to measure porosity are reviewed by Monicard (1980). It is generally useful to distinguish total porosity from that part that consists of interconnected pores (*effective porosity*): e.g., pumice may have a large porosity, but fluids cannot move through the pores because they are not interconnected. Geophysical techniques may measure the total water (or hydrogen) content of a rock, some of which may be too tightly bound to mineral surfaces to move freely. Porosities of unconsolidated sands are generally 35 to 40 percent but may be higher (particularly for irregularly shaped bioclasts): for recently deposited muds they are generally 50 to 80 percent, with considerable consolidation taking place in the first meter or two of burial.

Geologists are generally interested in classifying pore spaces according to their genesis. In sands part of the porosity may be depositional *intergranular porosity*, due to the original depositional packing (or what is left of it, after compaction): another part may be *secondary porosity* produced by dissolution of grains during diagenesis. Some may even be *intragranular*, due to pore spaces within the grains, either present already at the time of deposition, or produced later during diagenesis. Diagenetic processes tend to decrease porosity, especially during deep burial (see *Compaction*) but there are exceptions. For further details, see *Petrophysics of Sand and Sandstone*.

Carbonates, even original carbonate sands, tend not to retain their original intergranular porosity for long, due to extensive early diagenesis (see *Neomorphism and Recrystallization; Carbonate Diagenesis and Microfacies*). The result is that extensive classifications of pore types have been developed for carbonate rocks. Choquette and Pray (1970) divided pores into two major categories, according to whether their presence was determined by a preexisting fabric (*fabric selective*) or not. Much secondary porosity is fabric selective, because it is determined by dissolution or recrystallization or replacement of fossil fragments. Large vugs and fracture systems, however, are generally not fabric selective, and cut indiscriminately across the original depositional fabric. Lucia (1995) has proposed a revised system, based more closely on petrophysical rock properties (see below). It recognizes two major categories of pore space: (i) *interparticle*; and (ii) *vuggy*, subdivided into *separate*, and *touching* (i.e., interconnected vugs).

Permeability

Permeability expresses the ease with which fluids flow through rocks. Henry Darcy first established the law (now called *Darcy's law*) that the discharge of fluid per unit cross-sectional area of the porous medium, q , is proportional to the hydraulic gradient (dh/dx). The coefficient of proportionality is called the *hydraulic conductivity*. Hydraulic conductivity is commonly

used by hydrogeologists (e.g., Freeze and Cherry, 1979), but has the disadvantage that it depends not only on the porous medium but also on the properties of the fluid. A form of Darcy's law which separates the fluid and rock properties is:

$$q = -k (\gamma/\mu)(dh/dx) \quad (\text{Eq. 1})$$

Here γ is the specific weight of the fluid, and μ is the fluid viscosity. The coefficient of proportionality, k , in equation 1 is called the permeability, or *intrinsic permeability*, and for rocks saturated with a single fluid (e.g., water or air) it is determined only by the rock properties. Its units, therefore, are length squared. Permeability is related to some "average size" of the pore system, though the "average cross-section" of the pores, is not given by the units of intrinsic permeability. For intergranular porosity, permeability is related to the size and sorting of the grains (see *Petrophysics of Sands and Sandstone*; Chapman, 1981; Middleton and Wilcock, 1994, Chapter 6).

Unfortunately the same law does not apply (without major modification) for rocks or sediments that contain more than one fluid, e.g., air and water in the vadose zone; oil or gas and water in petroleum reservoirs. It is possible, however, to define a "relative permeability" which expresses the permeability to a single fluid, at a given fluid content, as a proportion of the intrinsic permeability: but once again, relative permeability is not a property only of the porous medium, but also of the other fluids present in the pores.

Permeability of relatively porous, high permeability rocks is generally determined by forcing gas through dry rock samples, or by pumping tests on wells. The older unit of permeability was the *darcy*. Very permeable coarse sediments may have a permeability of the order of one darcy, but the permeability of most reservoir rocks is best measured in *millidarcies*. Many good reservoirs have permeabilities of only tens of millidarcies. The SI unit is meters squared, a very large value (for comparison, a darcy is *roughly* one micrometer squared!). A portable "microporimeter" that can be used on outcrops in the field has been developed (Davis *et al.*, 1994), though the results do not always correlate well with measurements made on cores (Tidwell *et al.*, 1998). Almost all sedimentary rocks have some permeability, and although it is not easy to determine the *in situ* permeability of rocks with very low permeability, such as shales, it can be done (see Neuman and Neretnieks, 1990). Such rocks have measured permeabilities as low as 10^{-9} darcies.

Petrophysics

The term petrophysics was introduced by Archie (1942, 1952) as a discipline that is concerned with relating the physical properties of porous rocks, as measured, for example, by electrical conductivity, to the texture and composition of the rock. Most petrophysical studies are concerned with the detailed geometry of the pore space, because this determines not only the average bulk properties of the rock, such as porosity and permeability, and electrical resistance when saturated with water, but also with the way the rock transmits two fluids. In the petroleum industry, the two fluids are water (because essentially all reservoir rocks contain water) and oil or natural gas. For introductions see Greenkorn (1983) and Bideau and Dodds (1991).

To understand two-phase flow, consider the simplest case: movement of two fluid phases in a straight uniform capillary, with circular cross-section of diameter d . If the two fluids are water and air, then the water tends to be drawing into the tube, displacing air. The interface or *meniscus*, makes a *contact angle* θ (theta) with the solid surface. The *displacement pressure*, P , tending to drive the water along the capillary is given by

$$P = -4\gamma \cos \theta / d \quad (\text{Eq. 2})$$

where γ (gamma) is the *interfacial tension* between water and air (it is about 70×10^{-3} N/m for water, and $20\text{--}40 \times 10^{-3}$ N/m for crude oil, decreasing with temperature). For water, air and glass (or most mineral surfaces) the contact angle is about 30° , for oil and mercury it is greater than 90° . What this means is that water *wets* the mineral surface, but oil and mercury do not. Experience shows that almost all rocks are water-wet below the vadose zone: even when they are “saturated” with oil or natural gas, there is always a residual film of water between the mineral surface and the nonwetting fluid.

The geometry of pore space in sedimentary rocks is complex (see *Petrophysics of Sand and Sandstone*; Pitman and Duschatko, 1970; Enos and Sawatsky, 1981) and differs significantly from a bundle of capillaries. Nevertheless, the simple relationship linking displacement pressure with capillary size makes it possible to determine some important geometrical properties of interconnected pores by monitoring the displacement pressure needed to force a known volume of a nonwetting fluid, such as mercury into a dry, air-saturated sample of the rock, up to pressures high enough to (almost) saturate the rock with mercury, and then monitor the pressure again as the mercury is allowed to flow out. A typical graph (Figure F1) shows the displacement pressure (on a logarithmic scale, pressure increasing downward on the ordinate) plotted against the percentage of mercury saturation. It is also a way of displaying the size distribution of the pore system. As can be seen in the figure there is a hysteresis loop: No mercury enters the pore space until a certain critical pressure is exceeded (determined by the size of the largest pores), and progressively more mercury enters as mercury is forced into smaller pores (or the interconnecting *throats* between pores) up to 100 percent saturation, but when the pressure is released some mercury remains in the pores, because the internal pressure is no longer sufficient to force the mercury through the small throats connecting the larger pores. This factor limits not only the *recovery* of mercury from test samples, but also the recovery of oil from petroleum reservoirs. Note that extremely high displacement pressures are required to force fluids such as petroleum through very small pores: this is the reason why rocks of very low permeability, such as shales, will slowly “leak” water from underlying aquifers, but will serve as effective seals to form traps for petroleum.

Displacement pressure on such mercury injection plots serves as a proxy for pore or throat size (the smallest throats require the highest displacement pressure). For further discussion see *Petrophysics of Sands and Sandstone*. Diagenetic processes, particularly compaction and cementation (*q.v.*), frequently decrease the size of the throats (and the coordination) more than they do the absolute porosity. Burial generally produces a roughly linear decrease in porosity, but an exponential decrease in permeability, with depth. In sandstones, clay cements (illite and mixed layer clays) are

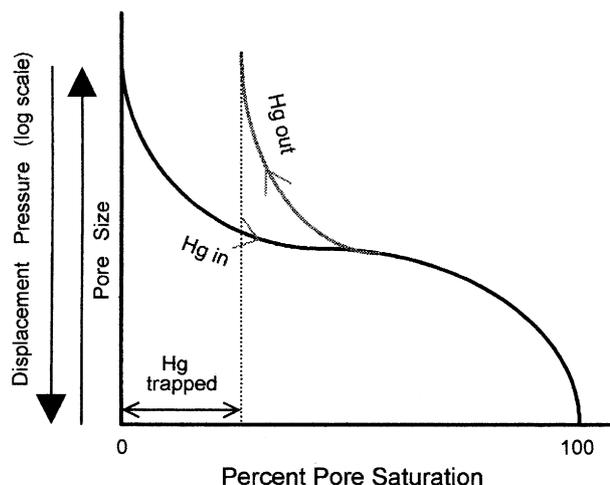

Figure F1 Schematic graph showing result of a mercury injection test. After the displacement pressure reaches a threshold value, mercury is driven into the (gas filled) pore space: as the pressure increases, more mercury enters smaller pores, until saturation is approached asymptotically. On decreasing the pressure, mercury flow out but not all it can be recovered. The displacement pressure can be considered to be a proxy for pore (and throat) size: the largest pores correspond to the least displacement pressure, and the smallest pores the most pressure, so the “in” curve corresponds roughly to the size distribution of the pores.

particularly effective in clogging throats. There are, however, exceptions, where diagenetic dissolution at depth produces secondary porosity with large interconnecting throats (see *Diagenesis*).

Mercury injection is not the only technique available to provide a more detailed measure of pore structure than bulk measurements of porosity and permeability or their geophysical proxies (see *Geophysical Properties of Sediments*; Prensly, 1994).

FACIES MODELS

Models are idealized simplifications set up to aid our understanding of complex natural phenomena and processes. They have been extensively used in the interpretation of sedimentary rock facies.

The concept of facies, that is a body of rock with specified characteristics, has been used ever since geologists, engineers and miners recognized that features found in particular rock units were useful in correlation and in predicting the occurrence of coal, oil, and mineral ores. The term was introduced by Gressly (1838) who used it to embrace the sum total of lithological and paleontological aspects of a stratigraphic unit. Since that time the term has been the subject of considerable debate, well summarized by Middleton (1973) and discussed extensively by Anderton (1985), Walker and James (1992), Reading (1987, 1996) and Miall (1999).

Ideally a rock facies should be a distinctive body of rock that formed under certain conditions of sedimentation, reflecting a particular process, set of conditions, or environment. It should differ from those bodies of rock above, below

and laterally adjacent. It may be a single bed or group of similar beds. A facies may be subdivided into subfacies or grouped into associations of facies (facies associations). Where sedimentary rocks can be handled at outcrop or in cores, a facies can be defined on the basis of color, bedding, composition, texture, fossils, and sedimentary structures. If the biological content of the rock is its dominant aspect, then it should be called a biofacies, an ichnofacies being distinguished by its suite of trace fossils. If fossils are absent or of little consequence and emphasis is to be placed on the physical and chemical characteristics of the rock, then it should be called lithofacies. Where definition depends on features seen in thin section, as is often the case with carbonates, the term microfacies is used.

Facies models developed out of facies classifications that had been based on observable and measurable features, but, as time went by and our understanding of process and of environment increased, the word facies came to be used in more genetic senses, that is for the product of a process by which the rock was thought to have formed or the environment in which it was deposited. Although all these senses overlap, it is necessary to be aware of the sense in which the word facies or the phrase facies model is being used, in an objectively defined descriptive sense, or as an interpretation of the generating process or the environment in which it was deposited.

Facies classifications

The earliest facies classification in clastic sediments was that of Mutti and Ricci Lucchi (1972) for deep water facies. It has continued, with slight modifications, to the present day. Deep water sediments are divided into 7 classes, 16 groups, and 59 facies based on grain size, internal organization, composition, bed thickness, and sedimentary structures. In alluvial sediments, a scheme initiated by Miall (1977) is also widely used with extensive modifications to suit particular sequences. It recognizes three major grain size classes, gravel, sand and fines, and several modes of bedding (e.g., massive, trough cross-bedded, planar/tabular cross-bedded, rippled, horizontal laminated, shallow scours, etc.). These facies schemes are invaluable in giving a rigorous objective record of the rocks and enabling different geologists to produce consistent results; and they also force the observer to look at every aspect of the lithology. However they can become unwieldy and time consuming. The observer should therefore be prepared to modify such schemes according to the time available for the study and the objective of the exercise.

Classification schemes for limestones began, as with clastic sediments, with ones based on grain size. Limestones and dolomites were divided into calcilutite/dololutite (grains <62 µm), calcarenite/dolarenite (62 µm to 2 mm) and calcirudite/dolorudite (>2 mm). From this facies scheme, built on grain size, there developed the two classical, and still used, classifications of Folk (1959) and Dunham (1962). These depended more on texture than on grain size, in particular on the proportion of grains to matrix, and on the manner in which the grains were supported. Whilst utterly objective and descriptive, the divisions reflected, as with any grain size subdivision of facies, the energy level of the depositional environment. For example, a wackestone, where the grains are supported by the surrounding mud and fine-grained carbonate (micrite) indicate deposition in quiet water; a grainstone

formed of detrital grains, supporting each other and lacking mud indicates agitated water.

Process facies models

Facies models based on the inferred process by which a sediment is considered to have formed generally have the suffix “-ite”. The term *evaporite* (*q.v.*) has long been used for precipitates formed by the evaporation of sea or lake waters in climates where losses by evaporation exceed additions by precipitation and influx of less saline waters either fresh or from the sea. In the 1950s, as it began to be realized that many “graywackes”, that is sandstones with a high matrix content, had been deposited by turbidity currents it became common to use the term “graywacke facies” for the deposits of a turbidity current. However, not all graywackes were formed by turbidity currents; nor does every deposit of a turbidity current have the high matrix content of a graywacke. The problem was solved by the introduction of the word *turbidite* (*q.v.*) for all rocks thought to have been deposited by a turbidity current. The term “graywacke” could then be restricted to a sandstone of a well defined composition regardless of whether the high matrix content was the result of deposition from a turbid current or diagenetic alteration of unstable Fe–Mg minerals as some had postulated.

The turbidite model, the classic facies model, was first developed by Kuenen (1950) and then more widely publicized in the paper by Kuenen and Migliorini (1950). They combined knowledge of graded beds as seen in outcrops of ancient rocks, flume experiments, and the increasing knowledge of present day deep oceanic processes into a genetic turbidite model. Their pioneering work was further developed by Bouma (1962) whose field measurements quantified the range and variety of turbidite facies. Bouma’s study was essentially descriptive. Harms and Fahnstock (1965) and Walker (1965), on the other hand, used our expanding understanding of the physics of sedimentation to explain the Bouma sequence of sedimentary structures in terms of flow regimes.

The turbidite model is only one of an increasing number of models for deep water mass-gravity flows. Soon after its arrival it was realized: (1) that turbidity currents could be of low density as well as of high density, as Kuenen had thought; (2) that grain flows (with grain-to-grain interactions), liquefied flows (where grains settle downward, displacing fluid upward) and fluidized flows (where fluid moves upward) may each produce their own suite of sedimentary structures. In addition, coarser material than sand can be transported into deep water by sudden falls of rock, by slumping, by sliding, and by slurry-like debris flows (*q.v.*) that yield a facies known as a debrite.

Since the processes of transport and deposition can never be known with surety, and since post-depositional modifications can add to or obliterate depositional structures, debate continues fiercely to this day as to how these deep-water facies should be categorized. Massive sandstones, for example, though generally thought to have been formed from high density turbidity currents, are argued by Shanmugam (2000) to have formed as sandy debris flows and therefore should be *debrites*, not turbidites.

Other deep water facies are *pelagites*, pelagic deposits consisting of various proportions of calcareous and siliceous microfossils and clay formed by slow settling in the oceans. Rocks formed in this way include chalk, chert, Fe–Mn nodules, phosphates and red clays. *Hemipelagites* are fine-grained

sediments that have not only the same biogenic and clay material as pelagites but also contain a significant terrigenous component (25 to 90 percent) derived from an adjacent land area.

Contourites are somewhat ambiguously termed. They form from relatively continuous semi-permanent currents in all depths of oceanic waters, and in lakes. Until the 1960s it was generally thought that the oceans were rather stagnant bodies of water where deposition below wave-base (approximately 200 m) was confined to continuous pelagic settling interspersed with rare catastrophic slumps and turbidity current flows that could bring sands and other coarser material into deep water. As it became possible to measure mass water flows in the ocean it was realized (e.g., Heezen *et al.*, 1966) that the oceans contained an enormous range of semi-permanent currents which are the deep-water expression of oceanic thermohaline circulation. Deep-ocean bottom water is formed by the cooling and sinking of surface water in polar regions that flows toward more equatorial regions with surface waters, such as the Gulf Stream, returning waters from the tropics to the poles. The distribution of land and ocean-bottom topography, and the Earth’s spin, all cause complications in any general pattern. Of particular importance is the Coriolis Force, due to the Earth’s rotation, that causes an anticlockwise rotation in the Northern Hemisphere and thus produces currents such as the Western Boundary Undercurrent that flows southwestward, paralleling the contours on the continental slope and rise. Such currents are known as contour currents and the facies is termed *contourites*.

In shallow marine and coastal waters, the two principal physical processes of sedimentation are tidal currents and storms. On some confined continental shelves, particularly in estuaries, tidal currents may be very powerful, giving rise to a facies known as *tidalites*, that can record the daily or, more commonly twice daily (semidiurnal) tidal rise and fall that give rise to flood and ebb tides. The very strong currents produced by these tides can give a facies dominated by tidal currents with their own distinctive pattern of cross beds, sometimes even bipolar, formed during the two ebb and flood current stages and mud drapes deposited during the intervening slack periods.

Where tidal currents are weak or absent the facies on continental shelves are documented by storm deposits (*tempestites*), coarse-grained sandy or bioclastic sediments, often graded, interbedded with finer, quiet water sediments. These graded, sharp-based sandstones have often been confused with graded turbidites because the sequence of sedimentary structures is very similar. They can be distinguished by the presence of wave ripples indicating that they formed above the level of wave base (see *Storm Deposits*).

Facies relationships, associations, and sequences

The interpretation of a facies can seldom be made in isolation. A rootlet bed can indicate deposition very close to or just above water level. But it does not tell us whether it formed in a backswamp, on an alluvial fan or river levee. Graded sandstone beds may be formed by a river flood, a storm in the sea or by the collapse of continental slope sediments into deeper water. Only the context in which we find the graded bed tells us the environment or the process by which it formed. We have to recognize the limitations of individual facies taken in isolation.

Facies have to be interpreted by reference to their neighbors and are consequently grouped into *facies associations* that are thought to be genetically or environmentally related (Collinson, 1969). The association provides additional evidence which makes interpretation of the environment easier than treating each facies in isolation, particularly in the elimination of alternative interpretations.

Facies associations are therefore the essential building blocks of facies analysis and model groups of facies associations have been constructed for most environments. For example, Miall (1985) postulates eight architectural elements in fluvial environments and Mutti and Normark (1991) suggest there are five primary elements in deep-sea fans, including large-scale erosional features as one of their elements.

In some successions, the facies within a succession are interbedded randomly. In others, the facies may lie one above another in a preferred order with predictable upward and downward changes. The importance of facies sequences has long been recognized, at least since Walther's Law of Facies (quoted in Middleton, 1973) which states that "only those facies and facies areas can be superimposed, without a break, that can be observed beside each other at the present time". This concept has been taken to indicate that facies occurring in a conformable vertical sequence were formed in laterally adjacent environments and that facies in vertical contact must be the product of geographically neighboring environments.

However, Walther's Law only applies to successions without major breaks. A break in the succession marked either by an erosive contact, or simply by a hiatus in deposition may represent the passage of any number of environments whose products, if they were deposited, were subsequently removed. Some breaks in the succession are essentially autocyclic, that is they reflect natural sedimentary processes such as the switching of a delta, the lateral migration and avulsion of a river channel or the build up of a carbonate platform. Other breaks, generally more laterally extensive, may be the result of allocyclic controls, external to the local environment due to tectonic movements or changes in climate, sediment supply or sea level.

Environmental facies models

The ultimate object of facies modeling is to interpret not only the depositional environment of the sedimentary body being examined, but the total context within which it formed, the climate, oceanic circulation patterns, rates of sedimentary supply, rates and nature of sea-level changes both local and eustatic, and local, regional and global tectonics. The stratigraphic age is also important; facies models change as organisms have evolved, and Precambrian oceans were very different in their chemistry to those of Mesozoic or Cenozoic times.

To this end we have not only to describe the facies and determine the physical, chemical, and biological processes involved, but to understand the depositional environment.

Environmental facies models were developed initially from studies of modern environments. Classic studies of these environments include: (1) Glennie (1970) on desert sedimentary environments: he was sent to study deserts by Shell after the discovery of huge amounts of gas in Permian desert deposits in the Netherlands; (2) Oomkens and Terwindt (1960) on estuaries, especially deposition in tidal channels; (3) Fisk (1944) and Bernard and Major (1963) on fluvial, especially

meandering river deposits; (4) Fisk *et al.* (1954) on delta deposits; (5) Illing (1954) on the carbonate platform of the Bahamas; and (6) Shearman (1966) on evaporites forming in sabkhas (*q.v.*).

Environmental facies models were then further developed by measurement of outcrops, particularly analysis of sequences and cycles, research into which had been considerable in previous decades (see *Cyclic Sedimentation*), the interpretation of sedimentary structures in terms of physical processes, and of composition by analogy with chemical theory and experimentation, and by comparing structures and composition with comparable features in modern sediments.

The best known and most influential studies were those of Allen 1964, 1965, 1970 who published a series of papers that interpreted fining upward cycles of the alluvial Old Red Sandstone of England and Wales as a consequence of lateral migration of point bars in meandering rivers (see *Meandering Channels*). The full cycle consisted of a sharp, channelled base overlain by an intraformational conglomerate of caliche fragments that passed gradually upward through parallel-bedded, cross-bedded, cross-laminated sandstones to siltstones capped by a calcrete soil bed. This fining upward meandering river model was used extensively by workers all over the world, sometimes to the detriment of alternative explanations for such fining upward cycles. One alternative model, particularly suitable for sediments deposited in semi-arid climates such as that of the Old Red Sandstone, is that the cycles are the result of ephemeral rivers that flow for limited periods of time, the channelling and deposition of sandstones occurring during the wet (pluvial) periods and with flows diminishing as rainfall is reduced. Another explanation for many of the smaller cycles is that they were caused by flash floods of very limited duration that can give rise to graded beds of some thickness.

Models for a wider spectrum of alluvial deposits were gradually developed over many years by Schumm (1972) who separated alluvial systems into streams dominated by bed-load, by mixed load and by suspended load sediments, by Miall (1985) who emphasized successions made up of building blocks termed architectural elements and by Orton and Reading (1993), who showed that models needed to be developed for a spectrum that went from alluvial fans (*q.v.*) through braidplains to the finer grained, low gradient normal river systems.

Delta models were developed very early on by the convergence of studies of coarsening upward cyclothem, especially in the Upper Carboniferous sediments of the USA and Europe, and studies of modern deltas, initially the Mississippi. The abundance of petroleum reservoirs in such deltaic deposits led to petroleum financed studies of other deltas such as the Rhône, Rhine, Niger, and Ganges/Brahmaputra and it was soon realized that delta shape and sediment accumulation patterns, especially reservoir sand bodies varied substantially according to whether the dominant processes of sedimentation were by river discharge or by marine reworking by waves, storms or by tidal currents and in particular the calibre of sediment supplied by the alluvial system (Orton and Reading, 1993).

Environmental facies models for carbonate sediments were initiated by Illing (1954) working on the Bahama platform and by Ginsburg from 1956 onward studying the Florida shelf. Their work on modern environments was then extended in the 1970s by Wilson (1975) who combined knowledge of ancient carbonate facies with the increasing research on modern

carbonate environments into a model of nine lateral facies belts that extended from a deep water basinal, euxinic environment through open, oxygenated marine, slope, organic build up to open or restricted platform. Each environment could be recognized by its facies, especially biotas. This very general facies model was then supplemented by a range of lateral facies models for isolated platforms, shelves attached to the land and carbonate ramps with gently sloping surfaces of less than 1°. In addition, models had to be created for platforms that do not exist today such as the very extensive epeiric platforms that were widespread in the late Precambrian and Paleozoic. They were some hundreds or thousands of kilometers across, developing on stable cratonic interiors and are characterized by distinctive sags or intraplatform basins.

At the platform margins, reefs (*q.v.*) may develop. Here, biological sediment production is realized to its maximum extent. Over geologic time a range of different organisms have contributed to the building of reefs so the biofacies is stratigraphically controlled. Corals and algae may predominate today, but in Cretaceous times rudist bivalves built reefs; at other times building may have been by bryozoa, sponges or crinoids.

Beyond the platform margin, a range of different slopes occur. Some margins, especially below reefs, are steep-sided; others are more gentle. Some are erosional; others are accretionary. Windward and leeward margins also differ. At the base of slope carbonate fans and aprons may form.

The three principal environments of deep water deposition, basin floor, submarine fan, and slope apron were first delineated in modern Californian basins by Gorsline and Emery (1959). However, facies models for submarine fans were developed primarily from the study of ancient rocks in the English Pennines (Walker, 1966) and Italian Apennines (Mutti and Ricci Lucchi, 1972) with the single "all-purpose" fan model of Walker (1978) widely used by everyone in the next decade. The reason for models being driven by studies of ancient rocks, rather than modern sediments was because, whilst the shape of modern submarine fans could be very roughly outlined (e.g., Normark, 1970) it was not possible to determine the nature of the sediments other than in the top few decimeters. On land, however, whilst submarine fan shapes and channels were only rarely exposed, vertical sections, kilometers in length could be measured. By analogy with the fining upward fluvial model and the coarsening upward delta model great emphasis was placed on sequences of bed thickness in submarine fans, thinning-upward sequences being thought to indicate channels and thickening-upward sequences to indicate prograding lobes. As DSDP, ODP and petroleum company cores have been recovered, vertical sequence models have now been developed for a much wider range of deep sea environments. For example, Stow (1985) differentiates 18 vertical sequences for turbidites, contourites, debrites, pelagites, and hemipelagites in the deep seas.

However, in the last 20 years, these earlier simplistic facies models have been shown to be inadequate. Ironically, our understanding of deep-sea sediments has been increasingly based on studies of modern environments rather than ancient rocks. This is not only due to the increasing number of cores in oceanic sediments, but is mainly the result of seismic profiling. Because seismic profiling is much easier in deep water than in shallow water or on land, models for deep water sediments are now derived more than any other facies models from studies of modern seas. Since the paper of Mitchum *et al.* (1977) in the

classic memoir edited by Payton (1977), seismic facies, based on reflection configuration, continuity, amplitude, frequency and interval velocity, together with the external form of the unit has become the standard tool for 3-dimensional facies patterns which are now well established for deep-sea sediments. The architectural elements of Mutti and Normark (1991) and the 12 distinctive facies models of Reading and Richards (1994) are largely based on data obtained from seismic profiles of base-of-slope depositional systems. The latter showed that separate models needed to be created, distinguished by the volume and calibre (grain-size) of the sediment supply and the nature of the supplying system whether it is a single point source, a multiple source or a linear slope apron.

Summary

Facies classifications were initially mainly descriptive, based on observable, measurable features such as the composition and texture of sedimentary rocks. As time went by, facies models were developed based on the inferred process of formation. Such genetic facies models generally have the suffix "-ite", e.g., "turbidite". Simultaneously, it was appreciated that individual facies could not be interpreted in isolation but had to be studied with reference to their neighbors. Such models emphasized the association of facies, sequences of facies, in particular those that coarsened or fined upward, and the presence or absence of breaks in the succession.

The establishment of environmental facies models is the ultimate objective of facies modeling. Only in this way is it possible to establish the nature of past climates, oceans, sea levels and global and local tectonic patterns. Environmental models are developed by the interaction of studies on modern and ancient rock sequences. Initially relatively simple, all embracing models were developed. These have become increasingly complex as our knowledge of the variability of nature has increased.

Complex though these models are, they are only simplifications of reality. In nature there are no models and the majority of past environments differed in some respect from modern environments. It must be remembered therefore that each environment and rock sequence is unique.

FAN DELTA

The most commonly adapted definition of fan delta is a coastal prism of sediments derived from an *alluvial-fan* feeder system and deposited mainly or entirely subaqueously at the interface between the active fan and a standing body of water (Nemec and Steel, 1988). The importance of the feeder system as a criterion for fan delta recognition roused significant discussion among students of fan deltas on what is an alluvial fan and how to recognize it in the fossil record, an issue that is still not resolved. Most fan delta researchers, however, refer to alluvial fan systems as steep gradient, often gravelly, cone-shaped fluvial systems, which can be dominated by either *sediment gravity-flow* processes or by shallow streams feeding the delta front essentially as a line source.

Fan deltas are taken to be sensitive recorders of climate change and tectonics. The response time of fan deltas is short compared to river deltas, because their drainage basins are generally small and the gradient of their feeder system is relatively steep permitting high rates of sediment transport.

Hence, supply pulses generated by climate and tectonics are likely to be preserved in the delta body in the form of bed thickness variation, grain size and sediment composition, while changes in relative sea-level would leave its trace in the form of stacking patterns of delta components.

Seismic studies of the subaqueous part of modern fan deltas that started in the late seventies (Prior *et al.*, 1981) added significantly to researchers' insight into the sedimentary processes that governed the morphology of the delta slopes. Due to the combination of extensive marine and outcrop studies of fan deltas in various tectonic and climate settings, progress in fan-delta research was significant in the eighties and early nineties (Kosters and Steel, 1984; Nemec and Steel, 1988b; Colella and Prior, 1990; Dabrio *et al.*, 1991; Chough and Orton, 1995).

Fan delta concept

Fan delta morphology and architecture is the result of the interaction of the alluvial fan feeder system with the receiving basin. Figure F2 shows how delta morphology is defined by alluvial processes (fluvial regime) on the one hand and basinal processes (basinal regime) on the other. The fluvial regime is controlled by hinterland characteristics such as drainage area, geology (e.g., lithological variation) and topographical relief of the catchment, which are all subject to continuous change. The rates at which these changes take place depend on the rate of variation in climate, tectonic and sea-level change. For instance, periods with increased run-off at times of climate deterioration, or periods of tectonic uplift of the hinterland will lead to an increase in sediment supply to the delta due to increased erosion rates in the hinterland. But also other factors, like vegetation and not to forget civilization, add to the total of the fluvial regime. The basinal regime is controlled by characteristics of the basin. Geographical setting, shape, depth and size of the basin define, by and large, its dynamics in terms of available tide and wave energy, but also other variables like the density of the basin water relative to the river water plays a role in the morphology of the fan-delta.

The control of the fluvial regime on fan delta architecture is best shown by fan deltas of low energy basins, i.e., in basins where wave and tidal influence is small. Figure F3 shows 6 prototype deltas based on the type of feeder system and the

basin depth. Feeder system type-A represents steep gradient (more than a few degrees), often gravelly, cone-shaped systems, dominated by mass-flow processes and type-B represents a steep-gradient (~0.4°) feeder system that is characterized by highly mobile (unstable) bed-load channels feeding the delta front essentially as a line source (cf. Postma, in Colella and Prior, 1990). The steepness of the fan-delta front depends most on the initial basin relief (e.g., absence or presence of a shelf) and the fluvial regime at the river outlet. In settings where the depth ratio (channel depth over basin depth) is small (e.g., fault scarps) and where bed-load transport is high, deltas with steep gradient delta slope (Gilbert-type deltas called after G.K. Gilbert: see *Sedimentologists*, types 3 to 6, in Figure F3) will form. In settings of high depth ratio and with high-competence streams of high suspension-bed-load ratio (occurring for instance during flooding), deltas will be characterized by shoal water profiles, possibly with mouth bars in the stream outlets (Hjulström-type deltas, types 1 and 2 in Figure F3).

The role of the basinal regime in creating delta morphology can be pictured as the relative contribution of wave and tide processes to river processes. Wave-dominated fan deltas have been described frequently from the modern and ancient record. They are often recognized by straightened, wave-worked delta fronts and gravelly beach facies overlying a flat erosion surface paved with a gravel lag and truncating the delta foreset. Tidal influence in steep gradient fan deltas is commonly assumed to be minimal.

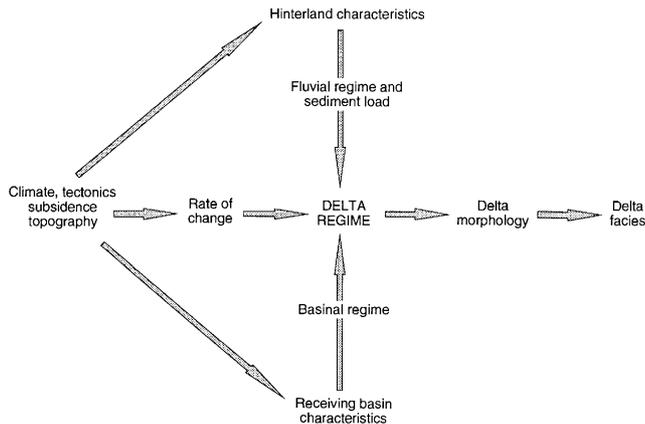

Figure F2 Conceptual framework for fan delta morphology, architecture and facies.

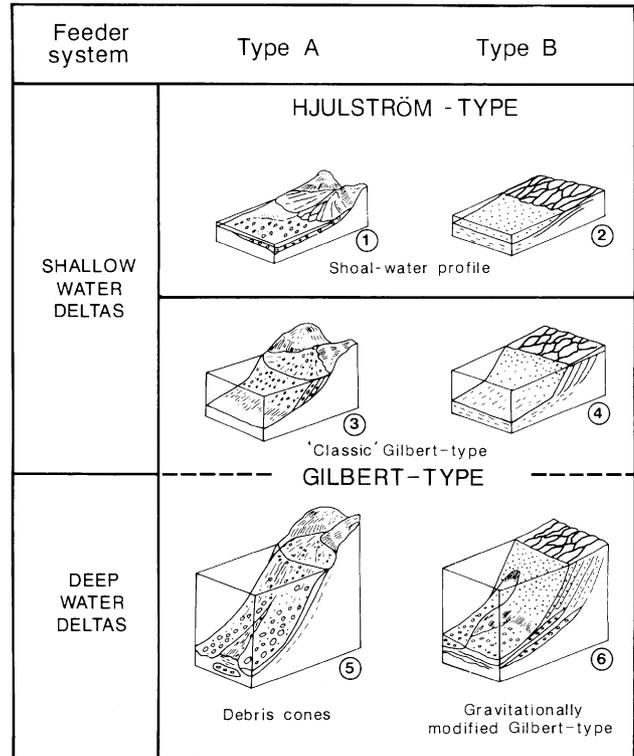

Figure F3 Morphology and architecture of various types of fan delta. Deltas built by the high gradient alluvial streams are generally small in size (few km's radius).

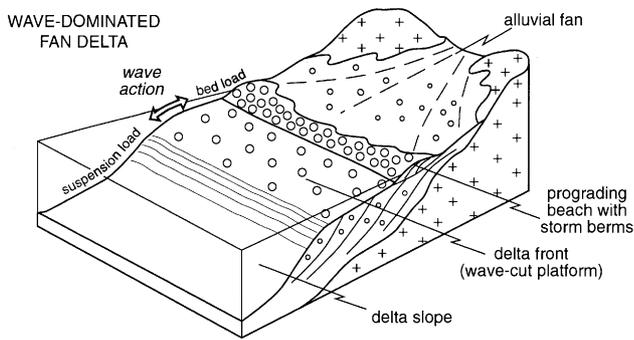

Figure F4 Wave-dominated fan delta with gravelly beach and storm-berms prograding onto the wave-cut platform (modified from Dabrio *et al.*, 1991b).

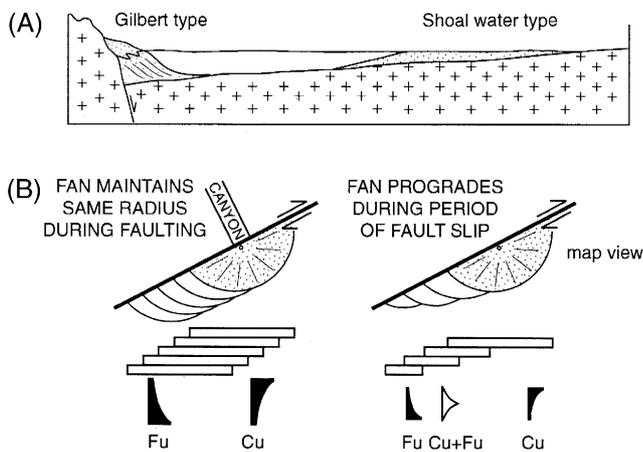

Figure F5 (A) Tectonically controlled delta architecture (Gulf of Corinth, redrawn from Leeder *et al.*, 1988); (B) Stacking of fan deltas in strike slip settings resulting in fining and coarsening upward cycles (Hornelen Basin, redrawn from Steel, 1988).

Physical signatures of allocyclic change

Physical signatures of climate change in delta successions occur at various scales and frequencies. Very high frequency changes occur in the form of catastrophic flood deposits. On a time scale of *Milankovitch cycles* (*q.v.*), orbital-forced climate change have been found to be recorded as distinct turbidite sequences in the prodelta of deep-water delta systems, where turbidite deposition occurred mainly during the wet periods of the precession cycle (Postma, 2001).

Sea-level changes are preserved in the form of distinct stratigraphical styles of delta development: Progradation, aggradation and retrogradation define the large-scale architecture of a delta and are principally governed by sediment yield and relative sea-level change (Postma, in Chough and Orton, 1995; Steel and Marzo, 2001).

Physical signatures of tectonics comprise distinct patterns of stacking, rotation, supply and erosion of delta systems. The development of grabens can significantly influence the supply to delta systems by closure and opening of sediment transfer zones. Gilbert-type deep water delta systems are likely to

form against the footwall, while shoal-water type deltas develop on the hanging wall crest. Strike-slip related subsidence may lead to a stack of rotated and offset stacked fan bodies, whose architecture is controlled by the relative rates of fan progradation and fault slip (Figure F5).

Current investigations and concluding remarks

Current research is focusing on the impact of allocyclic controls on the architectural style and distribution. Recently documented studies of the Eocene Montserrat and Sant Llorenç del Munt clastic wedges in northern Spain in Marzo and Steel (2000) illustrate nicely the progress that has been made in linking fan delta architecture and facies with tectonically controlled subsidence and relative sea-level changes. The importance of the work lies in careful 3-dimensional high-resolution reconstruction of the fan delta complexes, which allows detailed estimates of sediment volume and distribution in relation to relative sea-level change and climate. However, the values of the allocyclic variables cannot be determined from the architecture of deposits alone and need to be verified against other independent evidence.

FEATURES INDICATING IMPACT AND SHOCK METAMORPHISM

Asteroid/comet impact is now recognized as a fundamental process on the surfaces of all solid bodies in the Solar System. Some 170 impact structures have been identified on Earth—only a fraction of the predicted terrestrial impact record (Grieve, 1998). A few impactogenic horizons and two large impact structures have been recognized in the Archean-early Proterozoic record. One global mass extinction horizon, the Cretaceous–Tertiary boundary, has been positively linked with a giant impact event at Chicxulub (Mexico). Several other mass extinction horizons, including the largest one at the Permian–Triassic boundary, are still being investigated for conclusive evidence of impact (e.g., Dressler and Sharpton, 1999; Montanari and Koeberl, 2000; Koeberl and McLeod, 2001). Some impact structures have sedimentary fills that have remained virtually undisturbed since deposition and could provide outstanding sedimentological and paleoenvironmental records (e.g., Partridge, 1998). Detailed accounts of the impact process, the history of its investigation, and its environmental effects are given by, for example, Melosh (1989, 1992), Chapman and Morrison (1994), and French (1998).

Much remains to be learnt about Earth's impact record and the role that this process has played throughout Earth's evolution. Likely, much impact evidence is still hidden in the sedimentological record. This is reason enough to review the phenomena used for recognition of impact facies—particularly the mineralogical phenomena known collectively as *shock metamorphism*.

Impact cratering process and impactites

Upon impact of an extraterrestrial projectile traveling at hypervelocity (11–72 km per second), an intense shock wave is generated, with shock pressures in excess of several 100 GPa and shock temperatures of 10,000s°C near the point of impact. The rapidly expanding shock wave imparts a particle velocity onto the target material, thus excavating a crater, but quickly loses energy along its outward path, with concomitant deformation decrease. In the immediate impact area, target rock and much of the projectile are completely vaporized. The next zones are characterized by wholesale impact melting, followed by successive zones of mineral melting, plastic deformation, and, eventually, elastic deformation (cataclasis). In some structures it may be possible to identify this zonation long after the impact event, but crater collapse, erosion, and tectonic overprint may obscure this pattern (e.g., Melosh, 1989; French, 1998).

The deformation caused during propagation of the shock wave through the target and later structural modification lead

to a distinct crater geology and impact rock types in specific settings in and around the crater. The crater rim zone comprises up- and overturned target strata, is somewhat elevated above the pre-impact surface, and may display injections of *allogenic*, or formations of *authigenic*, impact breccia. Before the onset of erosion, the rim and wider environs are covered with a blanket of *fall-out* impact breccia that quickly decreases in thickness away from the crater. The crater interior is filled with *fall-back* impact breccia. Three impact breccia types are distinguished: *impact melt breccia*, formed in relatively close proximity to the impact site, resembles clast-laden, glassy or crystalline igneous rocks; *suevite* is composed of a matrix of clastic material containing clasts of impact glass or melt; and *fragmental (lithic) impact breccia* comprises clastic constituents only. Due to the turbulent processes in the crater, each breccia type may contain clasts of other types. All breccia types may also occur in the form of injections into the crater rim and floor. The floor zone is strongly brecciated, containing authigenic, polymict and monomict, fragmental breccias, as well as injections of allogenic breccia of different types. In addition, friction melting can occur and form pseudotachylitic breccia (Reimold, 1998). Fragmental impact breccia may macroscopically resemble sedimentary breccias, particularly those classified as *diamictites*. Indeed, some diamictites have been regarded in the past as possible impact ejecta, and vice versa (Reimold *et al.*, 1998).

Macroscopic recognition criteria of impact structures

Remnants of a meteoritic projectile provide unambiguous proof for the presence of an impact structure (cf. Koeberl, this volume). Where this is absent, circular crater morphology, occurrences of breccias, and other macroscopic indicators, e.g., massive occurrences of pseudotachylitic breccias, presence of shatter cones (Nicolaysen and Reimold, 1999), or geophysical anomalies (especially circular gravity and magnetic anomalies that contrast with regional potential fields) may provide useful indications for the presence of an impact structure. However, none of these criteria can be taken as unambiguous evidence. Only the detection of the uniquely impact-produced, ultra-high pressure mineral deformation effects known as *impact* or *shock metamorphism* represent acceptable proof for impact. They may be observed within *in situ* impact formations, in allogenic impact breccias in the environs of impact structures, or—in widely dispersed form—in sedimentary strata deposited after erosion of impact structures and impact breccia formations. Generally, these effects are studied by optical microscopy, but electron microscopic techniques may be required to confirm the true nature of some deformation features.

Shock metamorphism

Conventional metamorphism of upper crustal rocks is limited to the regime of <1,000°C and <5 GPa. In contrast, hypervelocity impact is capable of attaining shock pressures of >100 GPa and temperatures in excess of thousands of degree centigrade (Figure F6). In addition, the strain rates associated with impact processes (10^4 – 10^6) are many orders of magnitude higher than those associated with endogenous geological processes (10^{-3} – 10^{-6}). Under these conditions, rock-forming minerals will be subjected to *elastic deformation* (irregular and planar, crystallographically controlled

shock effects may already occur at comparatively lower shock pressures (Huffman and Reimold, 1996).

Planar deformation features (PDFs) occur as single or, at higher shock pressures, multiple sets of extremely narrow ($<2\mu\text{m}$) and closely spaced ($2\text{--}10\mu\text{m}$) isotropic features (Figures F8(A) and (B)). Optical and TEM investigations show that PDFs are either composed of amorphous, or amorphous and extremely fine-grained crystalline material. They occur in distinct crystallographic orientations, and the relative abundance of PDF orientations in quartz may be used to constrain the shock pressure range in which they formed (predominance of (0001) orientations of Brazil twins is characteristic of shock pressures $<10\text{ GPa}$, {10–13} orientations form abundantly between 10 GPa and 20 GPa , and {10–12} orientations between 20 GPa and 30 GPa). Where PDFs have been subjected to annealing, they may only be represented by so-called *decorated PDFs*, whereby planar fluid inclusion or solid inclusion trails may still be visible in lieu of the original PDFs. Orientation measurements of such decorated features may provide the proof that these features are of impact origin. Recently, much attention has been paid to sets of narrow-spaced, planar features in the refractory and weathering-resistant mineral zircon. In this case, it has not been possible yet to identify the true nature—planar fractures, PDFs, or high-density dislocation bands—of such features (Figure F8(C)), but they can be considered as diagnostic of impact deformation (Leroux *et al.*, 1999).

Diaplectic (or thetomorphic) mineral glass is different from conventional glasses formed by melting of a mineral to a liquid phase. Diaplectic glass forms through solid-state transformation and, thus, preserves the original textures of a mineral. Although optically isotropic, features such as original fractures, PDFs, or inclusions/fluid inclusions can still be recognized. The refractive indices of various SiO_2 shock phases have been calibrated against shock pressures (Stöffler and Langenhorst, 1994).

Transformations of minerals to their high-pressure polymorphs typically occur at moderate to high shock pressures: α -quartz is converted at 12 GPa to 15 GPa into stishovite and at $>30\text{ GPa}$ to coesite. About 10 GPa to 15 GPa are required to convert graphite to diamond, and the highly refractory mineral zircon, which is especially important in rocks that may have been subjected to post-impact thermal metamorphism capable of erasing shock effects in less refractory minerals, converts between 40 GPa and 60 GPa into a scheelite-structure phase. Planar microdeformation features in zircon form at shock pressures between 20 GPa and 40 GPa , and a granular recrystallization texture (strawberry texture) is thought to represent a high-temperature/high-shock pressure stage of shock metamorphism.

Whilst the recognition of shock deformation in a single mineral may suffice to prove an impact effect and presence of an impact formation, shock pressure determination studies should, if possible, consider shock effects in as many minerals as possible.

Summary

Large meteorite impact has been (and still is) a very important geological process on Earth. As only a fraction of the terrestrial impact cratering record—especially of the Archean-Proterozoic record—has been deciphered to date, and impact has played a major role in the evolution of life on Earth,

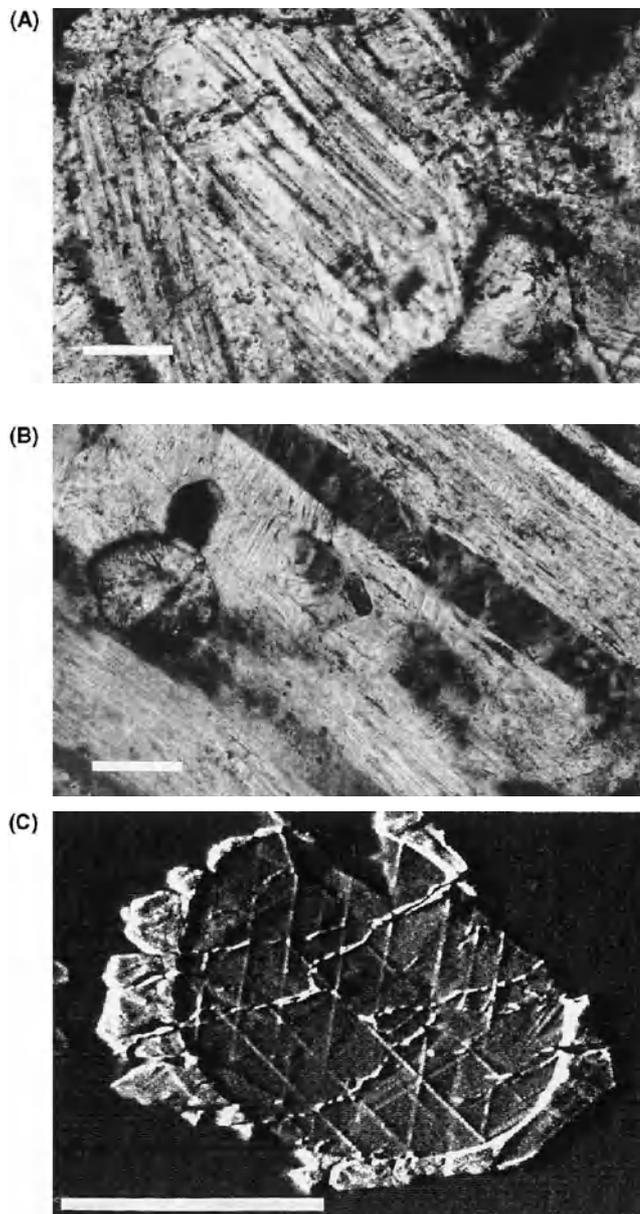

Figure F8 Typical examples of planar deformation features (PDFs): (A) Quartz from a granite in the Manson impact structure (Iowa, USA) displaying multiple sets of PDFs, many of which are decorated with fluid and solid inclusions. Scale bar: $50\mu\text{m}$, parallel nicols. (B) Plagioclase (also from Manson) showing alternating twin lamellae that are either melted (locally devitrified) or display numerous PDFs, mostly parallel to or at high angles to the lamellae orientation. Scale bar: $50\mu\text{m}$, crossed polarizers. (C) Planar features in a zircon crystal from the Vredefort Central Granite. The core of this grain, inherited from target crust, shows three orientations of planar features. It is overgrown by an undeformed generation of zircon that yielded a U-Pb age corresponding to that of the impact event. Scale bar: $200\mu\text{m}$, back-scattered electron-cathodoluminescence image (courtesy Dr. R.A. Armstrong, ANU).

impact cratering studies are a significant component of modern geoscience.

Shock metamorphic effects related to shock pressures between 10 GPa and 35 GPa provide unambiguous evidence for the identification of impact formations. In the absence of other definite evidence for impact (remnants of the meteoritic projectile), shock effects such as PDFs and diaplectic glasses are required as proof of impact.

FELDSPARS IN SEDIMENTARY ROCKS

Feldspars are the most abundant mineral group in the Earth's crust, mainly because they form at a wide range of temperature and pressure encountered in igneous, metamorphic and sedimentary environments. Feldspars in sedimentary rocks can be of detrital and diagenetic origins. Feldspars are a group of aluminosilicate minerals whose structures are composed of corner-sharing AlO_4 and SiO_4 tetrahedra linked in an infinite, three-dimensional array. Charge balancing, M cations with radius greater than 1.0 Å occupy large, irregular cavities in the tetrahedral framework. The general chemical formula of feldspars is MT_4O_8 , where T is Al and Si, M is Na and/or K for alkali feldspars [(K,Na)AlSi₃O₈] and Ca for plagioclase (CaAl₂SiO₈). There are several polymorphs of K-feldspar minerals, including microcline (triclinic), orthoclase (monoclinic) and sanidine (monoclinic). Si/Al is ordered in orthoclase but disordered in sanidine. The Na-plagioclase (NaAlSi₃O₈) is albite, whereas Ca-plagioclase is anorthite (CaAl₂Si₂O₈). There are several types of plagioclase minerals in igneous rocks according to Ca/Na ratios, which increase with increase in temperature and increase in Ca/Na ratio of the magma, as shown in page 279.

Detrital feldspars

Detrital feldspars, which are derived mainly from the erosion of igneous and metamorphic rocks, are second most abundant (average 10–15 volume percent), detrital mineral in sandstones after quartz. Sandstones that are considerably enriched in feldspars (>25 percent) are called arkoses. Due to their cleavage and twinning planes, feldspars have lower mechanical stability than quartz, and are thus more abundant in fine- than in coarse-grained sandstones. Feldspars are also common components in mudstones and siltstones, forming on average about 4.5 bulk volume percent. In carbonate rocks, detrital feldspars occur as a few scattered grains. Detrital feldspar content in clastic rocks decreases subsequent to deposition due to various diagenetic reactions, such as dissolution, alteration into clay minerals and replacement by calcite.

Detrital feldspars are dominated by K-feldspar, albite, and Na-Ca plagioclase. Albite and K-feldspars are derived mainly from felsic igneous rocks (such as granite in uplifted basement rocks), whereas Na-Ca plagioclase is derived from intermediate (e.g., diorite) and mafic (e.g., gabbro) igneous and companion metamorphic rocks, which occur in dissected island arcs. Ca-rich plagioclase is rare in clastic rocks due to their sensitivity to chemical weathering and diagenesis. Chemical weathering of feldspars is most extensive under warm, humid climate being enhanced by carbonic and organic acids.

Detrital feldspars (particularly plagioclase) are often riddled with inclusions of sericite and epidote due to hydrothermal/deuteric alteration which takes place due to the interaction of

Magma Composition	Ultramafic		Mafic	Intermediate	Felsic

	anorthite An ₉₀₋₁₀₀	bytownite An ₇₀₋₉₀	labradorite An ₅₀₋₇₀	andesine An ₃₀₋₅₀	oligoclase An ₁₀₋₃₀	albite An ₀₋₁₀
(Volcanic/ plutonic)	komatiite/ peridotite	basalt/ gabbro		andesite/ diorite		rhyolite/ granite

igneous rocks with hot fluids released during and subsequent to the final stages of magma solidification. This kind of alteration is referred to as saussuritization.

Sediments derived from tectonically stable cratons and from recycled, fold-thrust sedimentary and low-grade metamorphic rocks have consistently low contents of feldspar. Elimination of feldspars from basement rocks in cratons occurs during the prolonged weathering subsequent to exposure, long sediment transportation distance, and reworking prior to burial. Conversely, sediments enriched in feldspar and/or rock fragments are derived from the erosion of uplifted basement, such as along rifts and transform ruptures within continental crust. Such settings provide little time for chemical weathering of subaerially exposed bedrock and shorter transportation distances and reworking of the sand particles prior to final settlement and burial. Rapid sediment burial is caused by high rates of sediment supply to basins in the vicinity of uplifted areas (i.e., high rates of mechanical weathering and erosion). It is thus apparent that the types and amounts of detrital feldspars in clastic rocks provide important clues to provenance, tectonic setting of the area and climatic conditions prevailed during weathering.

Provenance of detrital feldspars

The source rock of detrital feldspar grains can be deciphered based on chemical and mineralogical zonation, chemical composition and structural state (Helmold, 1985). The chemical composition of feldspar grains is obtained by means of electron microprobe analyzes performed on thin sections. Feldspars are defined chemically based on the solid solution between three end members: albite, orthoclase, and anorthite. However, some feldspars may contain significant amounts of barium and strontium. Trevena and Nash (1981) have used the potassium content to decipher the origin of plagioclase and alkali feldspars. The potassium content of plagioclase decreases gradually from plutonic to metamorphic rocks. However, the fields of high-K volcanic and plutonic plagioclase partially overlap, and those of low-K metamorphic and plutonic plagioclase are similar. Alkali feldspars from volcanic rocks vary widely in potassium content and their molar solid-solution compositions range between $Ab_{74}An_{13}Or_{13}$ and $Ab_{12}An_1Or_{87}$. Conversely, alkali feldspars from plutonic and metamorphic rocks are K-rich, and have composition ranging from $Ab_{43}An_1Or_{56}$ to $Ab_2An_0Or_{98}$ and from $Ab_{47}An_2Or_{51}$ to $Ab_2An_0Or_{98}$, respectively. Trevena and Nash (1981) presented a ternary diagram of the molar proportion of albite, anorthite and orthoclase solid solutions in which they delineated eight provenance groups of compositional ranges of feldspars from various crystalline sources. Chemical zonation occurs in both plagioclase and alkali feldspars of volcanic and plutonic origins, whereas those of metamorphic origin are unzoned.

Parameters controlling the structural state (i.e., Si-Al disorder) of alkali feldspars in igneous rocks include the equilibration temperatures, rate of subsolidus cooling and the activity of H₂O. K-feldspars derived from volcanic sources are highly disordered structures (sanidine), whereas those derived from plutonic sources are moderately- (orthoclase) to well-ordered (microcline) structures.

Diagenetic feldspars

Diagenetic feldspars include K-feldspar and albite that are characterized by nearly stoichiometric, end-member composition (i.e., $KAlSi_3O_8$ and $NaAlSi_3O_8$, respectively) and lack of cathodoluminescence. Diagenetic K-feldspar crystals are monoclinic and, less commonly, triclinic with various degrees of Al-Si ordering, whereas diagenetic albite is well-ordered, triclinic. Authigenic buddingtonite, which is a hydrous, ammonium feldspar ($NH_4AlSi_3O_8 \cdot nH_2O$) with considerable amounts of orthoclase solid solution occurs in organic-matter rich mudstones and sandstones.

Diagenetic feldspars have three main habits: (i) overgrowths around detrital feldspars, (ii) discrete crystals that are devoid of detrital feldspar cores, and (iii) replacement of detrital feldspars by albite (albitization). Types (i) and (iii) dominate in sandstones whereas type (ii) is important both in sandstones and carbonate rocks. Types (i) and (ii) form by direct precipitation from pore waters, whereas type (iii) forms by dissolution of detrital feldspar and concomitant precipitation of diagenetic feldspar.

Feldspar overgrowths

Feldspar overgrowths are formed by precipitation of K-feldspars around detrital orthoclase and microcline (Figure F9), and of albite around detrital plagioclase. The overgrowths, particularly K-feldspar, are usually not in full optical continuity with their detrital cores. K-feldspar overgrowths do not show twinning, but albite overgrowths inherit the twinning pattern of the core.

Although K-feldspar overgrowths usually have a pure, end member composition, they may in some cases display small-scale zonation due to considerable variations in barium contents. Conversely, albite overgrowths display a pure, end-member composition and a high degree of crystal structure ordering.

K-feldspar overgrowths form mainly in continental and coastal sandstones that are enriched in detrital K-feldspars. In such sandstones meteoric waters can induce early diagenetic dissolution of detrital K-feldspars, and hence increase in the activities of K^+ , Al^{3+} , and Si^{4+} in the pore waters. Albite overgrowths dominate in sandstones rich in volcanic

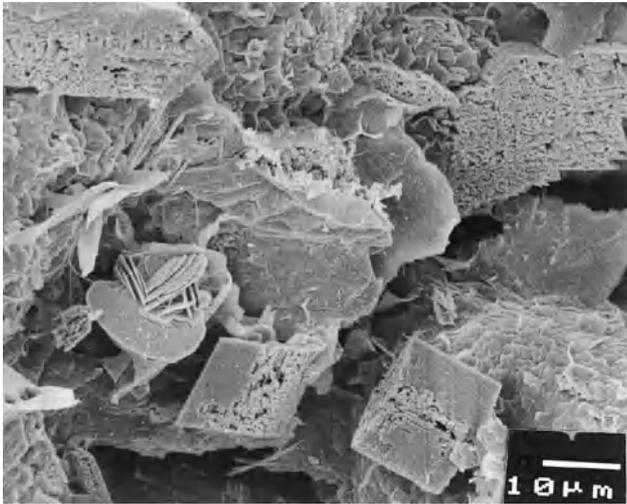

Figure F9 Scanning electron micrograph showing discrete K-feldspar crystals and K-feldspar overgrowths.

and metamorphic grains derived from magmatic and orogenic arcs.

Discrete authigenic feldspar crystals

Small, discrete (usually $<100\mu\text{m}$), untwined, authigenic K-feldspar (Figure F9) and twinned albite occur in sandstones as crystals scattered in pore space or associated with other diagenetic cements (e.g., clay minerals). Authigenic albite dominates in carbonate rocks, whereas K-feldspar dominates in sandstones (Kastner and Siever, 1979). In marine and non-marine, volcanic and volcanoclastic sediments, which are enriched in highly reactive grains (e.g., volcanic glass), discrete K-feldspar crystals may extensively fill the pore space. In saline alkaline, lacustrine environments, authigenic K-feldspar may form almost entire beds by alteration of tuffs and ash deposits.

Albitization of feldspars

During burial diagenesis and increase in temperature, detrital feldspars are transformed into chemically pure albite. The original outline of the feldspar grain is well preserved, making immediate identification of albitized feldspars difficult. Each detrital feldspar grain is replaced by numerous tiny, euhedral crystals of albite that are arranged parallel to cleavage and/or twinning planes (Figure F10), causing destruction of twinning pattern in the detrital feldspar. Hence, they can be easily mistaken for untwined feldspar, such as orthoclase. Albitization of detrital feldspar does not occur through solid-state replacement but by small-scale dissolution-reprecipitation.

The albitization of plagioclase commences at shallower burial depths (2 km) and temperatures (65°C) compared to potassium feldspars (Morad *et al.*, 1990). The higher the molar anorthite solid solution content, the more sensitive is plagioclase to albitization. Albitization consumes Si^{4+} and liberates Al^{3+} and Ca^{2+} , which often re-precipitate as kaolin

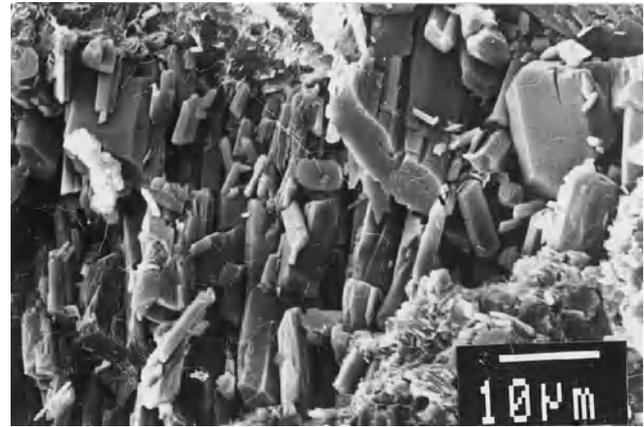

Figure F10 Scanning electron micrograph showing an albitized detrital feldspar comprised of numerous, euhedral authigenic albite crystals.

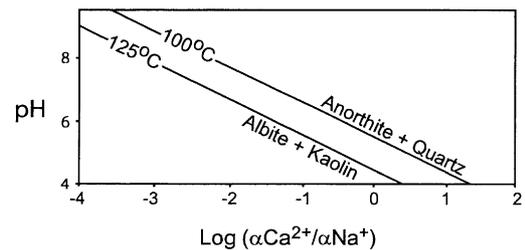

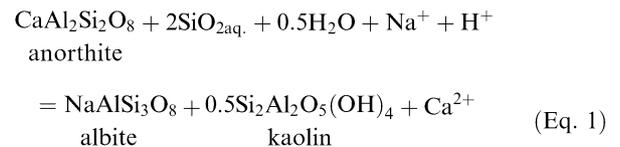

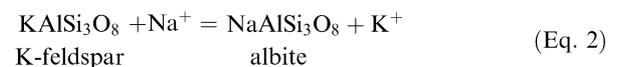

Figure F11 Equilibrium diagram showing the temperature-related plagioclase albitization (see equation 1).

and calcite, respectively, as follows:

Albitization of plagioclase is thus controlled by temperature, pH and $\text{Ca}^{2+}/\text{Na}^+$ activity ratio (Figure F11). Albitization of K-feldspar grains is strongly controlled by temperature and K^+/Na^+ activity ratio:

Importance of feldspars for reservoir quality of sandstones

Detrital feldspars exert important control on reservoir quality of sandstones in the various following ways:

(1) **Compaction:** feldspar grains contain abundant planes of weakness (cleavage and twinning planes), and hence have lower mechanical stability than quartz. Therefore, feldspar-rich sandstones undergo a more rapid and a greater degree of loss of primary porosity due to mechanical compaction than quartz-rich sandstones.

unconsolidated mud, while continued flow of the current depositing the sand produces a shear stress that results in down-flow vergence of the flames. They were formed experimentally by Kuenen and Menard (1952). Flames may also be roughly parallel to the current, forming part of the structure called “longitudinal ridges and furrows” by Dzulynski and Walton (1965, p. 66).

FLASER

Flaser bedding commonly occurs in association with lenticular and wavy bedding. All three sedimentary structures and their interrelationships are hence discussed in this section.

Definitions

Quoting Reineck and Wunderlich (1968), the Glossary of Geology (Bates and Jackson, 1987, 3rd edn.) defines the term “flaser structure” as “ripple cross-lamination in which mud streaks are preserved in the troughs but incompletely or not at all on the crests” (p. 246). The term “lenticular bedding” is defined as “a form of interbedded mud and ripple cross-laminated sand, in which the ripples or lenses are discontinuous not only in the vertical but also more or less in the horizontal direction” (p. 376), and the term “wavy bedding” as “a form of interbedded mud and ripple-cross-laminated sand, in which the mud layers overlie ripple crests and more or less fill the ripple troughs, so that the surface of the mud layer only slightly follows the concave or convex curvature of the underlying ripples (p. 734).

Origin of the terms

The term “flaser” (German word for streak) was probably borrowed from petrology where it was introduced earlier to describe streaky layers of parallel, scaly aggregates surrounding lenticular bodies of granular minerals in metamorphic rocks, giving the appearance of a crude flow structure (Bates and Jackson, 1987). In a sedimentological context the terms “flaser” and “lenticular bedding”, or rather their German equivalents, appear to have been introduced by Richter (1931).

He described sand lenses as depositional features involving sand transport by moving water (p. 314) and provided photographic evidence of fossil examples, calling the internal structure “Linsenschichtung” (lenticular bedding), adding “Flaserung” (flaser structure) in brackets (p. 317). The genesis of flaser bedding was subsequently described by Schwarz (1933, p. 102) who correctly interpreted the structure as resulting from the deposition of mud in ripple troughs which, in cross-section, produces a thin mud layer pinching out in both directions. Excellent documents of lenticular and flaser bedding structures were published by Häntzschel (1936) who systematically applied the impregnation technique invented by Schwarz (1929) to box cores from modern intertidal flats to visualize and preserve internal sedimentary structures in unconsolidated sediments (Figure F13). The term “wavy laminae” was already used by van Straaten (1951), whereas “wavy bedding” in the present context appears to have been introduced by Reineck (1960).

Genesis and classification

Flaser, lenticular, and wavy bedding structures form under conditions where periods of strong flow capable of transporting sand in bed-load alternate with periods of quiescence with little or no water movement in the presence of high concentrations of suspended matter in the water column, and

Figure F13 The first photographic document of a box-core resin cast displaying flaser structures and sand lenses draped in mud (from Häntzschel, 1936; scale added).

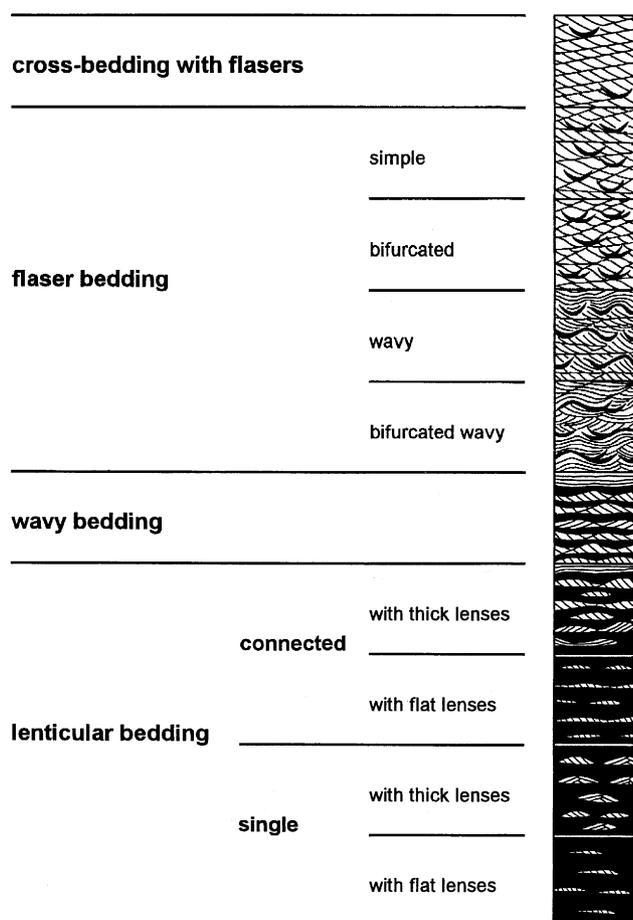

Figure F14 Composite succession illustrating the association of lenticular, wavy, and flaser bedding structures in a continuous, upward-coarsening tidal deposit (modified after Reineck and Wunderlich, 1968).

where the slack water periods are sufficiently long to allow some of the suspended matter to settle out. Although most examples documented in the literature are associated with tidal environments, the conditions are also met in a number of non-tidal environments, e.g., fluvial and deltaic (Coleman and Gagliano, 1965; Conybeare and Crook, 1968), marginal sea and continental shelf (Werner, 1968), deep sea fan (Mutti, 1977; Ricci Lucchi, 1995).

A systematic description, classification, and illustration of the variability of sedimentary structures associated with lenticular, flaser, and wavy bedding is given in Reineck and Wunderlich (1968). Four basic bedding types are distinguished, two of which are further subdivided. These are:

- lenticular bedding*: this group is subdivided into *connected* or *disconnected* (single) sand lenses which, in turn, may either be *thick* or *flat*.
- wavy bedding*: this group comprises thin, continuous mud layers which drape ripple crests while more or less filling ripple troughs, thereby assuming a wavy shape.
- flaser bedding*: this group is subdivided into (i) *simple flaser bedding*, in which the individual structures are neither in

vertical nor horizontal contact with each other; (ii) *bifurcated flaser bedding*, in which individual flasers frequently appear to split up or bifurcate because they are in contact with the remnants of an older generation of flasers which have not been completely eroded; (iii) *wavy flaser bedding*, in which individual flaser structures are frequently connected with their neighbors; (iv) *bifurcated wavy flaser bedding*, in which horizontally connected flasers show similar signs of splitting or bifurcation as described above.

- cross-bedding with flasers*: in this group, massive cross-bedded sands occasionally display isolated flaser structures.

The classification has been summarized in a composite vertical bedding succession showing the association of the various forms in a continuous, upward-coarsening tidal depositional sequence (Figure F14). Additional comments together with some excellent photographic documents are contained in Reineck and Singh (1980).

FLOCCULATION

Definition

Flocculation is the process where small particles suspended in water lump and form larger aggregates or flocs. A sediment floc consists of many small primary particles and the settling velocity of the sediment flocs normally are orders of magnitude higher than the single particles contained within the floc. There are three different processes causing aggregation of particles suspended in water. *Salt Flocculation*: clay and small silt particles are generally negatively charged because of broken bonds and isomorph substitution of the Si^{4+} ion with the Al^{3+} ion in the crystal lattice. Therefore they are surrounded by a cloud of positive ions when suspended in water, the so-called diffuse double layer. The cloud of positive ions surrounding the small particles repel each other and prevent the particles from aggregating. However, when the ionic strength of the water increases (typically where salt and fresh water mixes) an apparent compression of the double layer occurs and the particles can come so close together that the van der Waals intermolecular attractive forces dominate the electrostatic Coulombs expelling forces (van Olphen, 1963). *Bioflocculation*: in both fresh and salt water organic polymers may adsorb on the surfaces of sediment particles and bind particles together in large aggregates with high organic content (van Leussen, 1994). *Fecal pellet formation*: filter- and deposit feeders such as mussels and snails feed on fine-grained sediment particles and excrete these as fecal pellets or pseudo pellets (Edelvang and Austen, 1997). This process binds the sediment tightly together by organic glue and create very strong aggregates with characteristic shapes for different species.

Controlling processes

The formation of a sediment floc in a turbulent flow of natural water is mainly controlled by two factors. The number of sediment grains in the water and the probability that two particles collide and lump together. Number of grains are generally expressed as mass concentration and the probability of collision is mainly controlled by water turbulence, mostly expressed as the root mean square velocity gradient, (G):

$$G = \sqrt{\varepsilon/\nu}, \text{ which can also be expressed as } \quad (\text{Eq. 1})$$

$$G = \sqrt{\frac{u_f^3 [1 - z/H]}{\nu \kappa z}}$$

where: ε is turbulent dissipation rate per unit mass (Nm kg^{-1} per second), ν is the kinematic water viscosity (m^2 per second), u_f is friction velocity (m per second), z is height above the bottom (m), H is total depth (m), and κ is von Karman's constant. Collision caused by Brownian motions is unimportant in the natural environment whereas collision caused by differential settling may be important in quiescent water. Different clay minerals have different ability for flocculation, however, such specific abilities are often overshadowed by coating of the sediment surfaces by iron oxides and/or organic coatings.

Floc size, composition, strength and density

The smallest flocs are of the same size as the smallest turbulent eddies in the turbulent flowing water, the Kolmogorov micro scale. Krone (1986) defined such small flocs as zero order flocs. When zero order flocs lump together first order flocs are formed and so on. The higher the order of the floc the more water it contains and the lower the floc density becomes. But along with the growth in size floc strength decreases and eventually the floc will be broken up by turbulence and the flocculation process will start again. Therefore, floc size in any given turbulent flow is a dynamic equilibrium controlled by both sediment concentration and water turbulence. Another way of describing the floc structure is by describing its fractal dimension. It has been suggested that aggregates and flocs in suspension tends to arrange in a self-similar geometrical system. Kranenburg (1994) describes the process as follows: if the basic element of a fixed structure (e.g., a microfloc) is made up of m_1 primary particles and m_2 of these basic elements are connected in such a way that the geometric arrangement of the new elements is the same as the arrangement of the primary particles in the basic aggregate then the total number N of particles in such a fractal aggregate will be:

$$N \approx \left[\frac{R_a}{R_p} \right]^D \quad (\text{Eq. 2})$$

where R_a is the diameter of the aggregate and R_p is the diameter of the primary particle and D is the fractal dimension given by the expression:

$$D = \left[\frac{\ln m_1}{\ln m_2} \right] \quad (\text{Eq. 3})$$

where m_2 is a factor by which the aggregate size increases independent of R_a during each flocculation step similar to moving from one floc order to one higher order. Kranenburg (1994) states that the fractal dimension D can vary within the interval 1.0–2.7, where values of $D < 2$ indicates loose aggregates and values of $D > 2$ indicates more compact aggregates. Dyer and Manning (1999) found a mean value of D of 2.1 for *in situ* analyzes in the Humber estuary using the video device INSSEV, whereas Mikkelsen and Pejrup (2001) found values for coastal waters between 2.1 and 2.7 based on measurements of *in situ* floc size spectra.

Flocculation time

Because floc size is the product of a dynamic equilibrium process it must be anticipated that a characteristic time for this equilibrium to be reached exists in any given stationary turbulent flow. Few studies have been conducted on this parameter but Mikkelsen and Pejrup (2000) found *in situ* flocculation times in the order of 50 min whereas Milligan (1995) determined the time scale of flocculation to 10–15 min using a mesocosm (i.e., a part of the natural environment that has been closed off so that specific parameters can be controlled).

In situ settling velocity of sediment flocs

The settling velocity of a floc is controlled by its size, shape, and density. It is difficult to estimate *in situ* settling velocity theoretically. Therefore it must be determined by *in situ*

measurements. Such measurements were first carried out by Owen (1971) who used a 1 m long perspex tube deployed in the water to collect a water sample. The sample was taken with the tube in a horizontal position and subsequently used as a settling column raised to a vertical position. Owens experiments from the Thames for the first time suggested, that settling velocities of flocs measured *in situ* were much higher than measured in the laboratory. The so-called Owen tube has been used by numerous investigators in a slightly modified version, the BrayStoke SK 110 settling tube, as described by Pejrup (1988). Generally there is consensus that the following simple equation describe the relationship between median settling velocity and mass concentration:

$$W_{50} = a \cdot C^b \quad (\text{Eq. 4})$$

(Burt, 1986) but no generic equation has been established probably because of the omission of the parameter G and biological and mineralogical parameters.

Current investigations and state of the art

When modeling cohesive sediment transport in estuaries and harbors knowledge of the field settling velocity of the suspended flocs is extremely important. Because of the difficulties in measuring the field settling velocity of sediment flocs numerous devices have been constructed to serve this purpose. Besides many different kinds of settling tubes, video techniques have been applied to directly measure both size and settling velocity of flocs (e.g., Fennessey *et al.*, 1994; van Leussen and Cornelisse, 1996). Different techniques for measuring floc settling velocity and size are summarized and compared by Dyer *et al.* (1996) and Eisma *et al.* (1996). A new technique that has proved useful is laser diffraction and laser backscatter devices. Bale and Morris (1987) were the first to use a laser diffraction instrument *in situ*. Later devices have been improved and today *in situ* lasers are manufactured commercially. During the last few years results with especially the LISST-100 *in situ* laser have been published (e.g., Mikkelsen and Pejrup, 2000, 2001; and Agrawal and Pottsmith, 2000). An example of such *in situ* measurements of aggregate spectra are seen in Figure F15*. Mikkelsen and Pejrup (2001) furthermore suggested a method to compute mean settling velocity of a flocculated suspension from measurement of mass concentration, volume concentration and mean floc size.

Summary or conclusion

It is well-known that estuaries concentrate fine-grained sediment because of the estuarine processes settling-scour lag, tidal asymmetry, and estuarine circulation (see *Sediment Transport by Tides*). However, most of the fine sediment grains concentrated would never settle to the bottom during the short period of slack water if the field settling velocity was not increased dramatically by flocculation of the primary particles and aggregates. Therefore, the flocculation process is essential for the formation of muddy sediments in estuaries. All three forms of flocculation plays a role here but salt flocculation and pelletization are considered to be the two most important processes.

FLOODPLAIN SEDIMENTS

Introduction

Floodplain sediments are represented by a continuum of sediment types that range from clay- to gravel-size particles and include both terrigenous and organic deposits. Prior

investigations of modern floodplain deposits (e.g., Wolman and Leopold, 1957; Kesel *et al.*, 1974; Farrell, 1987; Brakenridge, 1989; Nanson and Croke, 1992; Zwolinski, 1993) provide a basis for interpreting ancient floodplains (Flores, 1981; Bridge, 1984; Platt and Keller, 1992; Kraus and Aslan, 1993; Willis and Behrensmeyer, 1994). Syntheses of modern and ancient floodplain sediments are presented in Allen (1965) and Miall (1996). The importance of floodplain sediments is two fold. First, these deposits represent economically important reservoirs of oil, natural gas, and water, and include significant coal reserves. Second, floodplain sediments provide detailed records of past and present geologic processes and continental environments.

Types of floodplain sediment

Floodplain sediments are represented by channel and overbank deposits. *Channel deposits* are dominated by coarse-grained sediments such as sand and gravel. The major exception to this generalization are abandoned channel fills, which are often fine grained (Fisk, 1947). *Overbank deposits* are fine grained and consist primarily of clay, silt, and lesser amounts of sand. Organic sediments are also important constituents in some settings (Flores, 1981). Previous workers have referred to channel and overbank sediments as substratum and topstratum deposits, respectively (Allen, 1965). Although overbank sediments have received considerably less attention than channel deposits (Farrell, 1987), studies of paleosols have significantly increased interest in overbank environments (Kraus, 1999).

Channel deposits

Channel deposits consist of channel-bar and channel-fill sediments. Channel-bar sediments are typically represented by stratified sands and gravels and accumulate in response to river migration and changes in stream hydrology. Channel fills range from coarse-grained (active) to fine-grained (passive) deposits. Active fills are represented by interbedded sand and silt that accumulates in response to gradual channel abandonment by chute cutoff or similar processes. Passive fills consist of silt and clay or organic sediments that are deposited within lakes or oxbows formed by neck cutoff (Fisk, 1947). More detailed treatments of channel deposits are found elsewhere (see Cross-references).

Overbank deposits

Overbank sediments accumulate during floods in natural-levee, crevasse-splay, and flood-basin environments. Modern and ancient examples of overbank deposits are numerous (cf. Gersib and McCabe, 1981; Bridge, 1984; Smith *et al.*, 1989; Aslan and Autin, 1999). Classifications of these deposits are presented in Platt and Keller (1992) and Miall (1996). Although overbank deposits are sometimes viewed as monotonous sequences of fine-grained alluvium, the recognition of paleosols in ancient overbank sediments has proved useful for subdividing and interpreting these deposits (Kraus, 1999). Analyses of modern Rhine-Meuse overbank sediment show that these deposits can be subdivided statistically, and that floodplain heterogeneity is closely linked to channel pattern (Weerts and Bierkens, 1993).

Natural-levee sediments

Natural levees are represented by wedges of sand, silt, and clay that typically thin and fine away from channel margins. Natural levees have widths of 2 to 3 km and are up to 5 m thick. These features are best developed along the outer bends of meanders in low-gradient sinuous rivers with large suspended-sediment loads such as the Mississippi. Natural-levee sediments are represented by rhythmically bedded sand and silt with lesser amounts of clay (Farrell, 1987). Sedimentary structures include ripple lamination. In proximal levee settings, beds are up to 1 m thick whereas distal positions contain thinner beds, and beds are typically disrupted by bioturbation. In ancient floodplain settings, natural-levee deposits consist of packages of interbedded fine sandstone, siltstone, and mudrock that commonly overlie channel-belt sandstones (Kraus, 1999).

Crevasse-channel and crevasse-splay sediments

Crevasse splays are tabular to lenticular accumulations of sand and silt that accumulate in floodplain depressions such as wetlands. In plan view, crevasse splays are lobate to sinuous and contain distributary channel networks that extend up to 10 km into flood basins (Smith, 1986; Smith *et al.*, 1989). Crevasse-channel deposits are typically lenticular, sandy, and coarser-grained than other types of overbank sediments. However, fine-grained crevasse-channel fills also occur (Smith and Perez-Arlucea, 1994). Stratification types include small-scale trough-cross-bedding and ripple lamination.

Crevasse-splay deposits are tabular sheets of interbedded sand and silt with lesser amounts of clay that are <10 m thick. Deposits thin or thicken away from channel margins depending on local floodplain topography (Willis and Behrensmeyer, 1994). Strata are commonly bioturbated and ripple laminated (Farrell, 1987). Individual splays show either upward-coarsening or upward-fining sequences (Smith and Perez-Arlucea, 1994). Upward-coarsening sequences reflect crevasse-splay progradation whereas deposition of overbank fines during waning flood stages produces upward-fining deposits. Crevasse-splay deposition is particularly important within avulsion belts (*sensu* Smith *et al.*, 1989) because this process causes rapid fine-grained floodplain aggradation.

Flood-basin sediments

Tabular deposits of clay, silt, and organic sediment fill flood-basin depressions. In large river systems such as the Mississippi, flood-basin sediments are up to 40 m thick, encase channel sand bodies, and interfinger with crevasse-splay and natural-levee deposits (Aslan and Autin, 1999). These deposits can extend along valley axes for hundreds of kilometers. Slow sediment accumulation rates in flood basins favor bioturbation and soil development. Shallow fluctuating water levels and large amounts of organic matter produce gray sediment colors and brown or red iron-oxide mottles. Authigenic minerals such as iron and manganese oxides, calcite, gypsum, pyrite, vivianite, and jarosite are also common. In settings where water levels fluctuate seasonally and smectitic clays are present, pedogenic slickensides are abundant. In contrast, perennial saturation and low amounts of clastic input leads to widespread peat and coal formation (Flores, 1981).

Summary

Floodplain sediments provide records of terrestrial environments that are essential for deciphering continental sedimentary rocks. These sediments are also important for evaluating petroleum, coal, and water resources. Future lines of potentially fruitful research include: (1) further evaluation of the influence of avulsion on floodplain construction; (2) quantification of relationships between flood hydrology and floodplain stratigraphy; and (3) continued study of overbank deposits and paleosols. This latter effort may be particularly important because fine-grained floodplain deposits are less studied than sands and gravels, yet overbank sediments volumetrically dominate many ancient alluvial sequences.

FLOODS AND OTHER CATASTROPHIC EVENTS

Floods occur when the stage of water flow exceeds some level, commonly marked by the banks of the stream or river that usually confine the level of flow. What one considers to be a flood is a notion very much limited by human experience, in which observations occur over days, months, or some rather short period of years. In contrast, the timescales of the natural world operate over centuries, millennia, and much longer time periods. When the time scale is enlarged, then the rare occurrence of an extreme flood event can yield magnitudes that seem bizarre relative to the observations made on shorter timescales. The concern of this article will be with those floods that are both rare and of great magnitude. Smaller, common floods are usually considered to be a part of the average process regime of rivers, though lying on the upper tail of the frequency distribution for flow events.

Extreme flood phenomena defy direct measurement in the field. Their recurrence intervals can greatly exceed the life spans of potential human observers. Even when very rare, extreme floods do occur, measurements of flow phenomena and sediment transport are not made because of: (1) difficulties in accessing measurement sites or inserting measurement equipment during conditions of extreme danger; and (2) destruction of any in-place measurement devices because of the intensity of the flow processes. The resulting lack of quantitative data, so essential for the testing of models for physical processes, may explain why catastrophic flood phenomena have received relatively little attention in fluvial studies.

What is a catastrophic flood?

To be considered catastrophic a flood must possess a combination of rare occurrence and very great intensity of operation. Flood processes have probably been most intensively studied for low-energy intensity, alluvial streams. The latter have channel beds and banks that are composed of the same types of sediment that they convey in transport.

Moreover, fluvial geomorphological studies in the 1950s and 1960s firmly established that the intensity of process operation, usually measured as stream power per unit area of bed, is actually adjusted to moderate, optimal values by the morphological response of channels and floodplains. Downstream channel evolution is directly related to an upstream drainage basin in which a network of contributory channels is optimally adjusted to rainfall-runoff conditions and to prevailing rock types. Such rivers are the self-adjusted authors of their own geometries (paraphrasing a quip by Luna Leopold and Walter Langbein).

These considerations do not apply to the less-studied, high-energy processes that can occur during extreme floods in bedrock channel situations. Moreover, there are causes that are much more rare and extreme than the usual rainfall-runoff processes of contributory drainage basins. These causes include the failure of landslide and glacial dams, the cutting of huge spillways by the overflowing of immense ice-marginal lakes, volcano-ice processes, and even the spilling of huge waves across the land. Especially intense, rare rainfall-runoff process from tropical storms or local thunderstorms may also yield catastrophic responses. Thus, catastrophic flooding can be characterized first by rarity, both in the temporal distribution of occurrence and/or in the unusual or observationally unprecedented nature of occurrence or causation. Second, the catastrophic flood should display an intensity of operative processes. This may be quantified in terms of velocity, bed shear stress, or stream power, though the real measure of catastrophe is the impact of the processes on landscape. When the flood generates spectacular effects of erosion and sedimentation that are similarly rare or unusual, then it is readily designated catastrophic. Finally, the human context can designate as catastrophic any flood that produces especially great loss of life or damage to property. That the rare or unusual floods of immense intensity are also less readily anticipated means that there is some overlap of the natural and human contexts of catastrophe. Of course, this overlap leads to some practical applications for the science.

Historical and philosophical perspective

When the terms were first introduced in 1832 by the polymath William Whewell, there was a clear distinction between “catastrophists” and “uniformitarians”. The former maintained or accepted that certain geological or biological phenomena are caused by sudden and violent disturbances of nature. The latter maintained that phenomena have always been and still are due to causes or forces operating continuously or uniformly in time. (The obvious corollary being that the causes or forces operative in the past are in continuous operation today and therefore accessible to current observation and study.) Thus, both scientific camps, as originally defined, made substantive claims about the world that could presumably be scientifically tested. Unfortunately, the original distinction became confused through advocacy by Sir Charles Lyell, who promoted “uniformitarianism” as a presumed basis for sound methodological reasoning in geology (Baker, 1998). One does not test a metaphysical claim as to how science is to be done; one either follows its precepts or one does not.

The substantive notion of past catastrophic events of causal character not readily observable in operation today has been thoroughly confirmed by scientific study subsequent to Whewell’s original definition of the problem. That it took so

long to achieve this recognition is illustrated by the great scablands debate of the 1920s. The debate began when Bretz (1923) described landforms in the Channeled Scabland region of Washington state that required cataclysmic flooding for their origin. Blindly applying Lyell’s methodological uniformitarianism, a great many geologists rose in sharp criticism of Bretz’s hypothesis (Baker, 1978). The resolution of the debate did not come until the 1960s and 1970s, when distinctive bedforms (giant current ripples) were documented, and quantitative methods showed the physical consistency of the cataclysmic flooding hypothesis (Baker, 1973). Of course, numerous other examples of catastrophic geological processes have also been documented, most notably the effects of meteor impacts and extremely large, explosive volcanic eruptions. We can now look upon the catastrophist versus uniformitarianist debates with hindsight: “...the paleocatastrophists of the early 19th century seem not to have been so much the bad chaps in the black hats, at war with the white knights of the uniformitarian camp, as they were precursors of today’s neocatastrophists” (Albritton, 1989, p. 177).

While the great scablands debate of the 1920s and 1930s opened awareness to catastrophic flooding as a geological agent, its resolution in the 1970s coincided with another important stimulus that was also a remarkable surprise. The discovery of immense flood channels on Mars in the 1970s (Baker, 1978) spread awareness of catastrophic flooding as a process of significance at the planetary scale. The Martian outflow channels were produced by the largest known flood discharges, and their erosional and depositional effects have been preserved for billions of years. In addition, the past 30 years has seen the recognition of evidence for great cataclysmic flows from spillways and ice-dammed lake failures in the basins of many of the world’s great river systems, including the Columbia, Yukon, Mackenzie, Mississippi, St. Lawrence, Irtysh, Ob, Yenesei, Lena, and Amur (Baker, 2002).

Flood dynamics and processes

Paleohydraulic calculations

Because of difficulties in the direct measurement of on-going processes, physical understanding of high-energy megaflooding has only been possible through the use of quantitative models applied inversely to the calculation of paleodischarges and other parameters, given preserved or inferred flow geometries. Computer flow models compute energy-balanced water-surface profiles for steady, gradually-varied flow on the basis of a form of the Bernoulli Equation in conjunction with the step-backwater method of profile computation. For application to catastrophic flood channel geometries, various water-surface profiles are computed with different combinations of discharge and energy loss coefficients until a profile is achieved that closely matches the water-surface profile suggested by field evidence of the past flow (O’Connor and Baker, 1992).

Based on paleohydraulic studies, the properties of past cataclysmic floods can be compared to the flow processes in modern rivers. Table F1 compares the hydraulic parameters for various catastrophic paleofloods with flooding on the largest alluvial river on Earth, the Amazon, and with flooding in a narrow, deep bedrock gorge, the Katherine Gorge of northern Australia. Note that slopes and flow depths for the ancient catastrophic floods, both on Earth and Mars, are much

Table F1 Paleohydraulic parameters for various cataclysmic flood channelways in comparison to a large alluvial river (Amazon) and a small bedrock gorge (Katherine River, Australia)

Location	Width (km)	Depth (m)	Velocity (m/s)	Discharge (m ³ s ⁻¹)	Slope	Bed shear stress (Nm ⁻²)	Power per unit area (Wm ⁻²)
Amazon	2	60	2	3 × 10 ⁵	1 × 10 ⁻⁵	6	12
Katherine Gorge	0.05	45	7.5	6 × 10	3 × 10 ⁻³	1.5 × 10 ³	1 × 10 ⁴
Missoula Flood	6	150	25	2 × 10 ⁷	0.01	1 × 10 ⁴	2 × 10 ⁵
Altai Flood (Chuja)	2.5	400	25	2 × 10 ⁷	0.01	4 × 10 ⁴	1 × 10 ⁶
Maja Vallis (Mars)	80	100	38	3 × 10 ⁸	0.02	2 × 10 ⁴	8 × 10 ⁵
Kasei Vallis (Mars)	80	400–1,300	30–75	1–2 × 10 ⁹	0.01	1 × 10 ⁵	3 × 10 ⁶

larger than for the modern Amazon River. Despite its rather large discharge, the Amazon has flow velocities, bed shear stress values, and stream power per unit area values that are in a similar range to all alluvial rivers. The cataclysmic flood features of very deep, high-gradient flows are generated by power values many orders of magnitude larger than those characteristic of alluvial rivers. Nevertheless, local bedrock gorges, such as that of the Katherine River, may experience modern high-energy conditions, somewhat comparable to those of the ancient catastrophic floods.

Flow dynamics

The enormous velocities achieved in high-energy floods (Table F1) leads to reduced absolute pressure in the flowing water, reaching the vapor pressure. Shock waves produced by the collapse of the vapor bubbles that form in such situations can produce intense erosion of rock, a process called *cavitation*. Another fundamental characteristic of such flows is the development of secondary circulation, flow separation, and the birth and decay of vorticity around obstacles and along irregular flow boundaries. Collectively known as *macroturbulence*, this three-dimensional flow phenomenon is poorly understood in theoretical terms. Immense pressure and velocity gradients in the turbulent vortices can produce phenomenal hydraulic lift forces. The most intense development of macroturbulence occurs during the following conditions: (1) a steep energy gradient and great flow depth; (2) a low ratio of sediment transported to potential sediment transport; and (3) irregular, rough flow boundaries optimal for generating flow separation. Macroturbulent processes are best evidenced in the erosional forms of bedrock rivers that experience extreme floods. The forms include longitudinal grooves, potholes, and inner channels that reflect the evolution interaction between the flow dynamics and the bedrock flow boundary.

Sediment transport

Boulder transport by large floods is well-documented (Costa, 1983). Many observations show that in very high-energy floods the boulders move in suspension, probably buoyed by the macroturbulent forces described above. At the energy levels of catastrophic floods the usual distinctions of bed-load, suspended load, and washload occur at much coarser grain sizes than in common river flows. Komar (1980) analyzed

criteria for these distinctions, and O'Connor (1993) extended the relationships further for the analysis of catastrophic floods. At sustained bed shear stresses of 1,000 Nm⁻² particles as large as 10 cm to 20 cm move in suspension, and coarse sand moves as washload. From the values in Table F1 it can be seen that even more extremes can occur in catastrophic floods, resulting in larger sizes moving in the various modes of transport.

Depositional forms and structures

Much of the evidence for the past occurrence of catastrophic floods is erosional, particularly for the bedrock-controlled settings of the floods. However, local depositional environments occur even within otherwise high-energy settings. This is possible because of the flow-separation effects noted earlier. While such deposits have little potential for long-term geological preservation in the sedimentary record, their study can be of great importance for understanding the flood dynamics and for hazard studies related to more recent flood regimes. The impact of catastrophic floods beyond the bedrock reaches may be best appreciated by studies of sedimentation in nearby continental or marine basins.

Large-scale patterns

The megafloods associated with the last glaciation show a pattern of spilling between tectonic basins. High-energy flows and erosional environments are generally confined to areas of cross-axial drainage across mountain or other uplands. Depositional environments, including very large fan complexes, occur in the tectonic basins that separate the mountain areas. Examples of this pattern can be found in the tectonic basins of the central Columbia Plateau region, impacted by Missoula Flooding (Baker, 1981), and in the upper Yenesei Valley of central Asia.

The role of catastrophic flooding has been documented for several large-scale submarine fans. In the Iceland Basin of the northern Atlantic the Maury Fan is dominated by turbidites that were emplaced by large Icelandic jokulhlaups (Lacasse *et al.*, 1998). The turbidites all consist of monolithologic glass volcanic glass shards produced by the subglacial volcanic eruptions of the source area. Long-distance submarine effects of catastrophic flooding are also documented for the Missoula Floods, which generated hyperpycnal gravity flows that induced turbidity currents flowing across 1,000 km of the Pacific Ocean floor from sources at the head of the Astoria Fan

(Zuffa *et al.*, 2000). It is likely that many fans, particularly those fed from tectonically active basins, show the influence of catastrophic flooding (Mutti *et al.*, 1996).

Bedforms

A classification of bedforms for catastrophic flood channels is shown in Table F2. This classification was developed for features studied in the Chaneled Scabland (Baker, 1981) and in the Altai of central Asia (Rudoy and Baker, 1993). The classification relates macroforms to flow width such that local flow conditions are not the primary factors in their origin. These forms persist through multiple flood events, and may show complex internal evidence of such a history. In contrast, mesoforms respond to the dynamics of an individual flow, and are scaled to the channel depth. The classification includes erosional forms, both those scoured in rock and those scoured in sediment, and depositional forms. The discussion here will emphasize the latter.

Longitudinal bars are elongated parallel to the flow direction. They may form at local flow expansions or they

may develop because of flow separations near the channel walls. Often such separations alternate in a downstream direction. They may also form as pendant bars, downstream of an obstruction in the bed of the flood channel. At the mouths of tributaries and other zones of dead water relative to the high-velocity flood channel, eddy bars may develop (Figure F16). In narrow, deep flood channels these various bars tend to be high and mounded. The great flood bars of the Chuya River valley have a sedimentary thickness of nearly 200 m. They consist of thick foreset beds of coarse sand and gravel that was carried in suspension in the main flood channel.

Large-scale transverse gravel ripples were recognized in the Chaneled Scabland (Figure F17), and their study contributed to the general acceptance of the catastrophic flood origin of that landscape (Baker, 1973, 1981). Although they were first named “giant current ripples” by J Harlen Bretz in his now-classic studies, their size and hydraulic relationships indicate that they are best classified as fluvial dunes (Baker, 1973). Nevertheless, the original name is often retained for historical reasons. In both the Chaneled Scabland and in central Asia,

Table F2 Cataclysmic flood landform assemblage (Earth and Mars)

Scale	Eroded in rock	Eroded in sediment	Depositional
Macroforms (Scaled to width)	Anastomosing pattern	Streamlined hills	Alternate bars Expansion bars Fans Pendant bars Eddy bars
Mesoforms (Scaled to depth)	Longitudinal grooves Butte-and-basin topography Inner channels Cataracts Potholes	Scour marks	Giant current Ripples (Dunes, Gravel waves)

Figure F16 Large eddy bar at the mouth of a tributary canyon along the Flathead River, Perma, Montana. The bar formed during the rapid late Pleistocene drainage of glacial Lake Missoula (Baker, 1973) as high-energy flood water moved from right to left in the main channel. Gravel in suspension in the channel was rapidly deposited in the slack-water zone of the tributary mouth to create the bar. Very similar bars were produced by late Pleistocene glacial outburst floods in the Altai Mountains of Siberia (Rudoy and Baker, 1993).

Figure F17 Giant current ripples (dunes) near Marlin, Washington. These gravel bedforms have average heights of 6 m and average spacings of 60 m (Baker, 1973). They occur on the divide between two preflood creek valleys, thereby illustrating the immense scale of the responsible late Pleistocene cataclysmic flooding.

the giant current ripples range in spacing from about 30 m to 200 m and are composed of pebble and cobble gravel. Internally they consist of foreset-bedded gravel dipping at angles of about 20° to 30°. They are generally superimposed on longitudinal, alternate bars or on expansion bars. Trains of giant current ripples as much as 10 km or 15 km long are found in parts of the Chaneled Scabland, and also in the Altai and Tuva regions of central Asia. Bedform dimensions have been related to hydraulic factors for both these areas (Baker, 1973; Carling, 1996).

Slack-water deposits

Slack-water sediments accumulate in areas marginal to main channelways, such as in the mouths of backflooded tributary valleys or in alcoves along channel margins. The sediments derive from the rapid fall of suspended coarse particles, usually sand and gravel, as these materials move from the high-velocity main thread of flow into the marginal zones of slack water. Because such deposits can be emplaced at high elevation, up to the level of the peak flood stage, they can serve as indicators of that stage. Moreover, their sequence of emplacement can reveal the history of flood events, especially when they are preserved in the low-energy flow environments marginal to main catastrophic floodways. This situation was recognized in the Chaneled Scabland region (Baker, 1973). There, the slack-water deposits display a great variety of sedimentary structures and stratigraphic relationships that can be used to infer aspects of the flood dynamics and history (Smith, 1993).

Paleoflood hydrology

Although its name was not introduced until 1982 (Kochel and Baker, 1982), the science of paleoflood hydrology has its origin in a century of geological studies of past floods. Using the experience from studies of the Chaneled Scabland flooding (Baker, 1973), it was found that similar methods of paleoflood reconstruction could be applied to late Holocene paleofloods, thereby extending discharge records used in flood hazard evaluation (Baker, 1987). In essence, paleoflood hydrology relies upon studies of those rivers that are, "...chroniclers of their own cataclysms" (Baker and Pickup, 1987). A wide variety of paleostage indicators are used to determine past flood magnitudes, but the study of flood slack-water deposits are especially important, given their preservation of the time sequence of past floods. The sequence of paleoflood magnitudes and their temporal distribution can be used to evaluate the flood-frequency estimates that assign risk to various hazardous sites or structures (House *et al.*, 2002).

Floods on Mars

The ancient floods of Mars are inferred from features recognized in terrestrial catastrophic flood channels, such as the Chaneled Scabland (Baker, 1982). The flows emanated from collapse zones or fractures at the heads of the flood-scoured troughs. Many of the largest such "outflow channels" surround the Tharsis volcanic province of Mars, an immense plateau of volcanic rocks, cut by a huge rift-related canyon system, the Valles Marineris. The flooding was likely genetically related to the volcanism, and its occurrence is related to the formation of extensive areas of ponded water

and associated climate change on a planet that is otherwise extremely cold and dry (Baker, 2001).

Continuing controversies

Giant wave deposits

Recent work on the possible action of giant waves along coastlines has documented a sequence of erosional and depositional landforms with considerable similarity to those described for catastrophic flooding in areas like the Chaneled Scabland (Bryant, 2001). The giant waves are presumed to be tsunami or direct splash effects of meteor impacts into the ocean. Such impacts on geological timescales that would lead to preserved effects are highly likely, given knowledge of impact frequencies on Earth. The best examples of the boulder deposits, streamlined deposits, and various erosional forms are documented along tectonically stable coastlines, like those of Australia (Bryant, 2001). However, the mechanics of the processes for generating these phenomena are not well understood, and the regional importance of such features is still a matter of on-going investigation.

Subglacial flooding

The landforms that develop beneath thick continental glaciers have long been controversial for their genesis. As in the catastrophic flooding problem, the modern analogs (modern glaciers) do not provide satisfactory information on the ancient ice sheets. During the glacial maxima of the Quaternary, the great ice sheets of North America, Eurasia, and Antarctica were warm based and associated with very large amounts of meltwater along their margins. Shaw (1996) developed a model that envisions a whole sequence of erosional/depositional processes beneath these ice sheets, particularly cataclysmic flooding of magnitudes comparable to those illustrated in Table F1 (10^7 m^3 per second). The flooding produces all the distinctive subglacial landforms, including drumlins, tunnel valleys, bedrock erosional marks, and Rogen moraines. The drumlins and Rogen moraines are generated by deposition into cavities formed on the sole of ice sheet by flood erosion. There is considerable controversy over this model (Benn and Evans, 1998), but its continuing testing against field evidence is leading to discovery of overall coherence in erosional and depositional features produced under the ancient ice sheets. The consistency of some of Shaw's documented patterns with those displayed by recognized catastrophic flooding is one of the major arguments in favor of this hypothesis.

Central Asia

During the Pleistocene glaciations the large, north-flowing Siberian rivers were dammed by ice sheets situated on the shelf areas of northern Eurasia. The resulting inundation produced spillways that carried flows southward to the present-day basins of the Aral, Caspian, and Black Seas. Additionally, these flows were augmented by the huge floods of ice-dammed lake bursts from the mountain regions of central Asia (Baker, 1997). A system of huge spillways connected the various elements of this system, which may temporarily have comprised the largest drainage basin on the planet. In a study of linear erosional and depositional features, visible on satellite

imagery and extending across divides through central Asia, Grosswald (1999) proposed the provocative hypothesis that immense volumes of water were conveyed from the margins of the great northern ice sheets. The flows were so great that they not only inundated the spillways, but also flowed across divides in a flow width of hundreds of kilometers. The mechanism for this water burst is the pressurized release of water from underneath the northern ice sheets, which are thought to have formed a circumpolar dam of arctic ocean water and subglacial water storage.

Noah's flood?

Based mainly on evidence for the transition from freshwater to marine conditions in the Black Sea basin, Ryan *et al.* (1997) proposed a catastrophic inflow of Mediterranean water through the Bosphorus about 7.5 ka. In subsequent popular accounts this inundation, estimated to have occurred in less than 2 years, was linked to the biblical flood of Noah. However, a climbing delta, dated at 10 ka to 9 ka, indicates that freshwater outflow from the Bosphorus was occurring prior to the presumed catastrophic flooding episode (Aksu *et al.*, 2002). If these observations are correct then the Bosphorus could not have passed later Holocene cataclysmic flood flows that would have removed these sediments. This issue is not completely resolved, but it illustrates the difficulty (and the controversies) that commonly surround catastrophic flood investigations. Moreover, it shows the importance of marshalling many diverse lines of evidence in support and any catastrophic flooding hypothesis.

Conclusions

Despite considerable controversy in their early study, the distinctive erosional and sedimentary features of catastrophic superfloods are now well-known. They include scabland erosion, streamlining of residual uplands, large-scale scour around obstacles, depositional bars, giant current ripples, and huge sediment fans. Moreover, the sequence of paleoflood events can be inferred from study of the deposition in bars and in slack-water areas marginal to the high-energy flood channelways. Further opportunities exist for study of catastrophic flood sequences in the deposits of both continental and marine sedimentary basins. For paleofloods of less intense magnitude, occurring in time frames closer to those of probable human hazard, the science of paleoflood hydrology has arisen to generate flood risk information from the geological evidence of past floods.

FLOW RESISTANCE

Introduction

Flow of any real viscous fluid (such as water or air) results in energy dissipation because the fluid must do work to overcome resistance due to fluid viscosity. This resistance produces an “energy loss” that must often be determined when computing water levels and velocity. (Note that the term energy loss is a convenient way to refer to the energy that is dissipated as turbulence or heat.)

Resistance develops in the presence of a velocity gradient, and can be likened to a shear stress acting between adjacent layers sliding overtop one another (Figure F18). Shear stress, τ , develops at the interface between adjacent layers, which are moving at different relative velocities. In open channel flow, the velocity gradient (Figure F18(A)) and the shear stress, τ (Figure F18(B)) usually originate at a solid boundary, such as the bed or banks of a river or stream. The shear stress within the fluid, τ , typically varies linearly from a maximum at the boundary, where τ equals the boundary shear stress τ_0 , to zero at the free surface. Flow resistance and shear stress can also develop at the interface between bodies of fluid moving at different velocities such as the interface between overbank and in-channel flow, at river confluences, and along the interface of ocean and air currents.

Viscosity that gives rise to flow resistance can be either laminar or turbulent depending upon the value of the flow Reynolds Number, $R = VD/\nu$, in which V = mean velocity, D = depth of flow, and ν = kinematic viscosity. For a wide channel or sheet flow, the fluid will remain laminar for values of R up to about 500. For Newtonian fluids such as water,

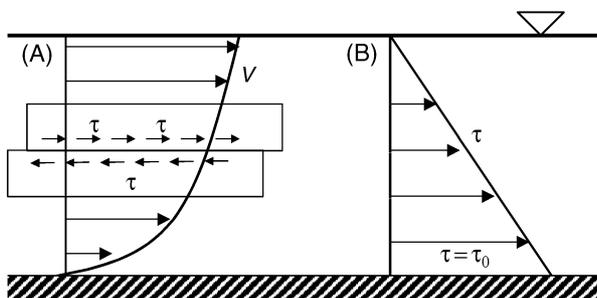

Figure F18 (A) Velocity gradient and (B) shear stress in open-channel flow.

laminar viscosity is strictly a property of the fluid. For values of $R > 2,000$ flow becomes turbulent. For values of R between 500 and 2,000, the flow is transitional between laminar and turbulent. Turbulent or eddy viscosity is not only a fluid property, but varies with velocity gradient, distance from the boundary, and other flow conditions. Because the turbulent viscosity is related in part to flow properties, and flow properties are influenced by fluid viscosity, it remains exceedingly difficult to fully describe turbulent fluid flow and the resulting flow resistance.

General theory

A common requirement in fluvial geomorphology or river hydraulics is estimation of flow resistance based on the mean velocity V . Several equations are available, of which the Darcy equation is most common:

$$f = \frac{8gDS}{V^2} \quad (\text{Eq. 1})$$

in which f = friction factor, which is a coefficient of flow resistance; g = gravitational acceleration; D = flow depth; and S = slope of the energy grade line. Equation 1 applies to wide channels where the contribution of the banks can be neglected. For narrow channels, closed conduits or pipes, the hydraulic radius R should be used in place of D .

For laminar flow it has been determined experimentally that $f = 64/R$, which when substituted into equation 1 yields a form of the Hagan-Poiseuille law:

$$V = \frac{gD^2S}{64\nu} \quad (\text{Eq. 2})$$

In practice, equation 2 is generally limited to very shallow and/or slow moving flows, such as overland sheet flow, or where the fluid is highly viscous, as in the case of some mud and debris flows (see *Debris Flow*).

Typical flow in rivers and streams and other open channels is usually described as fully-rough turbulent flow in which $R > 2000$, and f is independent of R . In fully-rough turbulent flow, the flow resistance is dependent only on the relative boundary roughness D/k_s , as in the well-known Keulegan equation (Keulegan, 1938):

$$\frac{1}{\sqrt{f}} = 2.03 \log \left(\frac{12.2D}{k_s} \right) \quad (\text{Eq. 3})$$

where k_s = equivalent sand roughness, and was originally defined as the diameter of the sand grains used to roughen pipe walls during early flow resistance experiments (Nikuradse, 1933). The Manning roughness coefficient, n , is also used as a measure of boundary roughness.

In flow over alluvial boundaries hydraulic roughness can occur at a range of scales from individual grains, to clusters of grains, bedforms such as ripples and dunes, to bars, meanders and other planform variables. Vegetation and large woody debris can also contribute significantly to flow resistance. It is commonly assumed that resistance can be divided or partitioned into individual components (e.g., Millar, 1999):

$$f = f' + f'' + f''' + \dots + f^n \quad (\text{Eq. 4})$$

where f' , f'' , ..., f^n represent contributions of the different components of the total resistance. In practice the term f' is

often referred to as the “grain” component due to the flow resistance that develops from the roughness of the grains on the bed. The additional components are collectively referred to as the “form” component that is due to bedforms, bars, vegetation, etc. (Einstein and Barbarossa, 1952).

Where these additional roughness elements exist, it may be difficult or even questionable to express the hydraulic roughness in terms of k_s or n . In some instances, k_s may actually exceed D . Nonetheless, the value of k_s is often assumed to be approximately equal to some multiplier times a characteristic grain diameter, such as $6.8D_{50}$ or $3.5D_{84}$ for gravel-bed rivers (Bray, 1982).

Flow resistance is directly related to the boundary shear stress by:

$$\tau_0 = \frac{f}{8} \rho V^2 \quad (\text{Eq. 5})$$

The boundary shear stress can also be partitioned into components (e.g., Buffington and Montgomery, 1999):

$$\tau = \tau' + \tau'' + \tau''' + \dots + \tau^n \quad (\text{Eq. 6})$$

where the terms τ' , τ'' , ..., τ^n represent the component of the total shear stress acting on different roughness elements. As with the resistance, the τ' term usually denotes the grain component. The value of τ' can be calculated by substituting f' into equation 6. Several bed material transport theories are formulated on the assumption that it is only the grain shear τ' that contributes to transport, a concept first proposed by Einstein (1950).

The preceding discussion considers the most common application of flow resistance, where a fully developed boundary layer (Schlichting, 1979) extends from the solid boundary to the surface. This is sufficient to describe steady flow in rivers, streams and other open channels, for currents in relatively shallow water ($D < 25$ m), sheet flow across surfaces, and flow in closed conduits or pipes. It is also adequate to describe moderately unsteady flows such as passage of a flood wave along a river, or tidally-forced currents.

For oscillatory flows due to ocean gravity waves, the flow resistance, f_w , can be expressed as:

$$f_w = \frac{2\tau_0}{\rho u_b |u_b|} \quad (\text{Eq. 7})$$

where u_b = bottom orbital velocity (Raudkivi, 1998, 327).

Measurement and prediction of flow resistance

There is no simple direct measurement of flow resistance or hydraulic roughness. Values of f , k_s , or n must in general be back calculated using measured values of V , D , and S , or obtained through model calibration. Different values of the coefficients will be associated with different model formulations. For instance, one-dimensional (1D) and 2D or 3D models will yield different values of f or n , even when calibrated using the same data. This is because in a 1D formulation, f or n are used to account for all resistance components. 2D and 3D models typically yield lower values for the resistance coefficients because eddy losses and other form components are better simulated by the physics of the model.

There remains considerable uncertainty associated with predictions of flow resistance in ungauged rivers and streams (Millar, 1999). In particular, the contributions of bank vegetation (Darby, 1999), nonemergent vegetation (Lopez

and Garcia, 2001), gravel bars, riffles and cluster bedforms (Lawless and Roberts, 2001) have yet to be quantified adequately. An ongoing research effort is directed toward understanding and predicting resistance due to interactions between overbank and in-channel flow in compound channels (Lyness *et al.*, 2001).

FLUID ESCAPE STRUCTURES

Fluid escape structures are sedimentary structures that form during the escape of pore fluids from loose, unconsolidated

sediments. Most are postdepositional in origin, but some, including convolute lamination, can form during sedimentation. Fluid escape structures may represent modified primary sedimentary structures, modifications of previously formed postdepositional structures, or entirely new structures. Deformation may result directly from: (1) pore-fluid movement; (2) current-induced shear; or (3) gravity forces acting on density contrasts within low-strength liquefied sediments. In most cases, the pore fluid is water, and the resulting structures are water-escape structures. However, gas escape structures can form within sediments deposited by dry pyroclastic flows (Cas and Wright, 1987). In general, fluid escape structures are most common in rapidly deposited, poorly sorted, fine- to medium-grained sands and less common in more slowly deposited, coarser- and finer-grained, and texturally mature deposits.

Processes of fluid escape

The development of denser packing due to rearrangement of sediment grains accompanied by fluid expulsion from a loosely-packed sediment is called consolidation. Fluid escaping from sediments during consolidation can interact with the sedimentary grains in four ways: seepage, liquefaction, fluidization, and elutriation.

Seepage

When the escaping pore fluids have low velocities, the rearrangement of grains takes place slowly, most grain-to-grain contacts are preserved, and even the hydraulically fine grains remain largely unaffected. This fluid escape process is called seepage (Lowe, 1975; Owen, 1987).

Liquefaction

During liquefaction, most of the grain-to-grain contacts are suddenly lost, the unconsolidated sediment collapses, and pore fluid pressure increases rapidly but temporarily. Grains settle briefly through their own pore fluid, fluid escape takes place in short time, and the result is a more tightly packed grain framework. Grains of different sizes and shapes will behave differently during settling and under the influence of the escaping pore fluid. This differential behavior commonly results in particle segregation, the formation of focused fluid flow paths separated by more quiescent sediments, and gravity instabilities associated with the presence of masses of sediment of differing densities within the liquefied material.

Fluidization

Fluidization occurs when escaping pore fluid is able to fully support a significant proportion of the grains; that is, it exerts an upward drag force on the grains equal to their immersed weight. The fluid flow rates are so high that the sediment ceases to be grain-supported and becomes fluid-supported, often accompanied by dilation and density reduction. Fluidized sediment masses are highly mobile and may flow from their original location into overlying or adjacent strata, forming clastic dykes and sills, respectively. In many cases however, fluidization occurs along discrete vertical fluid-flow paths with little bulk movement of the fluidized sediment. These paths can be preserved in the sediment as vertical fluid escape structures. Fluid escape can be further complicated by the development of ephemeral localized pockets or layers of fluid in sediment undergoing consolidation, especially if slight cohesiveness and/

or permeability heterogeneities are present (Allen, 1982: 366; Nichols *et al.*, 1994).

Elutriation

The fluid force exerted on grains by escaping pore fluids can exceed the fall velocities of individual grains, especially the smaller and less dense grain components, and these particles, where loose, will be carried upward and separated from the surrounding larger and/or denser grains, a process termed elutriation. Clays, organic particles, and micas are especially likely to be elutriated from associated quartz and feldspar sand during water escape to form dish and other water-escape structures.

Fine-grained silt and clay are cohesive and not readily liquefied; hydroplastic intrusions and soft-sediment folds can form, but they are usually load structures formed through density instabilities unrelated to water escape. Gravels are difficult to fluidize and tend to reaccumulate rapidly when liquefied. Both fine-grained cohesive and coarse-grained sediments tend to resist grain-by-grain reorganization by escaping pore fluids and dewater by seepage. As a result, fluid escape structures are most common in fine- to coarse-grained sands, which are easily liquefied and fluidized and from which more mobile grains can be easily elutriated.

Classification

Consolidation laminations and dish structures

The presence of slight cohesiveness and/or permeability heterogeneities in a sediment leads to the development of consolidation laminations and dish structures during seepage and liquefaction. Consolidation laminations are subhorizontal laminations that develop as a result of: (1) gravitational segregation of grains of different densities during settling within liquefied sediments; and (2) hydraulic segregation of particles during flow associated with fluid escape (Lowe, 1975). Primary semi-permeable laminations act as partial barriers to vertical fluid flow and cause escaping pore fluids to move laterally to points where the laminations disappear or have been breached. With time, flow beneath and slow seepage across such semi-permeable laminations result in the concentration of hydraulically finer grains carried within the escaping fluids along these laminations. Differential subsidence associated with fluid withdrawal may cause the laminations to become concave upward. The resulting structures are called dish structures (Lowe and LoPiccolo, 1974). Dish structures can also form through stoping, when ephemeral pockets of pore fluid develop in the sediment (Allen, 1982: 373–374; Tsuji and Miyata, 1987). Larger, more irregular zones of partially or totally homogenized sediment that underwent liquefaction or fluidization (Figure F19), with the possible involvement of ephemeral cavities, can be referred to as liquefaction or fluidization pockets and layers (Lowe, 1975).

Vertical fluid escape channels

Once discrete zones of vertical fluid escape are established within a dewatering sediment, the focused fluid flow is commonly strong enough locally to fluidize the sediment and elutriate hydraulically finer grains. Thus the permeability is increased and the fluid escape rate correspondingly rises. The resulting subvertical to vertical zones of mud-poor and usually

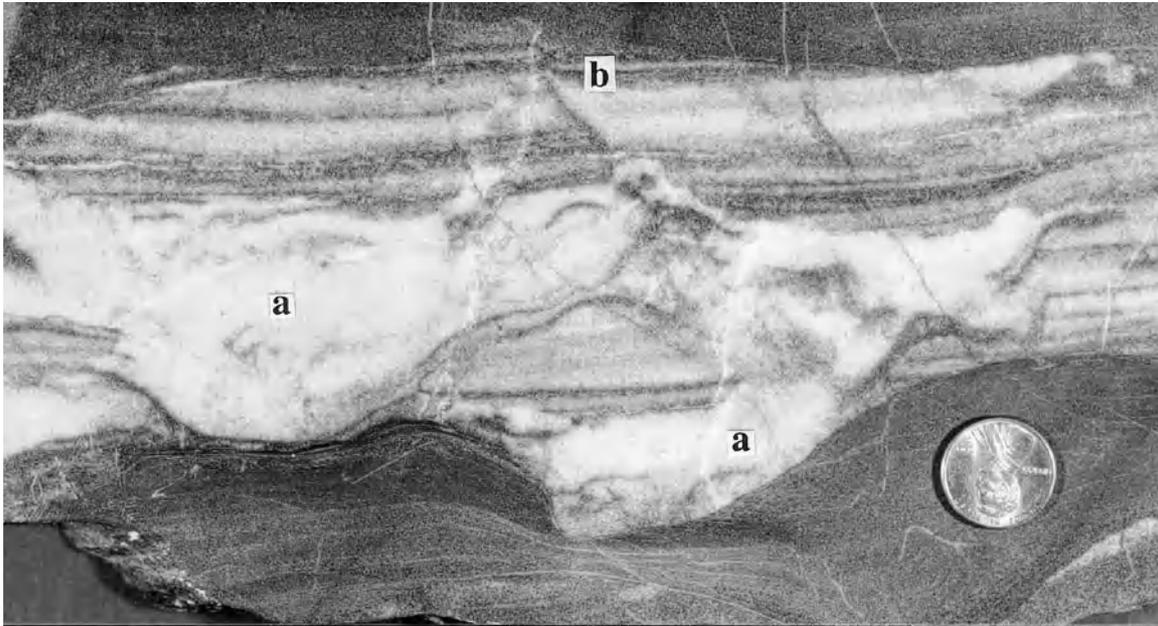

Figure F19 Irregular pockets (a) formed by sediment liquefaction accompanying water escape in a thin layer of flat- to cross-laminated sandstone. Within the liquefaction pockets, primary current lamination has been largely erased by mixing. A small subvertical water-escape conduit leads upward from the larger liquefaction pockets (b). Coin is 1.8 cm in diameter.

coarser-grained sediment are preserved as water-escape channels, sheets, or conduits, which have been termed pillar structures.

Soft-sediment folds

Soft-sediment folds can form due to processes other than fluid escape (Owen, 1987). However, two types of soft-sediment folds commonly form during and as a result of sediment liquefaction and water-escape: convolute lamination (convolute stratification) and recumbent or oversteepened cross-bedding. Convolute lamination formed during water escape is most common in the cross-laminated divisions of fine sandy turbidites and forms during concurrent deposition of the upper finer parts of the beds and dewatering of the underlying coarser sediments (Lowe, 1975). In many cases, the usually narrow anticlines represent subvertical zones of water escape, with sediment locally homogenized by fluidization. Upward decreasing permeability in individual turbidites and Rayleigh–Taylor instabilities may play a role in the development of convolute lamination. Oversteepened or recumbent cross-bedding occurs mainly in cross-bedded fluvial and cross-laminated turbiditic sands. Deposition through avalanching on the lee face of dunes or ripples results in loose packing of sediment that is easily liquefied. The liquefied foreset laminations are sheared in a downcurrent direction by the overlying current.

Soft-sediment intrusions

Sediment that is liquefied or fluidized during fluid escape long after burial can become mobilized and intruded into overlying and adjacent strata. Where tabular, such intrusions are commonly termed clastic dykes or sills, but more equant masses are locally developed. The driving forces for these processes include gravity forces resulting from low density of

liquefied and fluidized sediment or sudden pressure release through joint formation. Gravity-driven soft-sediment intrusions result from density instabilities in soft sediment, even in the absence of escaping pore fluids, in which case they represent load structures but not, strictly speaking, fluid-escape structures. The latter can generate sufficient fluid velocities that large volumes of sediment are not just supported but entrained by the escaping fluid.

FLUID INCLUSIONS

Fluid inclusions are fluid-filled vacuoles trapped within minerals. They may preserve the composition and density of any or all fluids present throughout the history of a sedimentary rock. Fluid inclusions typically are very small, micrometers in size (Figure F20), so they must be studied with a good microscope in relatively coarse minerals. An inclusion could consist of a single fluid phase, such as liquid water or natural gas, and could contain solid mineral phases, organics or bacteria, and could contain multiple fluid phases such as oil, aqueous liquid, natural gas, or water vapor. Commonly, fluid inclusions contain only one or two fluid phases when viewed at room temperature, one of liquid and another of gas (Figure F20).

In addition to fluid inclusions being interesting curiosities within crystals, they provide one of the most powerful tools for reconstructing temperature, pressure and fluid-composition history in sedimentary systems. Unlike many other geochemical tools, the fluid inclusion tool is normally petrographically based and provides a direct sample of conditions within ancient sedimentary systems. Useful compilations helpful in delving into the details of fluid inclusions in sedimentary rocks are Hollister and Crawford (1981), Roedder (1984), Goldstein and Reynolds (1994), and Andersen *et al.* (2001).

Entrapment

In sedimentary systems, sediments and rocks spend their entire history bathed in fluids. As a mineral precipitates from an aqueous solution, it is well-known that crystal growth is seldom perfect. Irregularities in the face of a growing crystal are commonly engulfed by further crystal growth, sealing inside a bit of the fluid. In samples where there is a petrographic relationship indicating that fluid inclusions were trapped during growth of the crystal, the fluid inclusions are considered “primary” in origin. Similarly, many diagenetic minerals tend to recrystallize through a fine-scale dissolution-reprecipitation process (see *Neomorphism and Recrystallization*). If there is petrographic evidence that inclusions were trapped during recrystallization, they are also considered as primary in origin. Minerals present in sedimentary systems are commonly fractured. As tiny micrometer-scale cracks form, they are filled with whatever fluid happens to be present in

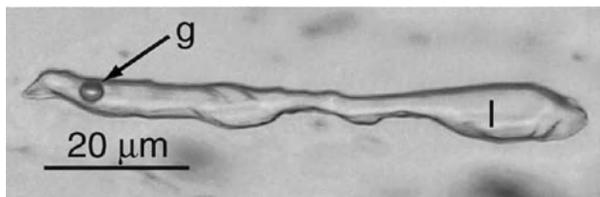

Figure F20 Transmitted light photomicrograph of large elongate fluid inclusion containing a gas bubble (g) within an aqueous liquid (l).

pore systems. These cracks are thermodynamically unstable, so the minerals on walls of cracks tend to dissolve and reprecipitate to “neck down” the crack to a planar array of fluid inclusions sealed within the mineral. Where petrographic evidence exists that inclusions were trapped in this way, after growth of the mineral phase, they are called secondary fluid inclusions. Where petrographic evidence exists that cracks have healed during and not after precipitation of the sequence of precipitated minerals, inclusions are termed pseudosecondary in origin. Determining the timing of entrapment of fluid inclusions is normally the most important part of any fluid inclusion study.

Where there is only a single fluid phase present during the entrapment of fluid inclusions, the composition and density of the entrapped fluid generally is representative of the bulk fluid that was present. However, if immiscible fluid phases are present at the time of entrapment of inclusions, the bulk composition of inclusions typically is not the same as the bulk composition of the pore fluids, because one phase is normally preferentially entrapped over another.

Preservation

It is important to evaluate the degree to which fluid inclusions are preserved in their original state of entrapment. Any fracturing or recrystallization of a mineral containing fluid inclusions has potential for resetting the inclusions. Thus, recrystallization and fracturing of minerals must be evaluated in all fluid inclusion studies.

Under normal conditions, it appears that many minerals containing fluid inclusions are good “bottles”, sealing in the fluid at its original density and composition over geologic time. However, aqueous liquid fluid inclusions develop internal overpressure during burial or hydrothermal heating. Because mineral volume changes little during burial, the volume of an inclusion cavity, in theory, would change little. Heating a liquid confined to such a fixed volume would induce high internal pressure. Thus, during burial heating, inclusions develop high internal pressures and follow steep, constant volume (isochoric) P–T paths. At a given temperature, external confining pressure normally is constrained by a thermobaric P–T path (Figure F21), and is lower than inclusion internal pressure. In many cases, the mineral contains the internal overpressure, but for some, pressure is relieved by expanding the inclusion’s volume through permanent plastic deformation of the crystal around the inclusion wall. This decreases the inclusion fluid’s density, but preserves its composition. Alternatively, the inclusion may burst, and the contents may leak and refill with new pore fluids. To place fluid inclusion data into a paragenetic context, such thermal reequilibration must be evaluated in all studies of fluid inclusions in sedimentary systems.

Fluid inclusions can change their shape over time through a process of dissolution and reprecipitation to yield more stable, negative crystal or globular shapes. A single large elongate inclusion may “neck down” into multiple inclusions during this process. If this happens while more than one phase is present in the inclusion, the new inclusions will have densities and compositions that differ from the original one. Necking down in the presence of multiple phases also must be evaluated to interpret fluid inclusion data.

Philosophy and practice

Normally, a fluid inclusion study begins just as any other scientific study, by defining a specific geologic problem to be solved. Then, samples are taken within a paragenetic, tectonic and stratigraphic context. Rock samples cannot have been heated in the lab before or during preparation. Polished thick sections are prepared without heating or fracturing. The overall paragenesis is worked out and the timing of entrapment of fluid inclusions is integrated using transmitted light, cathodoluminescence, UV epi-illumination and back-scattered electron imaging. If the fluid inclusions needed to answer the question posed are present, then the study is continued, but if they are not, the study is aborted. The most finely petrographically discriminated events of fluid inclusion entrapment (fluid inclusion assemblages; FIAs) are then defined. Composition and phase distribution of inclusions in FIAs are evaluated, providing preliminary interpretations about temperature and pressure of entrapment, extent of thermal reequilibration, and fluid composition. Problems with necking down in the presence of multiple phases and some thermal reequilibration can be recognized at this stage. Then, inclusions can be heated, frozen and melted on a microscope

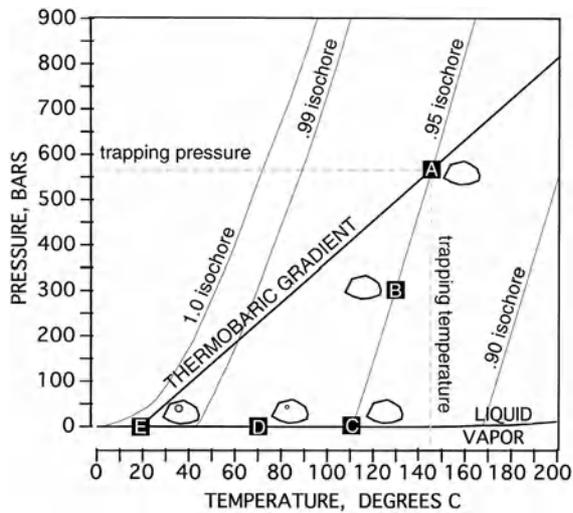

Figure F21 Pressure–temperature behavior of low-salinity aqueous fluid inclusions, with illustrations of fluid inclusion appearance.

heating and freezing stage; the temperatures and types of phase changes observed with this microthermometry yield compositional information on fluid inclusions and information on pressure and temperature of their entrapment. Problems with thermal reequilibration normally are recognized at this stage. Later, more sophisticated microanalytical techniques might be employed to further explore the composition of the inclusions.

Composition

Initially, simple petrographic approaches may be the best means for evaluating the composition of inclusions. Gas phases are typically dark in transmitted light whereas liquid phases are typically bright (Figure F20). Oil inclusions normally fluoresce with UV-epi-illumination and aqueous liquids do not.

The most commonly applied technique for evaluating composition is microthermometry. The composition of gas phases can be determined by their phase behavior at low temperature. Aqueous inclusions may be frozen, and as long as a bubble is present during warming, the temperatures of phase changes can be used to evaluate the major salts in solution and their concentration. For example, the initial melting temperature (T_e) can be used to identify major salts. The higher the salt concentration, the more is the melting temperature of ice depressed. If major salts are known or assumed, the temperature of final melting of ice (T_m ice) can be used to measure salinity (Figure F22). Normally, the exact composition of the salts cannot be known, so a model of the salts must be assumed, such as NaCl equivalent or seawater salt equivalent. The assumption of the model composition makes a small difference in calculating the overall salinity from a measurement of T_m ice.

Temperature

If an aqueous fluid inclusion is trapped as a single homogeneous liquid phase at high temperature (Figure F21(A)), and then is cooled, the P–T path followed is prescribed by the fact that the fluid inclusion vacuole is largely a constant density (isochoric) system. Thus, as the fluid inclusion cools, its pressure drops along an isochoric path (Figure F21(B)). After further cooling, the inclusion eventually intersects a vapor/liquid phase boundary (Figure F21(C)), where theoretically, a tiny bubble of vapor would be stable. With further cooling, the inclusion would follow the liquid/vapor phase boundary and the tiny bubble would grow slightly (Figure F21(D)) along its path toward earth-surface temperature (Figure F21(E)). In the laboratory,

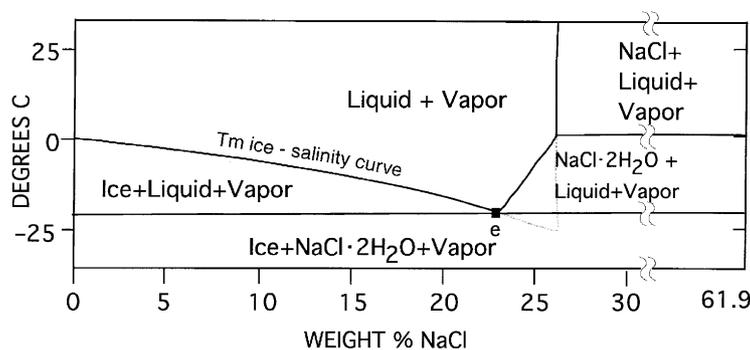

Figure F22 Low-temperature phase behavior of the H₂O–NaCl system.

the inclusion can be reheated until the bubble disappears (Figure F21(C)). The temperature of disappearance is called the homogenization temperature (T_h) and it is a measure of the minimum temperature of entrapment of the fluid inclusion. Validity of T_h data can be evaluated by examining the variability of T_h within each FIA. To correct unaltered T_h to actual entrapment temperature, the composition of the inclusion must be known, and either there must be evidence for immiscibility at the time of entrapment, or the pressure or thermobaric gradient must be known at the time of entrapment (Figure F21(A)). In aqueous systems that have not cooled significantly below the original entrapment temperature, the inclusion may remain all-liquid at room temperature, and depending on the degree of metastability, these all-liquid inclusions may provide evidence for low temperature of entrapment.

Pressure

Fluid inclusions provide a geobarometer for sedimentary rocks. With low-temperature entrapment of immiscible gas and aqueous liquid fluid inclusions, the pressure in inclusions, at surface temperature, is close to entrapment pressure. For higher temperature immiscible entrapment, where compositions of inclusions are known, the intersection of the isochore of the gas-rich end member and the homogenization temperature of the aqueous end member yields pressure of entrapment. For immiscible systems in which the composition of the aqueous end member is known, T_h can be used to determine the position on a bubble point curve to yield pressure. For nonimmiscible systems, in which compositions of the inclusions are known, the homogenization temperature can be used to determine an isochore; the intersection of an assumed thermobaric gradient with the isochore yields the pressure of entrapment (Figure F21(A)).

Applications

Fluid inclusions are developing as tools in global-change research. They provide actual samples of the composition of the ancient ocean-atmosphere system (Johnson and Goldstein, 1993; Lowenstein *et al.*, 1994). Fluid inclusions from non-marine settings provide paleoclimate information from composition of lake and groundwaters and their temperatures (Wenbo *et al.*, 1995; Roberts and Spencer, 1995). Inclusions may provide some of the best-preserved samples of ancient microbes (Vreeland *et al.*, 2000).

In petroleum exploration and development, fluid inclusions are an important tool, providing records of the history and pathways of hydrocarbon migration and generation. Petroleum fluoresces with UV epi-illumination, and its color of fluorescence is tied to maturity and API gravity (Tsui, 1990) providing a record of composition of petroleum fluid inclusions. Extraction and analysis of hydrocarbons from inclusions is useful for studying hydrocarbon systems (Burruss, 1987). Integrating hydrocarbon fluid inclusions, and their homogenization temperatures, into an overall basin and reservoir history is important in developing better understanding of reservoirs in general. Geothermometry using fluid inclusion T_h has proven helpful in constraining thermal history in sedimentary basins (Tobin and Claxton, 2000).

Most diagenetic systems are defined by the temperature, pressure and salinity of the fluids active in them (Figure F23). For that reason, fluid inclusions are one of the best techniques

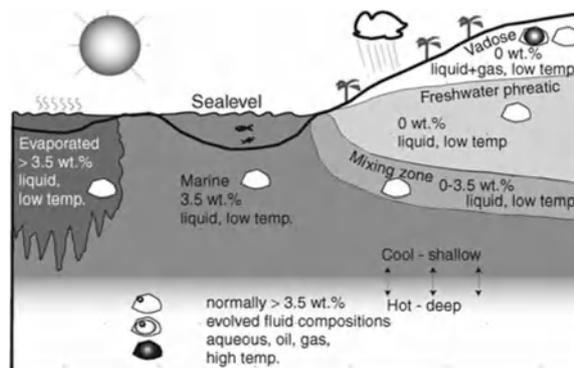

Figure F23 Linkage between temperature and fluid composition in diagenetic environments, with illustrations of fluid inclusion appearance at room temperature.

for constraining the diagenetic history of sedimentary rocks. Fluid inclusions have been successfully applied to all diagenetic systems in sandstones, carbonates and evaporites (Goldstein and Reynolds, 1994).

Summary

The study of fluid inclusions is an important discipline in sedimentary geology. It is the only technique that can directly provide temperature, pressure and compositional information for sedimentary systems. It is a discipline that is rapidly expanding and finding new applications.

FLUME

Most flumes comprise a straight, open-ended, inclined, rectangular trough with either a fixed or mobile bed, down which water flows under the influence of gravity. Water is either supplied continuously to the upstream end of the flume by an external feed, or recirculated. In an annular flume the flow is propelled through a closed, semi-circular conduit. Flumes have been used since the middle of the nineteenth century to study sediment transport. They range in size from channels one or two particle diameters wide and a meter or so long, in which the flow is a few centimeters deep, to channels several meters wide and many tens of meters long, in which the flow may be more than a meter deep. Compared to rivers, they have a significant advantage for direct investigations of sediment transport because clear water and transparent side-walls make the near-bed region more accessible. The most common objectives of flume experiments have been to evaluate competence and the force required to move and transport different bed materials, determine the conditions under which primary sedimentary structures form in unidirectional flows, and investigate the dynamics of the transport process.

Perhaps the most well-known flume experiments are those of Gilbert (1914) and Shields (1936). These and the plethora of other experiments conducted in the first half of the twentieth century sought to determine empirically the laws governing the initiation of motion and transport of bed load in natural channels. In Gilbert's (1914) experiments graded sediments were supplied to the upstream end of the flume and

transported over a bed with a slope (and flow depth) in adjustment with a given discharge. The sediment discharge was computed on the basis of the weight of material retained in a stilling basin located at the downstream end of the flume. This is still a standard experimental procedure, though a larger range of initial bed slope is obtainable in a tilting flume and, as in Shields' (1936) experiments, sediment may be placed in the flume and the bed leveled prior to starting a run. Shields (1936) measured bed load transport under conditions in excess of those required to initiate motion and determined the critical shear stress for the initiation of sediment transport by extrapolation to the point of zero transport. His innovative analytical approach relied on dimensional analysis.

Flume studies are usually experiments designed to investigate distinctive aspects of a natural phenomenon's development, and reproduce significant aspects of its form and function. They are not strictly scale models whose properties are defined, using dimensional analysis, through the principles of similitude (Herbertson, 1968). Dimensional analysis simplifies the scaling procedure by generalizing the conditions that must exist for similarity between the real world and a model, and thereby produce results that are independent of the scale of the system (Shields, 1936). Two systems behave similarly if they are geometrically (all the details of the system, ratios of critical dimensions, are in direct proportion); kinematically (corresponding velocities and velocity gradients are in the same ratios at corresponding locations); and dynamically similar (ratios of forces acting within the two systems are equal). Models of fluvial systems rely on the criterion of dynamic similarity. For complete dynamic similarity the Reynolds number (which determines the behavior and characteristics of viscous flows) and Froude number (which represents free-surface effects in systems where the effect of gravity influences the flow) must be the same in both the model and the real world. This implies that all length measures (e.g., width, depth, and representative particle size) in the real world and the model vary in the same ratio. But it is difficult to model sediment mixtures on the basis of strict similarity between the flow depth and grain size (Kramer, 1935); and because most liquids have densities close to that of water Froude and Reynolds scaling are, for practical reasons, impossible to achieve simultaneously. Parsimonious solutions are to adjust viscosity by heating the water (Boguchwal and Southard, 1990), and to relax the Reynolds similarity criterion for hydraulically rough and turbulent flows (Young and Davies, 1991).

Gilbert (1914) and Shields (1936) found that the characteristic bed form changed with the flow conditions. The initiation of bed forms remains a topic for investigation (Coleman and Melville, 1996), but data from subsequent experiments helped clarify the geometry and hydraulic relationships of bed configurations (Vanoni and Brooks, 1957; Guy *et al.*, 1966). These and many other experiments were conducted with bed material in the sand range, in flumes capable of recirculating both water and sediment. For sediment mixtures, transport relations derived from experiments undertaken in recirculating flumes may differ from those obtained in a sediment feed flume because the final equilibrium state achieved (of steady, uniform flow over an erodible bed) is dependent on the initial conditions; the rate and size distribution of the transport depend on the flow and size distribution of the bed surface (Parker and Wilcock, 1993). In the sediment feed configuration the final state is independent of initial conditions, and the

transport rate of every size range equals the feed rate. Neither configuration can simulate natural transport exactly, because in rivers the pattern of transport reflects the influence both of the bed state at an earlier time (as in a recirculating flume), and the sediment supply from upstream (as in the sediment feed configuration).

The dominant transport condition in many gravel-bed rivers may be one of partial transport, where only some of the particles in a given size range exposed on the bed surface move over the duration of a transport event. It affects the pattern of vertical sediment exchange between the bed surface and substrate, and therefore size sorting in both the vertical and downstream directions (Harrison, 1950; Paola *et al.*, 1992). Color-coding each size fraction permits the bed surface size distribution to be monitored directly by noninvasive means (Wilcock and McArdell, 1993). A variety of other innovative techniques, including high-speed photography and laser Doppler anemometry (Francis, 1973; Bennett and Best, 1995; Nelson *et al.*, 1995), have been used to investigate the dynamics of particle motion and the turbulent motions of the fluid and sediment phases. Many such experiments are conducted under simplified conditions, using a fixed rather than a mobile bed and solitary particles.

FORENSIC SEDIMENTOLOGY

The use of geologic materials as trace evidence in criminal cases has existed for approximately one hundred years. Palenick (1993) provides an overview and reminds us that it began as so many of the other types of evidence with the writings of Conan Doyle. Doyle wrote the Sherlock Holmes series between 1887 and 1893. He was a physician who apparently had two motives: writing salable literature and using his scientific expertise to encourage the use of science as evidence. In 1893 Hans Gross wrote his book *Handbook for Examining Magistrates* in which he suggested that perhaps you could tell more about where someone had last been from the dirt on their shoes than you could from toilsome inquiries. A German chemist, Georg Popp, in 1908 examined the evidence in the Margarethe Filbert case. In this homicide a suspect had been identified by many of his neighbors and friends because he was known to be a poacher. The suspect's wife testified that she had dutifully cleaned his dress, shoes the day before the crime. Those shoes had three layers of soil adhering to the leather in front of the heel. Popp, using the methods available at that time, said that the uppermost layer, thus the oldest, contained goose droppings and other earth materials that compared with samples in the walk outside the suspect's home. The second layer contained red sandstone fragments and other particles that compared with samples from the scene where the body had been found. The lowest layer, thus the youngest, contained brick, coal dust, cement and a whole series of other materials that compared with samples from a location outside a castle where the suspect's gun and clothing had been found. The suspect said that he had walked only in his fields on the day of the crime. Those fields were underlain by porphyry with milky quartz. Popp found no such material on the shoe although the soil had been wet on that day. In this case, Popp had developed most of the elements involved in present day forensic soil examination. He had compared two sets of samples and identified them with two of the scenes associated with the crime. He had confirmed a sequence of events consistent with the theory of the crime and he had found no evidence supporting the alibi.

Sedimentary and related materials have evidential value. The value lies in the almost unlimited number of kinds of materials and the large number of measurements that we can

make on these materials. For example, the number of sizes and size distributions of grain combined with colors, shapes and mineralogy is almost unlimited. There are an almost unlimited number of kinds of rocks and fossils. These are identifiable and recognizable. It is this diversity in earth materials, combined with the ability to measure and observe the different kinds, which provides the forensic discriminating power.

There have been many contributions to the discipline over the last 100 years. Many have been made by the Laboratory of the Federal Bureau of Investigation, the Central Research Establishment, McCrone Associates, The Centre for Forensic Sciences, Microtrace, The Japanese National Research Institute of Police Science, government, private and academic researchers.

Because much of the evidential value of earth materials lies in the diversity and the differences in the minerals and particles, microscopic examination at all levels of instrumentation is the most powerful tool. In addition such examination provides an opportunity to search for man made artifact grains and other kinds of physical evidence.

Individualization, that is, uniquely associating samples from the crime scene with those of the suspect to the exclusion of all other samples is not possible in most of the cases. In this sense earth material evidence is not similar to DNA, fingerprints and some forms of firearms and tool mark evidence. However, in a South Dakota homicide case, soil from the scene where the body was found and from the suspect's vehicle both contained similar material including grains of the zinc spinel gahnite. This mineral had never before been reported from South Dakota. Such evidence provides a very high level of confidence and reliability.

One of the most interesting types of studies is the *aid to an investigation*. There are many examples of cases where a valuable cargo in transit is removed and rocks or bags of sand of the same weight are substituted. If the original source of the rocks or sand can be determined, then the investigation can be focused at that place. In a high visibility case, DEA agent Enrique Camarena was murdered in Mexico. His body was exhumed as part of a cover-up. When his body was found, it contained rock fragments that were different from the country rock at that place and represented the rocks from the original burial site. Petrographic examination of those rocks combined with a detailed literature search of Mexican volcanic rock descriptions enabled the finding of the original burial location.

Most examinations involve *comparison*. Comparison is establishing a high probability that two samples have a common source. In comparison studies of soils, it is difficult to overestimate the value of findings in the soil artifacts or some other type of evidence. In an Upper Michigan rape case, three flowerpots had been tipped over and spilled on the floor during the struggle. It was shown that potting soil on the suspect's shoe compared with a sample collected from the floor and represented soil from one of the pots. In addition, small clippings of blue thread existed both in that flowerpot sample and on the shoe of the suspect. The thread provided additional trace evidence. In a New Jersey rape case, the suspect had soil samples in the cuffs of his pants. In addition to the glacial sands that compared with soil samples collected from the crime scene, the soil contained fragments of clean Pennsylvania anthracite coal. Such coal fragments are not uncommon in the soils of most of the older cities in eastern North America. In this sample there was too much coal when compared with

samples in the surrounding area. Further investigation showed that some 60 years before the crime scene was the location of a coal pile for a coal burning laundry. Again, the tying in of soil-evidence with an artifact and history increased the evidential value.

The alertness of those who collect samples, and the quality of collection, is critical to the success of any examination. If appropriate samples are not collected during the initial evidence gathering, they will never be studied and never provide assistance to the court. There is the case in which an alert police officer happened to look at an individual arrested for a minor crime. He observed, "that is the worst case of dandruff I have ever seen." It was not dandruff but diatomaceous earth, which was essentially identical with the insulating material of a safe that had been ripped the previous day.

The future of Forensic Geology holds much promise. However that future will see many changes and new opportunities. New methods are being developed that take advantage of the discriminating power inherent in earth materials. Quantitative X-ray diffraction may possibly revolutionize forensic soil examination. McVicar and Graves (1997) have reported important progress in this area. When developed to the point that this or similar methods become ordinary lab techniques, it will be possible to do a quantitative mineralogical analysis that is easily reproducible. However, the microscope will remain an important tool in the search for the unusual grain or artifact. Sampling methods should be improved and those people who collect samples for forensic purposes should be thoroughly and completely trained. Soils are extremely sensitive to change over short distances, both horizontally and vertically. Soil sampling in many cases is the search for a sample that compares. The collecting of all the other samples serves only the purpose of demonstrating the range of local differences. In collecting soil samples for comparison, we are searching for one that would have the possibility of comparison. Screening techniques during sampling that eliminate samples that are totally different is appropriate. For example, a surface sample offers little possibility for comparison with material collected at a depth of four feet in a grave.

Studies that demonstrate the diversity of soils are important. One approach is to take an area that one would normally assume was fairly homogenous in its soil character and collect a hundred samples on a grid. Each pair of samples would then be compared until all the pairs are shown to be different. Starting with color and moving on to size distribution and mineralogy, different methods are used to eliminate all of these pairs that appear similar. Junger (1996) performed several such studies and suggested methods for soil examination.

The qualifications of examiners are a very major problem. How do you learn to do forensic soil examinations? This requires a thorough knowledge of mineralogy and the ability effectively to use a microscope and the other techniques used in earth material examination. It is also important that examiners be familiar with the other kinds of trace evidence, and also with the law and practice of forensic examination.

G

GASES IN SEDIMENTS

Gases dissolved in pore waters of sediments are ubiquitous although free gases are confined to specific facies and sedimentary environments. Most dissolved gases are derived by equilibration with the atmosphere and their concentrations subsequently modified by diagenetic (principally biological) processes during shallow burial. Free gases, where present, derive from either diagenetic bacterial reactions (indigenous gases) or migration of thermally derived gases from greater depth.

Free gases of indigenous origin include hydrogen sulfide (H_2S), methane (CH_4), sometimes carbon dioxide (CO_2) and more rarely traces of nitrogen (N_2) or ammonia (NH_3). All of these are formed by microbial communities (see Bacteria in Sediments) operating on organic substrates and are therefore limited to organic-rich sediments, (see Organic Sediments). The relevant diagenetic zones for gas generation are summarized in Figure G1, although local microenvironments may result in disruption of this general vertical stratification. With progressive burial, bacteria utilize the most energy efficient oxidizing agent available until consumed, at which point a different bacterial ecosystem becomes dominant to utilize the next available oxidant (strictly speaking, the next ultimate electron acceptor since all the reactions represent consortia of bacterial groups working in concert). If oxygen is available in bottom waters, an aerobic bacterial community dominates shallowest burial. The end product of this is carbon dioxide although this is generally able to diffuse upward into the water column and rarely reaches concentrations high enough for a free gas phase to develop. Below this, in the suboxic zone, dissolved nitrate and iron and manganese oxides act as the oxidizing agents. In extreme cases this may give rise to free nitrogen and carbon dioxide although generally the carbon dioxide is either lost by diffusion or precipitated as solid carbonates and insufficient nitrogen is generated to form a free gas. Below this are the principal zones of gas generation—the sulfate reduction zone when hydrogen sulfide is formed and

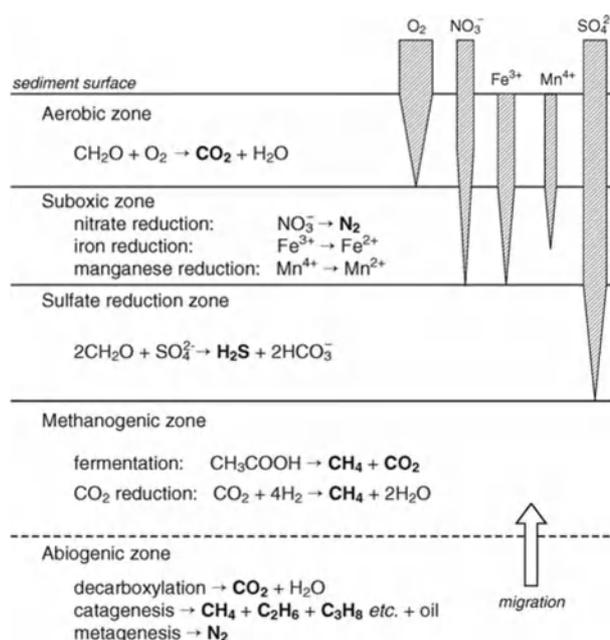

Figure G1 Principal diagenetic zones responsible for the formation of free gas within sediments. The lower limit of the aerobic, suboxic and sulfate reduction zones are dictated by availability of the oxidizing agent concerned (diffusion from the overlying water column in the case O_2 , NO_3^- and SO_4^{2-} or indigenous to the detrital minerals for Fe and Mn). The methanogenic zone is limited by the presence of sulfate above it and approximately the 65°C isotherm below.

the methanogenic zone where methane and carbon dioxide are formed. Below this, further carbon dioxide may be formed by thermal “decarboxylation” of the residual organic matter.

Hydrogen sulfide

When sulfate is available from the overlying water column (generally in marine environments), hydrogen sulfide is the

principal end product within the sulfate-reduction zone. Many bacterial groups operate in this zone to oxidize organic matter but the key reaction is that of the sulfate-reducing bacteria (SRB, notably *Desulfovibrio sp.*). Taking carbohydrate to represent the bulk organic matter, the net reaction can be represented by the reaction:

If iron is freely available within this zone, the H_2S will be buffered to form pyrite (see Sulfides in Sediments). Where insufficient iron is present, free H_2S may build up although the ultimate concentration is limited by bacterial oxidation of the sulfide as it diffuses upward into the suboxic and oxic zones.

Methane

The deepest bacterial zone in sediments is represented by the methanogenic zone. Here, two competing bacterial reactions generate free methane gas:

acetate (or similar) fermentation:

carbon dioxide reduction:

The acetate, CO_2 and H_2 substrates in both cases are provided by parallel, largely fermentation type, bacterial reactions. In general, CO_2 reduction is dominant in marine sediments while fermentation reactions are dominant, at least in the early stages, in freshwater environments although in all cases both reactions operate to some extent (Clayton, 1995). The so-called "biogenic" or "bacterial" gas formed in this way is economically important and may account for as much as 20% of the world's natural gas resources (Rice and Claypool, 1981).

Since no external oxidizing agents are required for methane production, the ultimate methane concentration is limited largely by the availability of organic matter although some methane is lost by anaerobic oxidation at the base of the sulfate-reduction zone (Iversen and Jørgensen, 1985) and methane generation ceases when the sediment is buried to temperatures above approximately 60–65°C due to metabolic limitations of the bacteria involved. Laboratory experiments show that the optimum temperature for methanogenesis using natural assemblages is around 35–45°C (Zeikus, J.G. and Winfrey, M.R., 1976). Under optimum conditions, up to about 10% of the organic carbon may be converted to methane (Clayton, 1992).

Carbon dioxide

Carbon dioxide is the ultimate fate of organic matter oxidation in all bacterial zones although it is not usually as abundant as a free gas as is CH_4 . There are a number of reasons for this. Firstly, during very shallow diagenesis, the majority of the CO_2 is able to diffuse upward back into the overlying water column (bottom waters are frequently enriched in CO_2 relative to surface or intermediate depth waters). Secondly, the collective bacterial reactions within each zone generally result in CO_2 released in the form of dissolved bicarbonate (HCO_3^-) or

carbonate (CO_3^{2-}) which can be precipitated as diagenetic concretions (Irwin *et al.*, 1977). Finally, CO_2 is itself consumed by the CO_2 reduction pathway within the methanogenic zone which generally results in lower CO_2 concentrations in marine environments (where CO_2 reduction is dominant over acetate fermentation) relative to freshwater environments (Clayton, 1995, 146).

Deeper within the sediment, thermal decarboxylation (i.e., abiogenic removal of carboxyl and similar oxygen bearing functional groups from the organic matter) contributes further CO_2 which may reach appreciable concentrations. This process occurs principally between 50 and 100°C (Sweeney and Burnham, 1990) and to some extent overlaps bacterial methanogenesis and deeper thermogenic production of hydrocarbons.

Nitrogen

Nitrogen is also released by bacterial processes during early diagenesis but is generally not as abundant as H_2S and CH_4 as a free gas. It is sourced by both dissolved nitrate (NO_3^-) and organic bound nitrogen (particularly in proteins) although the latter is overwhelmingly dominant. Nitrate reduction to form N_2 is generally considered to be a suboxic process but in practice there is considerable nitrate reduction within the aerobic zone also. The decomposition of proteins (deamination) occurs both within the aerobic zone and deeper and produces ammonia (NH_3) as an end product, usually in the form of dissolved ammonium (NH_4^+). In the presence of oxygen, the ammonia may then be oxidized to nitrate (by *Nitrosomonas sp.*) or nitrite (NO_2^- , by *Nitrobacter sp.*) and can then be bacterially reduced to molecular nitrogen deeper in the sediment.

Migrated gases

Gases migrated from greater depth are locally abundant in surface sediments within petroliferous sedimentary basins (i.e., those containing economic oil and natural gas accumulations). These gases result from thermal breakdown of the residual organic matter which has survived early diagenesis (see Kerogen), typically at temperatures above 100°C (Pepper and Corvi, 1995). They are characteristically dominated by methane with varying concentrations of higher hydrocarbons (ethane, propane, etc.), CO_2 and N_2 . Where migration from depth is highly active, such gases may escape to the water column as active "seeps", often associated with a number of associated sedimentary features such as diapirism, pockmarks, chemosynthetic communities, clathrates (q.v.) and carbonate cementation (see Hovland and Judd, 1988, for a full discussion of these features).

Summary

Where present, free gases in sediments are dominated by methane, hydrogen sulfide, carbon dioxide and sometimes traces of nitrogen or ammonia. Although occasional migrated deep-sourced thermogenic gases containing higher hydrocarbons are locally important, the gases are dominantly the result of *in situ* bacterial reactions during early burial diagenesis of organic rich sediments. Carbon dioxide is generated at all depths, N_2 is formed mainly in the suboxic zone, H_2S is formed

below this under sulfate reducing conditions and CH_4 is formed deeper still.

GEODES

Introduction

Geodes are nodules (i.e., mineral aggregates having a composition that contrasts strongly with that of the surrounding rock) containing an interior cavity lined with macroscopic crystals (i.e., crystals sufficiently large to be distinguishable without magnification). Geodes occur primarily within limestones, dolomites, and mudrocks, but some are found in volcanic rocks. The term geode is largely synonymous with “vug” (a crystal-lined cavity), but has the additional connotation that the object has, or could, weather free by virtue of its compositional and textural distinctiveness from the host rock. The sizes and shapes of geodes vary widely, but most are in the range of 5 to 10 cm across and roughly spherical or oblate. Geodes are recognized as a group partly on the basis of their

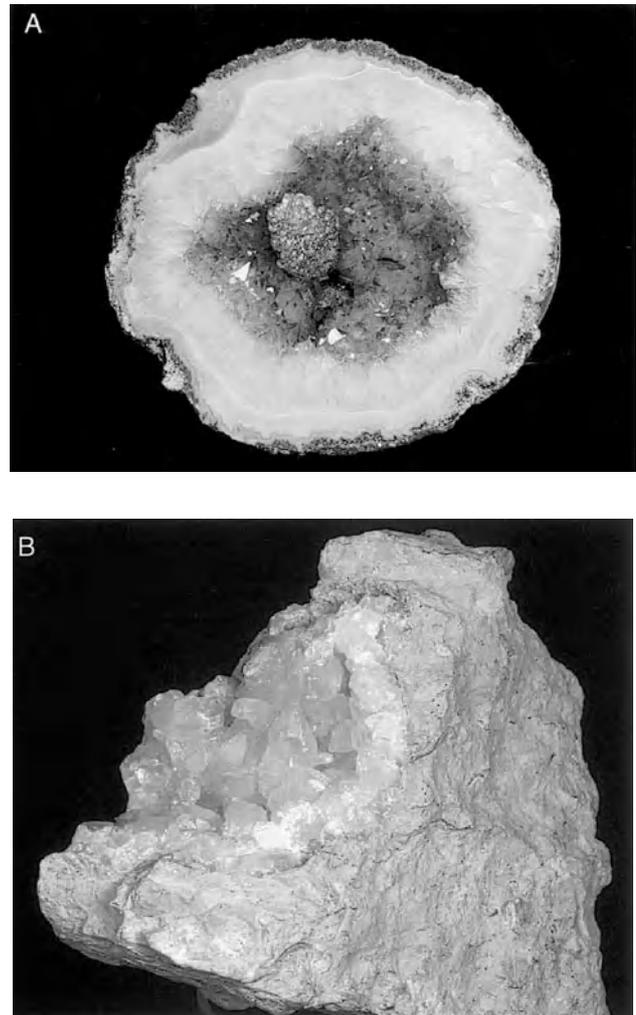

Figure G2 (A) Geode from a volcanic host rock. A chalcedony rim followed by coarse quartz crystals is a widely observed sequence in both volcanic and sedimentary geodes. A late precipitate of calcite is observed in the geode interior. Diameter 15 cm. Barron Collection, Texas Memorial Museum, University of Texas at Austin. (B) Calcite geode in a dolomitic limestone. Many geodes of this type form by replacement of earlier-formed nodular anhydrite. Diameter approximately 12 cm. Collection of the author. Photos by Joe Jaworski.

appearance and distinctiveness, in particular their attractiveness to mineral collectors. (Figure G2).

Geode formation

All geodes share certain genetic aspects. Foremost, crystals in geodes are emplaced by precipitation from aqueous solution (authigenesis) within cavities that are anomalously large in comparison to typical pore spaces in the surrounding rock. These essential characteristics and the attendant necessity for substantial volumes of mineral-bearing fluids to flow through low-permeability rocks were recognized in some of the earliest reports on geode formation (e.g., Dana and Shepard, 1845; Shaler, 1899). Abnormally large pore spaces form in a variety

of ways. Cavities created by dissolution of earlier-formed nodules, gas vesicles in volcanic rocks, cavities within fossils, desiccation cracks within early-formed concretions (see Sеп-tarian Nodules), and pore spaces associated with tectonic fractures can all become the locus of geode formation.

Categories of geodes

Most geodes belong to one of two major categories. Quartz replacement of former gypsum and anhydrite is responsible for the *cauliflower nodules* found in Carboniferous shallow-marine limestones and dolomites of the upper Mississippi Valley region of the central United States. The classic locality for such geodes is at Keokuk, Iowa (e.g., Van Tuyl, 1916; Hayes, 1964; Sinotte, 1969). Similar silicified evaporites are known worldwide in shallow marine rocks ranging in age from Precambrian to Cenozoic (e.g., Chowns and Elkins, 1974; Siedlecka, 1976; Fisher, 1977; Milliken, 1979; Radke and Nicoll, 1981; Matzko and Naqvi, 1983; Elorza and Rodriguez-Lazaro, 1984; Maliva, 1987; Ulmer-Scholle, Scholle *et al.* 1993). Many calcite geodes in sedimentary rocks also have features consistent with formation by evaporite replacement.

An intriguing aspect of silicified evaporite nodules is expansive growth during their early development. Formation of evaporite nodules is a syn-sedimentary or very early diagenetic process, occurring prior to lithification of the enclosing sediment. The exact nature of microenvironments responsible for evaporite localization is uncertain, but it is clear that in some cases precipitation was localized within the skeletal remains of marine invertebrates leading to dramatic expansion or “explosion” of the fossils (Figure G3) (Maliva, 1987; Foerster, 1991). Fossils expanded in this manner attracted great interest from early students of geodes (e.g., Shaler, 1899; Bassler, 1908), but a convincing mechanism for expansion eluded these workers. Growth within unconsolidated sediment, either through direct displacive precipitation of anhydrite, or by expansion (approximately 30%) during hydration of anhydrite to gypsum provides a plausible mechanism for the development of exploded fossils. Replacement of the early-formed nodules during later diagenesis is accomplished by dissolution of the evaporite minerals followed by precipitation of authigenic quartz into the resulting pore space. In *klappersteins* some of the later-formed quartz crystals, perhaps once encased in the now-vanished evaporite mineral, are loose within the geode interior and rattle audibly against the inner walls when the geode is shaken.

Figure G3 Cauliflower chert nodules (exploded fossils) formed by silicification of anhydrite. Specimen on the left (2cm tall) is a silicified blastoid of the genus *Pentremites*. The three specimens on the right show progressive disruption of similar blastoids by displacive growth of the anhydrite, now completely replaced by quartz. Specimen on the far right is a *klapperstein* (see text). Collection of the author. Photo by Joe Jaworski.

A second important category of geodes corresponds to silicified vesicles in tuffaceous volcanic rocks ranging in composition from rhyolite to basalt. Weathering of unstable minerals and volcanic glass provides high concentrations of dissolved silica to pore fluids in such rocks. In the northern Mexico state of Chihuahua, quartz-lined vesicles weathered from rhyolitic and andesitic tuffs supply an abundance of geodes to mineral collectors (Finkleman, 1974; Keller, 1979; Cross, 1996).

Precipitation of cavity-filling minerals

Although geode development must postdate the formation of the enclosing rock, the timing of mineral precipitation can vary from near-syn depositional to much later in the rock's history. Temperatures in the range of 25° to 100°C have been estimated for quartz in silicified evaporite nodules, based on two-phase fluid inclusions and stable isotopic evidence (Milliken, 1979; Roedder, 1979); similar temperatures are estimated for quartz in volcanic geodes (Keller, 1979). The necessity for a large, open pore space through which significant volumes of mineral-bearing fluids can flow most likely restricts geode formation to relatively shallow depths in the crust (<6 km?).

Quartz in a wide variety of textural and color subtypes is the most common geode-filling mineral. In both sedimentary and volcanic rocks, there is a common sequence of mineral formation from the outer rim to the center of the geode. Microcrystalline quartz, either equant or fibrous (chalcedony) microquartz, forms the initial precipitate on the interior surface of the cavity, followed by megaquartz which may develop inward-projecting euhedra around the central cavity.

Other common geode-forming minerals are calcite, dolomite, and, in volcanic rocks, zeolites. Most minerals that occur in geodes postdate the early-formed quartz and belong to a mineral assemblage that also occurs in associated veins and fracture fills. Aragonite, ankerite, celestite, magnetite, hematite, marcasite, pyrite, millerite, chalcocopyrite, galena, sphalerite, fluorite, and kaolinite are widely reported in silicified-evaporite-type geodes (e.g., Goldstein and McKenzie, 1997). Many of the same minerals are reported to occur in volcanic-associated geodes along with a wide variety of zeolites and authigenic feldspars (e.g., Finkleman, 1974; Ernst and Hall, 1975).

Particularly intriguing to collectors are geodes that retain fluids within the interior cavity. Water-bearing geodes, *enhydros*, are obtained from volcanic deposits in Brazil (e.g., Boutakoff and Whitehead, 1952; Prashnowsky, 1990). Petroleum-filled geodes are reported in limestones near Niota, Illinois (e.g., Robertson, 1942; Spitznas, 1949).

Research on geodes

Much information on geode occurrence is found within the mineral collecting literature. In the academic arena, geodes have received surprisingly little attention despite the fact that the large pore spaces within geodes permit the growth of relatively large crystals that represent accessible samples of authigenic minerals that may otherwise be pervasive through the host rock but also rare or cryptic. The sequence of mineral precipitation observable within geodes and the elemental and isotopic zoning within the geode's large crystals can record an eminently readable history of fluid/rock interaction across a

substantial range of diagenetic conditions (e.g., Milliken, 1979).

Summary

Authigenic mineral precipitation on the walls of large cavities in sedimentary and volcanic rocks produces the nodules known as geodes. The large crystals of authigenic minerals found within geodes have interest from the dual standpoints of their esthetic qualities and the intriguing record of rock chemical history that they represent.

GEOPHYSICAL PROPERTIES OF SEDIMENTS (ACOUSTICAL, ELECTRICAL, RADIOACTIVE)

Introduction

Geophysics is an important tool for investigating sediments in the Earth's subsurface. The conversion of geophysical data into geological information requires an understanding of the connection between the nature of the sediments and the physical properties that govern their geophysical response, a discipline called petrophysics or rock physics.

Sediments are heterogeneous systems; their effective physical properties are a function of the properties and volume fraction of the individual components (i.e., the minerals that compose the grains and the fluid species filling the pores), as well as the geometric configuration of these components. This heterogeneity occurs on a wide range of size scales, and these scaling effects on the macroscopic properties of rocks are an active field of investigation. This article will assume for simplicity that size scale of the heterogeneities are on the order of the individual rock grains and pores, forming a single lithologic unit for the larger size scale at which the effective properties are measured.

Even with this assumption, sediments are very complex systems from the petrophysical point of view. A specific physical property can have a broad range of values for a given lithology, making the analysis and interpretation of the geophysical properties of sediments in terms of geological factors a difficult task. With this in mind, the aim of this article to introduce the reader to petrophysical principles involved in the acoustical, electrical and radioactive properties of sediments; in-depth information on this subject can be found in a number of recent texts (e.g., Guéguen and Palciauskas, 1994; Mavko et al., 1998; Schön, 1996).

Acoustical properties

The propagation of elastic waves through geological materials is the basis for seismic methods and acoustic (or sonic) logging.

Table G1 A list of compressional (V_P) and shear (V_S) wave velocities for a variety of sedimentary rocks

Lithology	V_P (in m/s)	V_S (in m/s)
Chalks (water saturated) ¹	1530–4300	1590–2510
Dolomites (water saturated) ¹	3410–7020	2010–3640
Limestones (water saturated) ¹	3390–5790	1670–3040
Sandstones (water saturated) ¹	3130–5520	1730–3600
High porosity sandstones (water saturated) ¹	3460–4790	1950–2660
Poorly consolidated sandstones (water saturated) ¹	2430–3140	1210–1660
Tight-gas sandstones (dry) ¹	3810–5570	2590–3500
Shales ⁵	1830–5180	
Anhydrite ²	6090	3470
Gypsum ²	5800	
Halite ³	4590	2660

Sources: ¹Mavko *et al.*, 1998; ²Schön, 1996; ³Guéguen and Palciauskas, 1994.

With minor exceptions, these methods use body waves (i.e., waves that travel through a body's interior) to investigate the Earth's subsurface. There are two types of body waves that differ in terms of their particle motion relative to the propagation direction of the wave. P waves (or compressional waves) have particle displacement in the direction of wave propagation; S waves (or shear waves) have particle displacement perpendicular to the propagation direction. The commonly measured and analyzed acoustic properties of geological materials are the velocities of these two body waves.

For a homogeneous and isotropic medium, the P and S wave velocities are given by

$$V_P = \sqrt{(k + 4\mu/3)/\rho} \quad \text{and} \quad V_S = \sqrt{\mu/\rho}, \quad (\text{Eq. 1})$$

respectively, where k and μ are the effective bulk and shear moduli of the medium and ρ is its density. The elastic moduli quantify the deformation a material undergoes when subjected to different types of applied stress. The bulk modulus k relates volumetric changes to variations in applied pressure. The shear modulus μ describes the shape distortion due to a pure shear stress; there is no volumetric change accompanying the pure shear stress. The dependence on density is due to inertial effects, such as those described by Newton's laws of motion. The overwhelming majority of seismic and acoustic well logging data involves the propagation of P waves; however, information about S wave propagation is becoming more readily available. A list of P and S wave velocities for a variety of sedimentary rocks is given in Table G1.

The velocity ratio V_P/V_S is also used in the analysis of velocity data; Table G2 give the ranges of their ratio for different sedimentary lithologies. It can be seen from Equation (1) that this ratio only depends on the elastic moduli. The composition and microstructural elements of sediments affect k and μ differently; these differences are reflected in the V_P/V_S ratio.

Acoustic velocities of carbonates and sandstones

Due to their importance as potential hydrocarbon reservoirs, the acoustic velocities of carbonates and sandstones have been more extensively studied than other sedimentary lithologies. An obvious factor affecting these velocities is the composition of the solid grains. Typically, carbonates have higher V_P than sandstones having the same porosity (Table G1). This is related to the differences in V_P for the rock forming minerals calcite (6650 m/s), dolomite (7370 m/s) and quartz (6060 m/s).

Table G2 Typical range of the velocity ratio V_P/V_S for common lithologies (Domenico, 1984)

Lithology	V_P/V_S
Dolomites ¹	1.78–1.84
Limestones ¹	1.84–1.99
Sandstones ¹	1.59–1.76
Shales ²	1.70–3.00

Sources: ¹Domenico, 1984; ²Schön, 1996.

However, variations in porosity and microstructure produce a range of acoustic velocities for each lithology. These factors produce significant overlapping of the velocity ranges that makes it difficult to differentiate between carbonates and sandstones using only V_P .

Ambiguity is reduced in the lithology-velocity relationship by analyzing the velocity ratio V_P/V_S . It can be seen from Table G2 that this ratio is commonly larger for carbonates than for sandstones. Further, the velocity ratio V_P/V_S has been used to infer composition in mixed siliceous carbonate systems. Lithological discrimination using the velocity ratio is based on the large difference in V_P/V_S between quartz ($V_P/V_S = 1.47$) and carbonate minerals ($V_P/V_S = 1.93$ for calcite and $V_P/V_S = 1.85$ for dolomite).

Another lithological element affecting acoustic velocities is clay content in siliciclastic rocks. Small amounts of clay in sandstones can reduce its elastic moduli, producing lower velocities. The effects of clay content are greater for V_S due to the lessened rigidity or stiffness (i.e., lower μ) associated with clay; this produces higher V_P/V_S ratio with increasing clay content. Further, it has been found that clay effects are determined by its position among the sand grains. Clay in load-bearing positions, such as contact clay cements, affects sandstone stiffness; non-load-bearing clay that occupies pores has little impact of sandstone stiffness.

A significant factor affecting acoustic velocities of carbonates and sandstones is the porosity and pore structure. Increasing porosity lowers V_P and V_S ; the magnitude of this effect depends on the shapes of the added pore space. Experimental and modeling results show that the cracks and fractures lowers the acoustic velocities of rocks much more than the same amount of more spherical pores such as vugs and main intergranular voids. This effect is due to the increasing ease with which flatter pores can be deformed.

Further, pore shape affects μ more than k ; hence, V_S is more sensitive to the presence of crack-like pores than V_P . Increasing V_P/V_S ratio is used as indicator of fracturing.

The grain composition and pore structure are dependent on many geological factors such as the source material, depositional environment and diagenesis. Attempts have been made to connect these geological factors with elastic wave velocities, starting with Faust (1951) relating V_P of siliciclastic rocks to age of burial. More recently, a number of systematic studies have been published that analyze the relationship between acoustic velocities and geological parameters for carbonate rocks (e.g., Anselmetti and Eberli, 1997) and siliciclastic rocks (e.g., Vernik and Nur, 1992).

Acoustic properties of shales

While shales constitute a majority of the sedimentary rock mass, their acoustic properties have not been well documented in the past due to their lack of importance as reservoir rocks and the exceptional difficulty of performing laboratory measurements on them. However, their importance as source rocks and their effects on seismic imaging is leading to greater interest in their properties. From Tables G1 and G2, it can be seen that shales have a wide range of acoustic properties. Their acoustic velocities rise with an increasing degree of induration due to growing stiffness; hence, the V_P/V_S decreases with induration.

The preferred alignment of clay platelets in shales produces significant velocity anisotropy (i.e., directionally dependent acoustic velocities). Both V_P and V_S are consistently lower in the direction perpendicular to bedding than parallel to bedding. Velocity differences up to 30% for V_P and 35% for V_S have been measured.

Both the presence of kerogen and its maturity are factors that influence the acoustic properties of shales. Acoustic velocities decrease with rising organic content due the lower elastic moduli of the kerogen. Acoustic velocities also decrease with kerogen maturity; several factors have been suggested for this behavior, such as the formation of free phase hydrocarbons and fracturing associated with the development of overpressuring. The orientation of these fractures will affect the velocity anisotropy of the shale.

Unconsolidated sediments acoustic velocities

Unconsolidated sediments have distinctly lower velocities than their equivalent consolidated lithologies. For instance, a typical range of V_P is 200–500 m/s for dry sediments and 1600–2000 m/s when water-saturated. These lower velocities are due to the low rigidity possessed by unconsolidated sediment, especially near the transition to a fluid supported suspension. This condition produces the extreme low V_S values observed in situ for some unconsolidated sediments (e.g., ~ 100 m/s in water saturated marine sediments). Hence, very large values of V_P/V_S (i.e., 3 and greater) are possible for unconsolidated media.

These sediments can be divided into two groups: granular media, such as sands and gravels, and muds principally composed of clay and silt. Experimental and theoretical investigations have been chiefly directed toward the behavior of granular sediments. In granular materials, acoustic wave propagation through the solid framework is dependent on the

number of grain contacts per particle and the contact micromechanics.

The number of contacts per grain determines how elastic energy is transmitted throughout a granular medium. The number of contacts per grain is determined by the nature of grain packaging, particle shape and grain-size distribution. For example, the compact hexagonal packing of identical spheres gives 12 contacts per sphere, whereas the simple cubic packing has 6 contacts. A dense random packing is a more realistic representation of unconsolidated sediments, these systems have an average of 6.8 contacts per sphere with 2.1 near contacts that can close to form additional contacts as pressure conditions change.

The contact micromechanics describe how elastic energy is transmitted between adjacent grains at an individual contact. Different types of contact micromechanics have been used to explain the velocity data for granular sediments. These contact phenomena are dependent on a number of parameters such as bulk grain properties, grain shapes, surface energy, surface roughness and the macroscopic sense of the applied stresses. In unlithified sediments, these interactions occur at the relatively small contact areas. As lithification occurs, pressure solution and cementation modify the nature of the contact micromechanics by strengthening the bond between spheres and increasing the contact area. The lithification process enhances the rigidity of the sediments and is reflected in increased acoustic velocities, especially V_S . Hence, the lithification process is accompanied by decreasing V_P/V_S .

Acoustic velocities of evaporates and coal

Evaporates (e.g., halite, gypsum) are essentially zero porosity rocks; the velocities of these lithologies strongly reflect their mineral content (Table G1). However, these velocities are not significantly different from porous sedimentary rocks. Coal is distinguished from other sedimentary rocks by its very low V_P . P-wave velocities in coals are a function of grade, ranging from a low of 1790 m/s for lignite to 3050 m/s for anthracite.

Dependence on pore fluids

Pore fluid properties determine the elastic behavior of the pore space; they are strongly dependent on pore fluid composition, temperature and fluid pressure. At seismic frequencies (i.e., less than 2 kHz), V_P is affected by variations in pore fluid properties. V_S is relatively insensitive to these changes, responding only to fluid density variations. This condition results from lack of rigidity in fluids (i.e., $\mu_{\text{fluids}}=0$) and complete pressure equilibration throughout the pore structure.

Pressure equilibration between the pore spaces means its contents act as a single effective pore filling. The effective bulk modulus k_{eff} for a pore space containing water (k_w) and gas (k_g) phases is given by

$$k_{\text{eff}}^{-1} = S_w k_w^{-1} + (1 - S_w) k_g^{-1} \quad (\text{Eq. 2})$$

where S_w is water saturation (i.e., volume fraction of the porosity filled with water). Since the bulk moduli of liquids is much greater than those of gases, Equation (2) predicts that the presence of a gas phase, even in small amounts, will significantly lowers the bulk modulus of the pore filling. For example, consider a pore space containing 98% water ($k_w = 2.2 \times 10^9$ Pa (or N/m²)) and 2% air ($k_g = 1.55 \times 10^5$ Pa); it acts as if it is filled with an effective fluid with $k_{\text{eff}} = 7.7 \times 10^6$ Pa.

Hence, the introduction of gas can produce large decreases in V_p relative to its value when the medium is liquid saturated. Given the insensitivity of V_s to changing pore fluid properties, a decreased V_p/V_s ratio is used an indicator for natural gas. Further, the presence of a dissolved gas phase, such as occurs in live oils, can reduce the pore fluid bulk modulus and lower V_p .

Effects of pressure and temperature conditions on velocities

Pressure effects are primarily dependent on effective (or differential) pressure Δp which is the difference between the external confining (or overburden) pressure p_c and the internal fluid pressure p_f . Increasing Δp causes pore closures in consolidated reservoir rocks, resulting in velocity increases. The velocity changes are more rapid at lower Δp values and slacken as Δp grows. This behavior is due to the swift closure of the more compliant intergranular cracks and fractures, leaving the more spherical pores that are much harder to collapse. In unconsolidated materials, increasing Δp narrows the distance between grains in the medium. This phenomenon produces stronger bonding at existing grain contact and creates new contact as smaller intergranular gaps close. Conversely, the existence of geopressure will reverse this closure process and produce lower velocities. Variations in p_f can also affect pore fluid properties, particularly the gas phase compressibility and density, as well as gas solubility in liquids.

Temperature change generally has a relatively small affect on the elastic wave velocities of reservoir rocks with increasing temperature causing minor velocity decreases. Major variations in velocities that are observed are primarily due to changes in pore fluid properties. Significant temperature induced change can result if it associated with fluid phase transformations (e.g., freezing) or large bulk modulus and viscosity changes in heavy oils.

Velocity dispersion

Dispersion is the variation of a physical property with measurement frequency. Most laboratory measurements of elastic wave velocity are performed at ultrasonic frequencies (i.e., above 100 kHz) while acoustic well logging and seismic exploration are done at lower frequency ranges (i.e., 10–20 kHz and below 1 kHz, respectively). Since there is a significant difference in measurement frequencies, an understanding of dispersion is necessary for relating laboratory results to the interpretation of geophysical field measurements.

Both V_p and V_s increase with increasing measurement frequency for porous rocks containing pore liquids. While there are very few direct measurements of velocity dispersion; it can be estimated using ultrasonic measurements on dry samples to predict low frequency velocities. This method predicts that the magnitude of velocity dispersion can range up to 20% or more; however, it is frequently 10% or less for water-saturated sedimentary rocks. Dispersion is enhanced by the presence of intergranular cracks; hence, dispersion decreases as cracks close with increasing effective pressure. In addition, dispersion can be significantly large for sedimentary rocks containing gas-liquid mixtures and viscous oils.

Several mechanisms have been proposed as the cause of velocity dispersion in porous rocks. Current evidence indicates that the local flow mechanism (Murphy *et al.*, 1986) is the

dominant mechanism in most porous rocks. At low frequencies, fluid pressure equilibration is maintained by fluid flow between pores in response to varying degrees of deformation within sections of the pore space. Dispersion due to this mechanism results from the breakdown of interpore fluid flow as frequency increases due to viscous forces. In the absence of this flow, individual pores act as isolated units within the porous rock at high frequencies. Under these conditions, pore spaces, in particular the intergranular cracks, become harder to deform and result in larger k and μ for the porous rock.

Another dispersion mechanism that is proposed for sedimentary materials is the Biot (1956) dynamic poroelasticity. Dispersion due to this mechanism is due to the progressive decoupling of the average motion of the solid component from that of the pore fluid as frequency increases. At low frequencies, the motions of the solid and pore fluid are perfectly coupled. At high frequencies, the decoupled motions lead to inertial effects that change the effective elastic moduli and density of the rock. Laboratory results and theoretical modelling indicate that this mechanism is important in materials with open pore structures where local flow effects are small.

Petrophysical relationships for acoustic velocities

A wide variety of relationships are available for analyzing and predicting the elastic wave velocities of reservoir rocks. Some are empirical relationships between velocity and parameters (e.g., lithology, porosity, clay content, pressure) obtained from the statistical analysis of laboratory and field measurements. However, an empirical relationship could have limited accuracy when applied to sediments different from those used in its development.

One of the most commonly used relationships is the time-average equation of Wyllie *et al.* (1956); this relationship has been extensively used in acoustic well logging analysis. It assumes that the traveltime for a P-wave through a unit thickness of porous medium is the sum of the traveltimes through the volumetric fractional thicknesses of the solid matrix and pore fluid. The resulting relationship between the velocities of the porous medium, solid matrix and fluids (V , and V_m , V_f , respectively) is

$$\frac{1}{V} = \frac{(1 - \phi)}{V_m} + \frac{\phi}{V_f} \quad (\text{Eq. 3})$$

where ϕ is porosity. Table G3 gives a list of solid matrix and pore fluid velocities for use in this relationship. While this mixing formula can give reasonable estimates for V_p , it neglects the effects due to the geometrical configuration of the constituents, in particular the pore structure. This element of the time-averaging approach is partially reflected in the range of V_m values in Table G3 used for each lithology.

Relationships given by Gassmann (1951) are frequently used to analyze the effects of pore fluids on acoustic velocities. These relationships are valid for any porous medium when complete fluid pressure communication occurs throughout the pore space (i.e., perfect interpore fluid flow); this condition is approximated during seismic wave propagation. However, the Gassmann relationships use effective moduli to implicitly incorporate pore structure effects; this feature limits its predictive capacity.

Table G3 Range of solid matrix and pore fluid velocities used in Wyllie's time average relationship (Matrix values from Schön, 1996)

Material	V_m or V_f (in m/s)
Sandstone (general)	3049–5977
Sandstone (consolidated)	5797–5882
Sandstone (semi-consolidated)	5291–5482
Sandstone (unconsolidated)	2500–5184
Limestone	6402–7008
Dolomite	6969–7008
Fresh water	1524
Brine (200 kppm NaCl)	1737
Oil	1311
Air	332

Another approach used to analyze the elastic wave velocities of sedimentary rocks is the inclusion-based formulation. This formulation treats a porous rock as a solid matrix and embedded inclusions representing individual pore spaces. Hence, the pore structure of the rock is defined in terms of the inclusion shapes and concentration. These formulations commonly assume that no fluid pressure communication between pores (i.e., complete inter pore fluid flow breakdown); this condition replicates the high frequency condition for the local flow dispersion mechanism. Therefore, inclusion-based formulations have been found to be more accurate than the Gassmann's relationships when predicting ultrasonic velocity measurements. The connection between Gassmann's relationships and inclusion-based models has now been established, permitting a framework to analyze the effects of pore geometry and pore fluid properties on velocity dispersion.

Electrical properties

Electrical measurements of various types are made along the Earth's surface or within boreholes. These geophysical methods involve either the flow of an electrical current between electrodes or the propagation of an electromagnetic (EM) field from a transmitter to a receiver. The behavior of the current or field in a medium is dependent its electrical resistivity, or its reciprocal electrical conductivity, which quantifies the transport of electric current. It is one of the most variable physical properties for geological materials, extending over a range of values greater than 10^5 for typical sediments.

Resistivity of porous sediments

The extensive use of electrical and induction logging in reservoir evaluation has lead to wide-ranging research on the electrical resistivity of sandstones and carbonates. Since the sediment grains are essentially insulators, the electrical resistivity of clean (i.e., clay-free) sediments is controlled by electrolytic (or ionic) conduction through the pore water. The magnitude of the electrolytic conduction is a function of the pore water resistivity ρ_w and the pore structure.

The value of ρ_w is directly related to the concentration of the dissolved ions, and both can vary widely. For instance, at 75°C water resistivity will decrease from 10 to 0.04 ohm-meters (Ω -m) as the dissolved NaCl concentration increases from 500 to 250000 ppm (i.e., from freshwater to brine). Further, ionic species differ in terms of valence and mobility; hence, the ionic

composition of the pore water is also important. While the porosity establishes the number of charge carriers available in the porous medium, it is the pore space connectivity that determines the paths followed by the ionic charge carriers. Materials with open pore structure, such as those occurring in well-sorted sands and gravels, permit more efficient current flow than in media with narrow, tortuous pore spaces.

Electrical resistivity is also affected by surface conduction along silica-fluid interfaces; this conduction is the combined result of different surface phenomena. The magnitude of the surface conduction for a material is proportional to its specific surface area (i.e., surface area per unit pore volume); hence, it is important conduction mechanism in clayey materials such as shaly sandstones. It has been found that the style of clay distribution influences this mechanism. Dispersed clay that occurs between grains and along grain surfaces has more surface area than clay laminations or framework grains. Clay mineralogy is also a factor as surface area varies widely with clay type. The strength of the surface conduction has been observed to be nearly independent of ρ_w ; it becomes the dominant conduction mechanism in clayey materials when fresh or low salinity water (i.e., large ρ_w) is present.

Archie's equation for resistivity

The petrophysical relationship most commonly used for the electrical resistivity of clean sediments was given by Archie (1942). This relationship states that the electrical resistivity of a water saturated porous medium ρ is given by

$$\rho = a \phi^{-m} \rho_w \quad (\text{Eq. 4})$$

where a and m are empirical parameters. The combined terms $a\phi^{-m}$ are also referred to as the formation factor F ($=\rho/\rho_w$). The proportionality coefficient a takes on values between 0.5 and 3.5.

The parameter m implicitly incorporates the effects of pore structure on resistivity. The observed value of m systematically varies with the degree of consolidation in sandstones (Table G4a); hence, it is often called the cementation exponent. A correlation between the value of m and porosity type also has been noted for carbonates (Table G4b). For unconsolidated samples, the exponent m has been related to particle shape, varying from 1.3 for spherical grains to 1.9 for thin disc-like grains.

The presence of immiscible pore fluid species (e.g., air, hydrocarbons, chlorinated solvents) is another factor affecting electrolytic conduction porous sediments. Since immiscible pore fluids are commonly electrical insulators, their presence impedes electrolytic conduction through the pore space, leading to higher resistivity values. Immiscible fluid effects on the resistivity of porous media are described by the second form of Archie (1942) equation:

$$\rho = a \phi^{-m} S_w^{-n} \rho_w \quad (\text{Eq. 5})$$

where S_w is the water saturation and n is an empirical constant called the saturation exponent. The observed values of n for sandstones and limestones range between 1.1 and 2.6; it is commonly assumed to be 2 when laboratory measurements are not available. Further, it has been found that n for a given sample is dependent on wetting conditions, immiscible species present and saturation history. These factors influence the pore scale fluid distribution, affecting the geometry of the electrolytic conduction path through the water phase.

Table G4 The typical values of the cementation exponent m for (a) sands with varying degrees of consolidation and (b) carbonates with different porosity types (Doveton, 1986)

(a) Unconsolidated sands	$m = 1.3$
Very slightly cemented sands	$m = 1.4-1.5$
Slightly cemented sands	$m = 1.5-1.7$
Moderately cemented sands	$m = 1.8-1.9$
Highly cemented sands	$m = 2.0-2.2$
(b) Fractured carbonates	$m = 1.4$
Chalky limestones	$m = 1.7-1.8$
Crystalline and granular carbonates	$m = 1.8-2.0$
Carbonates with vugs	$m = 2.1-2.6$

Petrophysical relationship for shaley sediments

The combined effects of electrolytic and surface conduction in clay bearing sediments are generally treated as an equivalent circuit consisting of parallel conductors. A commonly used petrophysical relationship based on this model for water-saturated shaly sands given by Waxman and Smits (1968) is

$$\frac{1}{\rho} = \frac{1}{a\phi^{-m}\rho_w} + \frac{BQ_v}{a\phi^{-m}} \quad (\text{Eq. 6})$$

The electrolytic conduction term $1/a\phi^{-m}\rho_w$ is obtained from the first Archie equation (Equation 4). In the surface conduction term, Q_v is the total charge in the electrical double layer per unit pore volume and is related to the cation exchange capacity of the material; hence, it can vary widely with clay mineralogy. The empirical parameter B is the counterion mobility. A similar relationship is available for partially saturated shaly sands that accounts for the pore space occupied by the insulating nonaqueous fluid phases.

Resistivity of shales, coal and evaporites

Shales generally have lower resistivity than sandstones and carbonates due to their water content and the surface conduction associated with clay minerals. An important factor that can affect shale resistivity is the degree of thermal maturity of their organic matter. Hydrocarbons are released and displace pore water as kerogen matures, increasing shale resistivity. Coals are often considered to have high resistivity. However, both anthracite and lignite can have low resistivity. In the case of lignite, resistivity can be used as a measure of water content. Due to their lack of porosity, evaporites have very high resistivity; this is used as a diagnostic property in well log analysis.

Temperature and pressure effects on resistivity

Temperature changes affect aqueous solutions resistivity with declining ρ_w as temperature rises. This response is due to lowering of fluid viscosity with warmer temperatures that leads to greater ion mobility. The dependence of ρ_w on temperature is significant (e.g., a 2% change in ρ_w for a 1°C variation at 20°C); hence, temperature effects need to be considered in the analysis of resistivity data.

Fluid pressure changes have a minimal influence on ρ_w , and its effect is generally neglected. However, applied pressure variations alter the pore structure and affect pore connectivity. Pore closure with higher effective pressure increases tortuosity that results in higher ρ for porous rocks.

Table G5 The abundance of potassium, uranium and thorium content in sediments and rock forming minerals. Brackett indicates average value (Bateman, 1985)

	K (%)	U (ppm)	Th (ppm)
Lithologies			
Carbonates	0.0-2.0 [0.3]	0.1-9.0 [2.2]	0.1-7.0 [1.7]
Sandstones	0.7-3.8 [1.1]	0.2-0.6 [0.5]	0.7-2.0 [1.7]
Shales	1.6-4.2 [2.7]	1.5-5.5 [3.7]	8-18 [12]
Colorado Oil Shale	<4.0	up to 500	1-30
Minerals			
Quartz, Calcite, Dolomite	0	0	0
Plagioclase	0.54	-	<0.01
Orthoclase	11.8-14.0	-	<0.01
Glauconite	5.08-5.30	-	-
Montmorillonite	0.16	2-5	14-24
Kaolinite	0.42	1.5-3	6-19
Illite	4.5	1.5	-
Micas	6.7-9.8	-	<0.01
Phosphates	-	100-350	1-5
Zircon	-	300-3000	100-2500

Radioactive properties

Radiometric methods, such as natural γ -ray well logging, are used to measure the radioactivity of sediments due to the spontaneous decay of radionuclides present in these materials. There are three series of natural radionuclides that are common in the Earth's crust: the uranium (^{235}U and ^{238}U) series, thorium (^{232}Th) series and potassium (^{40}K). Both the thorium and uranium series involve a decay chains with a number of daughter products. The isotope ^{40}K decays to ^{40}Ca and emits a γ -ray. The relative abundances of these radionuclides are variable in sedimentary rocks (Table G5). While total γ -ray tools count all γ -ray without differentiation, spectral γ -ray tools determine the contribution due to each series.

Shales and clays produce a higher γ -ray count due to clay minerals that contain K and Th; hence, total γ -ray count is used as measure of shale content. Since clay minerals differ widely in terms of their Th/K ratios (Table G5), it has been suggested that spectral γ -ray data be used for clay mineral identification. Organic matter in black shales preferentially adsorb U ions; the U concentration is a function of U ion species, amount and degree of organic matter maturity, and pH/Eh conditions. Therefore, the Th/U ratio is useful in source rock characterization.

Pure quartz sandstones contain very small concentrations of radioactive isotopes and exhibit low γ -ray count. The presence of K-rich minerals (i.e., feldspars and micas) produces significantly higher γ -ray count and can be used as a sediment maturity indicator. Some heavy minerals (e.g., zircon) are Th and U bearing, and sandstones with these minerals also produce significantly higher γ -ray counts. These two cases can be identified using the Th/K ratio. Both calcite and dolomite have very low K, Th and U contents that explain the very low γ -ray activity commonly measured in carbonates. Elevated γ -ray count in carbonates can be attributed to the presence of clay mineral or U associated with organic material and phosphate minerals.

Coals commonly have little, if any, K or Th. Their γ -ray activity is very low; coals may have readings even lower than clean sandstones on γ -ray logs. Natural γ -ray logging is an

excellent method for distinguishing coal from interbedded shales. Potassium bearing evaporites (e.g., sylvite) are very radioactive which combined with their very high resistivity can be used for lithologic identification. Other evaporites are non-radioactive, and their low γ -ray readings separate them from most shales.

Summary

The physical properties of sediments are dependent on the properties and abundance of the individual components as well as their geometrical configuration. Since sediments are complex heterogeneous systems, their physical properties can vary widely for a given lithology. However, there are general petrophysical principles that govern the physical properties of sediments.

The acoustic wave velocities for sediments are a function of the elastic moduli and densities of the rock forming minerals composing the solid grains and the fluid species that fill the pore space. For seismic waves, the pore fluids act as a single effective fluid that is very sensitive to the presence of gases. The acoustic velocities decrease with increasing porosity; this effect is greater for crack and fractures.

Since solid grains are insulators, the electrical resistivity of sediments is primarily controlled by electrolytic conduction through the pore water. The transport of electrical current by this mechanism is dependent on the water resistivity and the pore structure. In addition, electrical current can flow along solid-fluid interfaces due to surface conduction. This mechanism can significantly contribute to transport of electrical current in materials with large surface area such as clayey lithologies.

The natural radioactivity of sediments is a function of their potassium, uranium and thorium content. Total γ -ray count is used as measure of shale content due to clay minerals containing potassium and thorium. Source rocks can have elevated levels of uranium due to preferential absorption by organic matter. The presence of potassium bearing minerals can significantly increase the radioactivity of sandstones and evaporites that otherwise have low γ -ray count.

GEOTHERMIC CHARACTERISTICS OF SEDIMENTS AND SEDIMENTARY ROCKS

It has been known for centuries that temperature in the Earth increases with depth. This increase towards the interior is the natural process of general cooling of the lithosphere and where a portion of the heat flow is generated by the decay of radioactive constituents contained in the crust. The escape of the heat (the heat flow), is measured by determining differences in temperature with depth (the gradient), at various places usually in mines, tunnels, or well bores and the type of rock through which the heat is transmitted (rock conductivity). Heat flow is expressed as:

$$Q = -K (dT/dx) \quad (\text{Eq. 1})$$

where Q is the heat flow, K is the thermal conductivity, T is the temperature, and x is the distance (depth).

Heat flow is computed either by the: (1) interval method; or (2) Bullard method (thermal depth method) (Jessop, 1990). Both methods utilize the temperature gradient (measured in a well bore, mine, or tunnel) and rock conductivity value(s) for each geological unit through which the gradient is determined.

Where the crystalline basement (crust) is covered by younger sediments or sedimentary rocks, the heat flow, may be influenced by the blanket effect of the cover. Physical properties of the sedimentary cover, including the rock type and contained radioactive elements, thermal conductivity, and their contained fluids or gas, affect the thermal regime. In addition, topography and past climatic conditions may be important factors.

Table G6 Average heat-production values of some igneous rocks (from Haenel, Ryback, and Stegena, 1988, p. 136)

Rock type	Heat production μWm^{-3}
Granite	2.45
Granodiorite/dacite	1.48
Diorite, quartzdiorite/andesite	1.08
Gabbro/basalt	0.309
Peridotite	0.012
Dunite	0.002

Table G7 Representative heat generation units (HGUs) for sediments/sedimentary rocks (Haenel, Rybach, and Stegena, 1988, p. 136)

Rock type	Heat production (μWm^{-3})
Limestone	0.62
Dolomite	0.36
Quartzitic sandstone	0.32
Arkose	0.84
Graywacke	0.99
Shale and siltstone	1.80
Black shale	5.50
Salt	0.012
Anhydrite	0.090

The heat (H), partly generated by the radioactive isotopes of Uranium (U), Thorium (Th), or Potassium (K), is dissipated through the crust and overlying sediments or sedimentary rocks and is measured in μWm^{-3} . The heat is transmitted by conduction, convection, or radiation. The amount of heat, timing, and cause of heating is of prime importance to many geological applications such as understanding cratonic sedimentary basin development, generation and migration of petroleum, emplacement of ore deposits, and sedimentary diagenesis.

Igneous and metamorphic rocks which constitute the Earth's crust are naturally radioactive and have different heat-production rates. For example, granites usually contain more radioactive elements than gabbros and basalts. Some representative values are given in Table G6.

Some heat may be generated by radioactive elements within the sediments themselves (Table G7). For example, black shales may be highly radioactive, but other rock types such as limestones and sandstone contain few radioactive elements, except in special conditions, and, therefore, their heat generation unit (HGUs) values are small. Evaporites essentially are devoid of any radioactive elements and therefore the HGUs are extremely small or nil. The radioactive sediments, of course, contribute to the overall heat flow, but generally this contribution is small (because of the thinness of the sedimentary package) relative to the basement rocks (= crust), which constitute infinitely more mass.

The heat flow in sedimentary basins, for the most part, is computed from temperatures measured in boreholes, usually drilled for purposes other than measuring temperature. A vast amount of these data are available as bottomhole temperatures (BHTs) or temperatures taken in drillstem tests (DSTs) during logging of commercial wells drilled in search of petroleum, ore

Table G8 Thermal conductivities of some sedimentary rocks (from Blackwell and Steele, 1992; Jessop, 1990)

Rock type	Conductivity range (W/mK)
Limestone	2.50–3.10
Dolomite	3.75–6.30
Sandstone	2.50–4.20
Clay and siltstone	0.80–1.25
Shale	1.05–1.45
Anhydrite	4.80–5.80
Salt	4.80–6.05
Basalt	1.69–1.96
Granite	307–3.50

deposits, or water. Temperatures also may be recorded in well bores by conventional continuous temperature logging techniques or by the new Distributed Optical-Fibre Temperature Sensing technique (DTS). Temperatures measured during well logging may be of questionable value depending on the circumstances and conditions during their recording and collection. If certain conditions are known and controlled, then the values can be corrected to obtain a 'true' temperature.

Topography

In lowland areas or areas with little topographic relief, a correction for topographic irregularities is not needed. In other areas with considerable topographic relief, however, a correction factor needs to be applied.

Rock type and conductivity

Different rock types exhibit different thermal conductivities and these values have been measured carefully in laboratories under controlled conditions. A summary of values is presented in Table G8.

Porosity and contained fluid or gas

The type of fluid or gas contained in pores of a rock affect their conductivity and thus the computation of any value dependent on the thermal conductivity (Table G8). Water, oil, or natural gas all have different conductivities and alter the overall rock conductivity, but usually the interporosity substance is known and can be considered in the computations.

Past climatic conditions

This factor affects only the upper hundred meters or so of the subsurface and the effect can be determined from any reliable temperature log taken in a borehole. The correction for the climatic change is relatively small, but could be important, especially in areas of permafrost.

The computed heat-flow values, then, can be compared from one location to another, plotted on a map, and contoured for further interpretation (see for example Blackwell and Steele, 1992; Čermák and Hurtig, 1979; Hamza and Munoz, 1996).

For reference, the average heat flow on continents is approximately 62 mWm^{-2} and for oceanic areas, it is slightly higher at about 80 mWm^{-2} (Jessop, 1990, p. 205).

GLACIAL SEDIMENTS: PROCESSES, ENVIRONMENTS AND FACIES

Introduction

Significance of glacial deposits

The importance of glacial sediments can be gauged from the fact that 10 percent of the Earth's land surface currently is covered by glacier ice, a figure that exceeded 30 percent during the Quaternary glaciations of the last 2 Ma. Glacier ice has left a complex, often patchy, record of deposition on land, and offshore has contributed substantially to the build up of continental shelves. In earlier geological history, the Earth experienced several continental-scale glaciations, some of them even more extensive than those of the Quaternary Period. Glacial deposition is intimately associated with a wide range of other processes, including fluvial, mass flowage, eolian, lacustrine, and marine. The resulting facies associations are highly variable, and without detailed investigation can be subject to a wide range of interpretations. It is only within the last three decades that studies of glacial processes in modern settings have made it possible to develop plausible models of past glacial depositional environments.

Understanding the nature of Quaternary glacial sediments and their associated landforms is vital in glaciated areas of North America and Europe, where sand and gravel extraction is essential for construction purposes, and for sensible management of water resources and waste disposal. Ancient glacial deposits and associated facies are also economically important; in some regions, since they control the presence of petroleum resources, as for example in the Permo-Carboniferous and Neoproterozoic sequences of the Middle East and South America.

Historical background

Today, it is common knowledge that the Earth experienced a series of ice ages but, when the concept was first mooted in the early 19th century, it met with fierce opposition, as most of the unconsolidated deposits (*drift*) that are familiar to geologists were attributed to Noah's flood of the Old Testament, often with the proviso that larger boulders ("erratics") were deposited from icebergs (Hambrey 1994, Chapter 1 for review). The Swiss natural historian, Agassiz, became the chief protagonist of the "Ice Age Theory", and when he delivered his ideas in 1837, they had a Europe-wide impact. In the following decades, through Agassiz's influence, geologists in

the UK and North America gradually accepted the theory as being applicable to their areas. In the second half of the 19th century, "ancient" glacial deposits (*tillites*) were recognized in many parts of the world. However, even in the second half of the 20th century, the glacial origin of supposed tillites was challenged, notably those of Neoproterozoic age. It has taken systematic sedimentological investigations, coupled with an appreciation of modern glacial processes, to settle these debates.

Extent of glacier ice today

The areal extent of glacier ice today has been documented by the World Glacier Monitoring Service (1989) (Table G9). By far the greatest expanses of ice are the ice sheets of Antarctica (85.7 percent of area) and Greenland (10.9 percent). However, it is the remaining 3.4 percent that impinges directly on human civilization, and most detailed sedimentological studies have focused on these smaller ice masses. The potential contribution of the Antarctic ice sheet to sea level rise is 56 m, with the Greenland ice sheet adding a further 7 m. The remaining glaciers account for a mere fraction of this. Fluctuations of the world's ice masses continue to affect global sea levels, providing on-going eustatic controls on the sedimentary processes on continental shelves.

Characteristics of glaciers

Mass balance

The state of health of a glacier is a reflection of the balance between accumulation and ablation over periods of decades to hundreds of years, or thousands of years in the case of the polar ice sheets. The difference between accumulation and ablation in any one year is referred to as *mass balance*, which is positive if accumulation exceeds ablation and negative if the reverse. Accumulation mainly takes the form of snow, which is transformed or metamorphosed by burial, through *firn*, to glacier ice. Ablation is largely accomplished by melting on temperate glaciers, while in some regions calving from ice masses into the sea accounts for the bulk of ice losses. Glaciers are typically subdivided into an *accumulation zone* and an *ablation zone*, separated by an *equilibrium line* where there is no net gain or loss of mass (Figure G4).

Table G9 Distribution of glacierized areas of the world (World Glacier Monitoring Service, 1989)

Region	Area (km ²)
Africa	10
Antarctica	13,593,310
Asia and Eastern Europe	185,211
Australasia (i.e., New Zealand)	860
Europe (Western)	53,967
Greenland	1,726,400
North America excluding Greenland	276,100
South America	25,908
World total	15,861,766

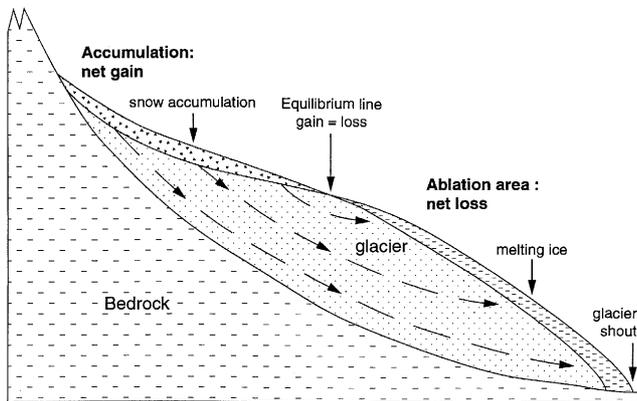

Figure G4 Longitudinal profile through a valley glacier, illustrating flow lines (particle paths) in relation to the equilibrium line.

Glacier dynamics

In order to interpret the origin of glacial sediments and landforms, it is necessary to understand the mechanisms of ice deformation and glacier flow. Glaciers flow by one or more of three main mechanisms: internal deformation, basal sliding, and movement over a soft, deformable bed (Paterson, 1994). *Internal deformation* is best explained by Glen's flow law for polycrystalline ice; this law relates the effective shear-strain rate ($\dot{\epsilon}$) to shear stress (τ) in the following equation:

$$\dot{\epsilon} = A\tau^n$$

where n is a constant, typically 3, and A depends on ice temperature, crystal size and orientation, and impurities. Internal deformation results in the slowest flow occurring at the surface and at the base of a glacier (Figure G5). *Basal sliding* is important where rain or melt-water is able to lubricate the bed (Figure G5), and varies according to the season and time of day or night. Frictional and geothermal heating may add to the availability of meltwater. Many glaciers flow over a bed of unconsolidated sediment which, when saturated, is readily deformed. Deformable beds exist beneath modern fast-flowing ice streams in Antarctica. Much of the movement of the Quaternary ice sheets in North America, has also been linked to subsurface deformation. The relative importance of these mechanisms is highly variable. In moist temperate regions as much as 80 percent of glacier flow is from sliding. Cold polar glaciers, which are frozen to their beds, flow almost entirely by internal deformation. Where a deformable bed exists, the bulk of movement may be within the sediment layer beneath the ice. In *surge-type glaciers*, flow is unstable, with long periods (often decades) of quiescence punctuated by short bursts (several months to a few years) of high velocity (*surges*). At its peak, the velocity may reach several orders magnitude above normal, and the glacier may advance rapidly, and redistribute large volumes of sediment.

Glacier structure

Glacier structures are principally the product of internal deformation, and are intimately associated with the transport of debris. Glacier ice is similar to any other type of geological material in that it comprises strata that progressively deform

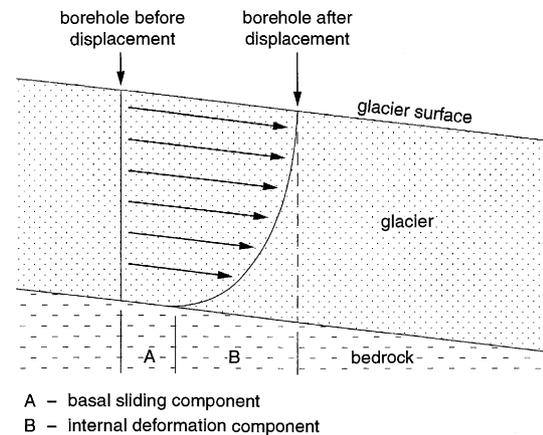

Figure G5 Vertical longitudinal profile through a glacier, illustrating the two main components of glacier flow, internal deformation and basal sliding. Arrows indicate relative displacements, as determined from borehole studies.

to produce a wide range of structures. Primary structures include sedimentary stratification derived from snow and superimposed ice, unconformities, and regelation layering resulting from pressure melting and refreezing at the base of a glacier. Secondary structures are the result of deformation, and include both brittle features (crevasses, crevasse traces, faults and thrusts) and ductile features (foliation, folds, boudinage). Typically, a glacier reveals a sequential development of structures as in deformed rocks, so that by the time the glacier snout is reached, ice may record several phases of deformation.

Thermal regime

The temperature distribution or *thermal regime* of a glacier is fundamental to glacier flow, meltwater production and routing, and to styles of glacial erosion and deposition. The most active glaciers are so-called *temperate* or *warm*, in which the ice is at the pressure-melting point throughout. These glaciers slide rapidly on their beds and induce much erosion; they are typical of alpine regions. At the opposite end of the spectrum are *cold* glaciers, which are below the pressure melting point throughout. Since they are frozen to the bed, cold glaciers are generally regarded as having little ability to erode, although this assumption has been challenged by observations in the Dry Valleys of Antarctica recently. An intermediate type of glacier, found in the High-Arctic, is referred to as *polythermal*. In such glaciers, it is typical for the snout, margins and surface layer of the glacier to be below the pressure-melting point, whereas thicker, higher level ice is warm-based.

Glacier hydrology

Meltwater within, beneath and beyond glaciers plays a vital role in the processes of erosion and deposition. Water, derived from melting snow and ice, flows in channels on the glacier surface, until plunging *via* moulines into the interior or bed of the glacier, finally emerging at the snout. Drainage routes differ according to the thermal regime of the glacier. In cold

and polythermal glaciers, meltwater is forced toward the glacier margins, while in temperate glaciers water flows in discrete channels at the bed, often emerging from the glacier at a single portal. Glaciers act as natural storage reservoirs, retaining water in winter and releasing it in summer. Thus discharge is markedly seasonal. Furthermore, summer discharge is strongly diurnal, peaking in the early afternoon. On the braid-plain, beyond the glacier, marked fluctuations in discharge result in rapid continuous channel shifts. Meltwater also accumulates in ice-constrained lakes, including ice-dammed, proglacial, supraglacial, and subglacial types. Many of these are ephemeral, and those dammed by ice are particularly prone to catastrophic failure, resulting in outburst floods called *jökulhlaups*. Glacial meltwater is not only a powerful erosive agent, but is also responsible for the most important sedimentary facies in glacierized regions.

Morphological classification of glaciers

Glaciers range in size from ice masses only a few hundred meters across to the huge ice sheets that cover Antarctica and Greenland, and there are thus many different types (Hambrey, 1994; Bennett and Glasser, 1996; Benn and Evans, 1999). The largest features are *ice sheets*, arbitrarily defined as exceeding 50,000 km² in area. *Ice caps* form dome-like masses, burying the topography. Ice sheets and ice caps commonly have zones of faster flow called *icestreams*, which is where erosion is most strongly focused, and where debris transfer is most marked. *Highland icefields* also bury much of the topography, but are punctuated by upstanding peaks or *nunataks*. *Valley* and *cirque (corrie) glaciers* are constrained by topography in alpine terrain. Where coalescing ice streams in Antarctica meet the sea, floating slabs called *ice shelves* are formed. The extension of an individual ice stream into the sea results in an *icetongue*. One of the key roles of the sedimentologist and geomorphologist is to reconstruct the morphological characteristics of former ice masses, to constrain the interpretation of past climates and sea-level response.

Glacier fluctuations

Glaciers, together with their sediments and landforms, are important sources of information about environmental change. Reconstructions of pre-Pleistocene ice masses are based on correlation of strata (especially those of marine origin) and erosion surfaces over wide areas. Reconstruction of Late Quaternary glacier variations are usually based on the distribution of glacial landforms and surficial sediments, including moraines and trimlines, coupled with radiometric, lichenometric, or dendrochronological dating. Reconstructions of more recent historical fluctuations rely on repeated measurements of glacier frontal positions, aerial photograph interpretation, or historical records such as maps and reports of early expeditions to glacierized areas. Most of the world's mountain glaciers are currently in recession from their historical maxima, attained during the Little Ice Age between AD 1600 and AD 1850. Glaciers do not generally respond instantaneously to climatic change. The lag-time varies from just several years for dynamic alpine glaciers to hundreds or thousands of years for the polar ice sheets.

Glacial processes

Erosion

Glaciers and ice sheets are agents of net erosion because they flow outwards from a source area toward their margins. Glacial erosion occurs by three main processes: *glacial abrasion*, *glacial plucking* (or *quarrying*), and *glacial meltwater erosion* (Hambrey, 1994; Bennett and Glasser, 1996; Benn and Evans, 1998), and gives rise to a wide range of landforms (e.g., Figure G6). Since glacial erosion is the starting point for debris entrainment and transport by glaciers and ice sheets, an understanding of this topic is essential if we are to understand the sedimentary products of ice masses.

Glacial abrasion is the process by which particles entrained in the basal layer of a glacier are dragged across the subglacial surface. The scratching and polishing associated with glacial abrasion tends to create smoothed rock surfaces, often with striations or grooves.

Glacial plucking (or *quarrying*) is the process whereby a glacier removes and entrains large fragments of its bed. The processes of rock fracture are controlled by the density, spacing and depth of pre-existing joints in bedrock, together with the stresses applied by the glacier. Fracturing of bedrock is also aided by the presence of meltwater beneath the glacier, where bedrock is loosened by subglacial water pressure fluctuations. Plucked blocks and fine material are then entrained in the basal ice by freezing-on (regelation), when surrounded by flowing ice, or when incorporated along thrusts.

Glacial meltwater erosion involves both mechanical and chemical processes. Mechanical erosion occurs primarily through fluvial abrasion by the transport of suspended sediment and gravel in traction within the meltwater. Locally, fluvial cavitation (the sudden collapse of bubbles within turbulent meltwater under high pressure) may also be important. Chemical erosion involves the removal in solution of rock and rock debris, especially in areas of carbonate lithology. Rates of chemical erosion beneath ice masses are high because of high flushing rates, the availability of large

Figure G6 The pyramidal peak or 'horn' is the product of glacial plucking on three or four sides of a mountain, here epitomized the Matterhorn (4,476 m) and Dent d'Hérens (4,171 m), Switzerland in this photograph. Rock faces provide an intermittent supply of angular supraglacial debris to the glaciers on the flanks of the mountain.

amounts of chemically-reactive rock flour, and the enhanced solubility of CO₂ at low temperatures.

To these three main processes we may add a fourth: the relatively poorly understood process of *subglacial sediment deformation*. Sediment deformation beneath ice sheets contributes to glacial erosion wherever there is a net removal of material from the bed during sediment deformation (Boulton, 1996).

Debris entrainment and transport

It is widely recognized that debris is incorporated mainly at the bed and on the surface of a glacier, and that the transport paths and textural character of glacial sediments are related to the dynamic and thermal characteristics of the glacier. In general terms, polythermal glaciers tend to carry a high basal debris load, and their surfaces rarely have a substantial cover of debris. In contrast, temperate glaciers, especially those in alpine terrain, normally carry little debris at the bed, but their surfaces commonly have extensive areas of supraglacial debris. The resulting sedimentary products can thus be used to infer the thermal and topographic regimes of the glacier.

The entrainment of debris at the bed, by a combination of pressure melting and refreezing (regelation), to create a basal debris layer is well-known from studies of both temperate and polythermal glacier margins (e.g., Knight, 1997) (Figure G7). Basally derived debris is subject to comminution at the ice/bedrock interface, and typically is dominated by clasts up to boulder-size, with subangular and subrounded shapes, faceted surfaces, and striations (if the lithologies are fine-grained) (Figure G8). Much clay- or silt-grade sediment is produced by abrasion. In contrast, debris that falls on the glacier surface as a result of frost shattering of the overlooking cliffs is generally very angular to angular, and the proportion of fines is small.

Ice deformation results in reorganization of the debris that is incorporated at the base and surface. In polythermal glaciers in Svalbard, three main modes of entrainment have been recorded in addition to regelation:

- (i) Incorporation of angular rockfall material within the stratified sequence of snow, firn, and superimposed ice (Figure G9(A)). This debris takes an englacial path through the glacier, and becomes folded. Near the snout the debris emerges at the surface on the hinges and upper limbs of the folds, producing medial moraines that merge toward the snout. The resulting lines of debris are deposited on the proglacial area in the form of regular trains of angular debris, as the glacier recedes.
- (ii) Incorporation of debris of both supraglacial and basal character within longitudinal foliation. This is particularly evident at the margins and at flow unit boundaries where the folding is commonly isoclinal. The folding has an axial planar relationship with the foliation. As these features melt out, "foliation-parallel ridges" form.
- (iii) Thrusting, whereby debris-rich basal ice (including regelation ice) and rafts of subglacial sediments are uplifted into an englacial position, sometimes emerging at the ice surface (Figures G9(B), G10). This material is more varied than rockfall debris, and reflects the substrate lithologies: typically poorly sorted sediment (diamicton) with striated clasts, and sandy gravel. As thrusts melt out, groups of roughly aligned hummocks are formed.

Figure G7 Deformed debris-rich basal ice zone (strongly layered), overlain by clean glacier ice, and underlain by basal debris released from the ice. Taylor Glacier, Dry Valleys, Antarctica. A frozen lateral melt-stream is at the bottom of the picture; glacier flow is toward the right.

Figure G8 Striated and faceted clast from Neoproterozoic diamictite (originally deposited as a basal till), Nordaustlandet, Svalbard.

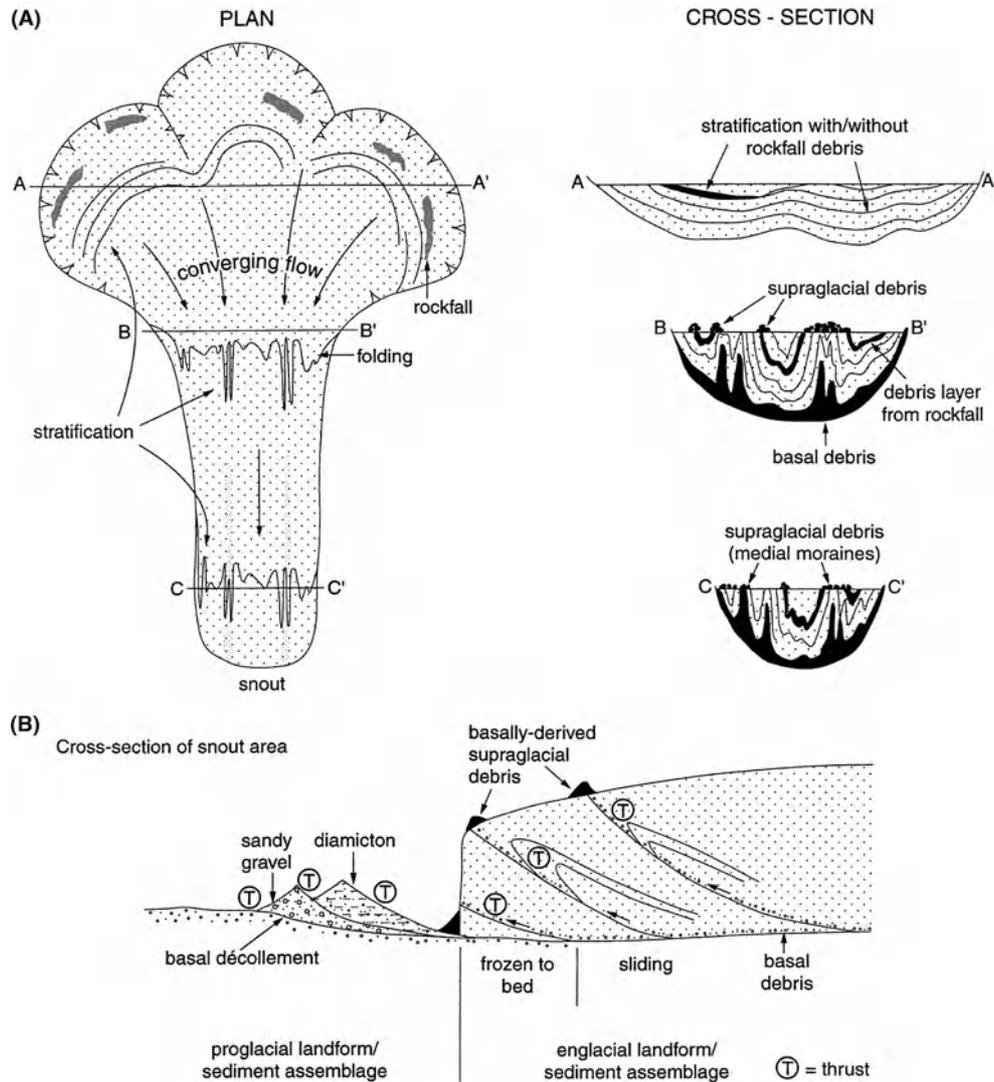

Figure G9 Conceptual models of debris entrainment. (A) Folding of supraglacial debris with stratified ice and of basal debris as a result of converging flow from multiple accumulation basins (simplified from Hambrey *et al.*, 1999). (B) Thrusting of basal, subglacial, and proglacial debris in a polythermal glacier as found in the maritime High-Arctic (after Hambrey *et al.*, 1997).

Of these mechanisms, only thrusting is well-known from temperate glaciers, but usually the amount of debris involved is insufficient to leave a landform imprint. The other mechanisms are likely to exist in temperate glaciers, but have not yet been documented, although it is well-known that shearing at the margins of alpine valley glaciers, and at the confluences of two flow units, incorporate debris.

Deposition

Glacial deposition involves the release of debris that has been transported on or within glacier ice. Debris is modified during transport primarily by basal processes (e.g., abrasion and quarrying during intra-clast collision, subglacial sediment deformation), and by water in subglacial, englacial, and supraglacial stream channels. Debris that follows a passive

transport path (supraglacially or englacially) tends to retain its primary characteristics.

Sediment may be deposited directly beneath the glacier or at its margins, or it can be transported significant distances from the glacier itself by other agents such as rivers or by iceberg calving. During release from the ice, numerous glacier-related processes, including reworking in marginal streams and lakes, debris flows and eolian activity, may modify sediment. Many glacial sediments may be related to specific glacial environments. For example, the temperate terrestrial glacier system is commonly regarded as being dominated by a mixture of basal (actively transported) and supraglacial (passively transported) sediment, with a strong element of glaciofluvial modification upon release (Figure G11(A)). Glaciers terminating in fiords produce a facies association that is also dependent on thermal regime. Temperate and polythermal

Figure G10 Thirty meter-high terminal cliff of advancing Thompson glacier, Axel Heiberg Island, Canada, showing debris-laden thrusts, and ice-debris apron in front. Note person for scale, slightly left of base of waterfall.

glaciers, such as those in Alaska and Greenland, respectively (Figure G11(B)), not only provide basal and supraglacial debris inputs, but also sediments released from subglacial streams emanating at or below water level close to the ice margin, sediment released from suspension over the whole depositional basin, and iceberg-rafted debris. The resulting facies associations reflect thermal regime, which primarily controls the balance between direct glacial deposition and fluvial inputs. For the coldest glaciers, terminating as ice shelves on the continental shelf, as in Antarctica today, direct glacial deposition is restricted to the grounding-line, the volume of meltwater sediments is limited, whereas biogenic sedimentation in the form of diatom ooze may become dominant (Figure G11(C)). Indeed, rather than releasing sediments, some ice shelves accrete saline ice at their base, trapping sediment, which is released only when the tabular icebergs, calved from the ice shelf disintegrate.

Glaciotectonism

Glaciotectonic deformation is now recognized as a widespread phenomena. Not only is deformation associated with internal processes, such as folding and thrusting, as noted above, but it is also transmitted subglacially and proglacially (e.g., Maltman *et al.*, 2000). Glaciotectonic deformation operates in any topographic setting, both during advancing and recessional phases, and involves all types of material, including frozen, saturated and dry unconsolidated sediments, as well as bedrock. Deformation may detach blocks of rock and sediment, occasionally hundreds of meters across, incorporating them into the ice by thrusting, or pushing them in front of the glacier. Faults and brecciated zones are common in such materials. Sediments may also be deformed in a ductile fashion, especially if wet and fine-grained. Beneath ice sheets, deformation may affect sediment and bedrock to depths of several hundred meters.

Reworking of glacial sediments

Glacial sediments are typically subject to syndepositional and post-depositional modification by fluvial, mass-movement, and eolian processes. In terrestrial settings, fluvial modification by proglacial streams is particularly important in temperate climates, and many temperate glaciers terminate at the head of large *outwash* or *sandur* plains composed almost entirely of reworked glacial sediments (Figure G12). Resedimentation by mass-movement processes is common in ice-cored terrain where water, released by the melting of buried glacier ice or permafrost, mixes with sediment to create *glacigenic sediment flows*. Eolian modification involves the redistribution by wind of smaller, readily entrained particles, particularly in more arid areas, creating *deflation surfaces* and *ventifacts*. The extent to which each of these processes operates is controlled to a great extent by the local topographic, meteorological and climatological conditions. Resedimentation by subaquatic gravity flows is also important in glaciomarine and glaciolacustrine environments, where large amounts of sediment may accumulate on relatively steep ice-contact slopes, which become unstable during recession.

Chemical processes

As noted above, glacial meltwater is often enriched in solutes. Mineral-rich waters may leave thin deposits of calcite, silica or iron oxides, especially on the lee side of bedrock obstacles.

Depositional landforms

Glaciers and ice sheets produce a huge variety of depositional landforms. These are commonly grouped according to their origin into ice-marginal and subglacial landforms (Hambrey, 1994; Bennett and Glasser, 1996; Benn and Evans, 1998).

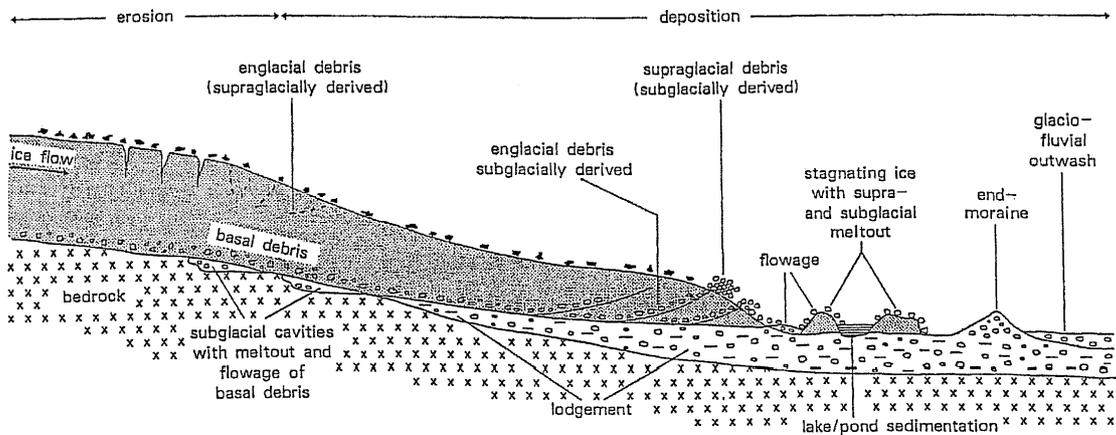

Ice-marginal landforms. Ice-marginal landforms can be produced by advancing, static or receding ice margins, as well as during seasonal fluctuations of an ice front. They may be deposited directly from glacier ice or be composed of facies previously deposited by other processes (Figure G13). Ice-marginal landforms are commonly used to reconstruct changes in glacier size, morphology and extent over time.

Glaciotectonic moraines encompass a broad range of different types of moraine formed by deformation of ice, sediment and rock. *Push moraines* (both seasonal and annual) are formed when a glacier flows into sediment and bulldozes material into a ridge. Other types of glaciotectonism include: thrust-block moraines, where large slabs of material are entrained and partially overridden; englacial thrust moraines, where material is elevated along thrusts as a result of longitudinal compression near the ice margin; and proglacial thrust moraines where compressive stresses from the glacier propagate into the foreland.

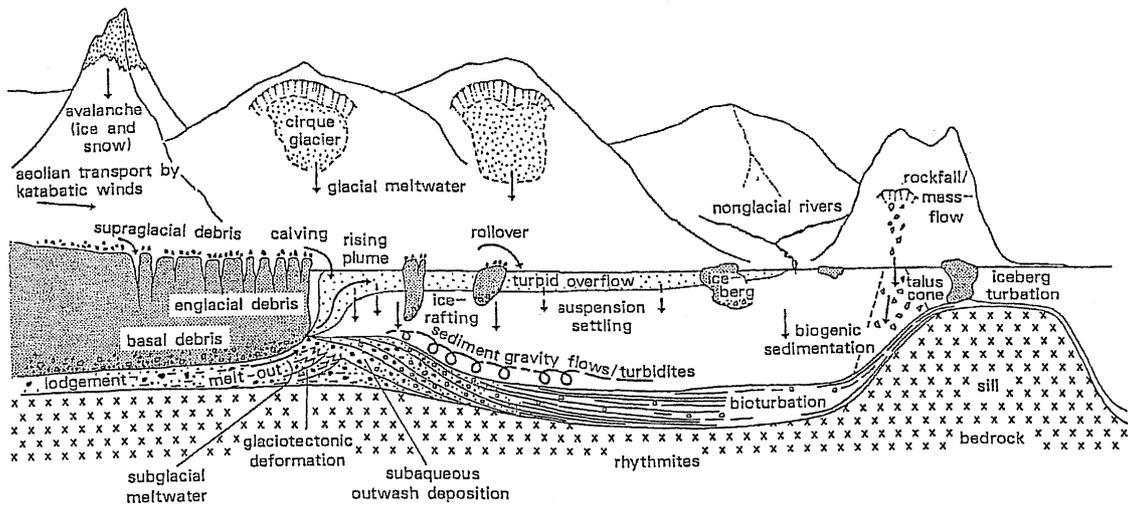

Dump moraines are formed at stationary or near-stationary ice fronts where debris accumulates along the margin or front of a glacier to form a ridge of sediment. The size of these features is controlled by ice velocity, debris concentration and the rate (if any) of marginal recession.

Ablation moraines (sometimes referred to as *ice-cored moraines*) form wherever ice melt is retarded beneath a cover of supraglacial debris (Figure G13). This supraglacial debris may be derived from rockfalls and avalanches in the accumulation area, often arranged in flow-parallel medial moraines, or it

Figure G12 Braided river system emanating from debris-covered Casement Glacier (left), southern Alaska. Small pits on the outwash plain are kettle holes arising from slow melting of buried ice blocks.

Figure G13 Ice-marginal landforms, especially ablation moraine, comprising a mixture of supraglacially and basally derived debris, Vadrec da Morteratsch, Switzerland.

may be composed of subglacial or englacial debris elevated to the ice surface by folding, thrusting or upward-directed flow lines in the ablation area. If the cover of insulating debris is irregular, as is commonly the case, irregular ridges and mounds of debris, often known as *hummocky moraines*, will develop as ablation proceeds. Although initially large and with a pronounced morphology, ablation moraines reduce dramatically in size as the ice-core melts and material is subject to debris flowage.

Outwash fans and *outwash plains* (or *sandar*, plur; *sandur*, sing.) are formed as glacial meltwater emerges from the glacier and sediment is deposited at or beyond the ice margin. Outwash fans form at stationary ice margins where meltwater is concentrated at a particular point for a length of time. Outwash plains are much larger features, formed where individual fans merge away from the glacier to create a braided river facies association (Figure G12). Characteristics of the glaciofluvial environment are braided river channels with rapidly migrating bars, terraces, frequent channel avulsions and the formation of *kettle holes* where sediment is deposited over buried ice.

Kame terraces are formed when sediment is deposited by meltwater flowing laterally along an ice margin. *Kames* are more fragmentary features, formed in a similar manner, but often in ice-walled tunnels and against steep valley sides. *Kame-and-kettle topography* is the term used to describe the landform-sediment assemblage often found on glacier forefields where there was formerly a high proportion of buried ice.

Subglacial landforms (sometimes referred to as *subglacial bedforms*) are produced beneath actively flowing ice. They provide information about former subglacial conditions, including ice-flow directions, thermal regime and paleohydrology. The most common of these is a family of ice-molded landforms, all of which are parallel to ice-flow. *Flutes* are low (typically <3 m), narrow (<3 m), regularly spaced ridges that are rarely continuous for less than 100 m. *Megaflutes* are taller (>5 m), broader and longer (>100 m) than flutes. *Mega-scale lineations* are much larger (tens of kilometers in length and hundreds of meters in width) that are often only visible when viewed on satellite imagery. *Drumlins* are typically smooth, oval-shaped or elliptical hills composed of a variety of glacial sediments. They are generally between 5 m and 50 m high and 10 m to 3,000 m in length. Drumlins normally have length-to-width ratios of less than 50. Their steeper, blunt end often faces up-ice and they are often found in large groups known as *drumlin swarms*. The origin of drumlins is unclear, but they have been ascribed to subglacial deformation, to lodgement, to the melt out of debris-rich basal ice and to subglacial sheet floods.

Ribbed moraines (also known as *Rogen moraines*) are large, regularly and closely spaced moraine ridges consisting of glacial sediment. They are often curved or anastomosing, but their general orientation is transverse to ice flow. They often show drumlinoid elements or superimposed fluting. Ribbed moraines may represent the fracturing of a pre-existing subglacial till sheet at the transition from cold- to warm-based, presumably during deglaciation.

Geometric ridge networks and *crevasse-fill ridges* are subglacial landforms that are not generally ice-molded. These features, composed of subglacial material, are low (1–3 m high) ridges that, when viewed in plan, show a distinct geometric pattern. The traditional explanation for these features is that they form by the squeezing of subglacial

material into basal crevasses or former subglacial tunnels, commonly during surges. Alternatively, geometric-ridge networks also form beneath glaciers as a result of the intersection of foliation-parallel ridges and englacial thrusts.

Eskers are glaciofluvial landforms created by the flow of meltwater in subglacial, englacial or supraglacial channels. They are usually sinuous in plan and composed of sand and gravel. Some eskers are single-crested, whilst others are braided in plan. *Concertina eskers* are deformed eskers, created by compression beneath overriding ice.

Bathymetric forms resulting from glacial processes

Erosional forms

Various erosional phenomena, mainly associated with grounded ice or subglacial meltwater are found in marine settings. The larger scale forms are filled by sediment and may be recognizable in seismic profiles (e.g., Anderson, 1999). *Submarine troughs* are found on continental shelves, and are genetically equivalent to fjords and other glacial troughs, but are generally much broader. The largest occur in Antarctica where they attain dimensions of over 400 km in length, 200 km in width and 1,100 m in depth. They are formed by ice streams and, where two streams merge, an *ice-stream boundary ridge* is formed. Steep-sided channels a few kilometers wide, carved out by subglacial meltwater and subsequently filled by sediment, are known as *tunnel valleys*. These are well-known from the NW European continental shelf around Britain, the Scotian Shelf off Canada, and in Antarctica. Icebergs can also cause considerable erosion as they become grounded on the seafloor. Large tabular bergs can scour the bed of the sea for several tens of kilometers, leaving impressions up to 100 m wide and several meters deep. *Slope valleys* are groups of gullies forming a dendritic pattern, and develop just beyond the ice margin, on the continental slope, as a result of erosion by sediment gravity flows emanating from sediment that accumulated at the ice margin. On continental shelf areas, where the ice repeatedly becomes grounded, and then releases a large amount of rain-out sediment, alternations of diamicton and *boulder pavements* may be observed. The pavements build up by accretion of boulders around an obstacle, by subglacial erosion, or as a lag deposit from winnowing by bottom currents.

Depositional forms

The morphology and sediment composition of subaquatic features, particularly in fjords and on continental shelves are less well-known than their terrestrial counterparts, but major strides have been made in identifying such features in the last two decades. As on land, depositional assemblages reflect the interaction of a wide range of processes.

Ice-contact features form when a glacier terminus remains quasi-stationary in water, particularly in fjords (Powell and Alley, 1997) (Figure G14). *Morainial banks* form by a combination of lodgement, meltout, dumping, push and squeeze processes, combined with glaciofluvial discharge; poorly sorted deposits are typical of such features. *Grounding-line fans* extend from a subglacial tunnel that discharges meltwater and sediment into the sea, and are typically composed of sand and gravel. Developing out of grounding-line fans are *ice-contact deltas* that form when the terminus

Figure G14 Tidewater glaciers in Harriman Fiord, southern Alaska. Glaciers such as this deliver large amounts of sediment, especially via subglacial streams to the marine environment, and sediment accumulation rates may be tens of meters per year.

remains stable long enough for sediment to build up to the surface of the fiord. Where a glacier becomes disconnected from the water body, alluvial sediments may prograde to form *fluviodeltaic complexes*, again dominated by sand and gravel. In addition to these large-scale forms (measured in 100s of meters), there are small-scale features (measured in meters or less), found particularly on beaches, such as iceberg tool-marks, ridges, depressions from melting of buried ice, bounce-marks, chattermarks and roll-marks. Icebergs can also churn up submarine sediment, particularly on shoals, producing iceberg turbates.

Depositional forms on continental shelves are best known from a combination of deep drilling and seismic profiling. Some, as in Alaska, are simply larger scale analogues of fiordal features, such as delta-fan complexes, but others form under floating tongues that are typical of the colder ice of the polar regions. These include subglacial deltas, till tongues, diamicton aprons and the immense (up to 400 km wide) trough-mouth fans. Other features are similar to those on land, including shelf moraines, flutes and transverse ridges.

Terminology and classification of glacial sediments

The terminology used to describe glacial sediment has always been in a state of flux, and the evolution of terms may be linked to progressive improvement of understanding glacial processes. For an objective study of sedimentary facies, a non-genetic classification of poorly sorted sediments is required, before process-related terms such as “till” are used. The terms *diamicton* (unlithified), *diamictite* (lithified) and *diamict* (both) are now well established for “a non-sorted or poorly sorted terrigenous sediment that contains a wide range of particle sizes” (Flint *et al.*, 1960). However, this definition hides a vast range of textures, and the literature abounds with conflicting

ideas about what constitutes a “diamicton”. A textural classification, based on the relative proportions of sand and gravel, has subsequently been developed (Hambrey, 1994) (Table G10).

The genetic terminology is perhaps even more confused. First, we need to define some widely used general terms:

Glacialigenic sediment: “of glacial origin”; the term is used in the broad sense to embrace sediments that have been influenced by glacier ice.

Glacial debris: material being transported by a glacier and thus in contact with glacier ice.

Glacial drift: all rock material in transport by glacier ice, all deposits released by glaciers, and all deposits predominantly of glacial origin deposited in the sea by icebergs, or from glacial meltwater.

For a more detailed process-based classification of glacial sediments, the recommendations of a commission of the International Quaternary Association are followed (Dreimanis, 1989; Hambrey 1994). Although somewhat out-of-date, this is the only scheme that has achieved a wide measure of consensus (Table G11). In this genetic classification, the key term is *till* (*tillite* where lithified). *Primary till* is defined as ‘an unsorted sediment with a wide range of grain sizes deposited directly from glacier ice, without subsequent disaggregation and flow’. Secondary tills are the products of resedimentation of glacial debris that has already been deposited by the glacier, with little or no sorting by water. Within these categories several varieties of till have been documented, although these represent end members in a continuous spectrum of depositional types (Dreimanis, 1989). Benn and Evans (1998: 386–399) have provided a concise review of the characteristics of tills, and the main types (with their textural characteristics) are:

Meltout till: deposited by slow release of glacial debris from ice that is not moving. Typically, meltout tills inherit the

Table G10 Textural classification of poorly sorted sediments (from Hambrey, 1994; modified from Moncrieff, 1989). In order to derive sediment name, percent of gravel is first estimated (horizontal axis) and then proportion or percent of sand in the matrix (vertical axis)

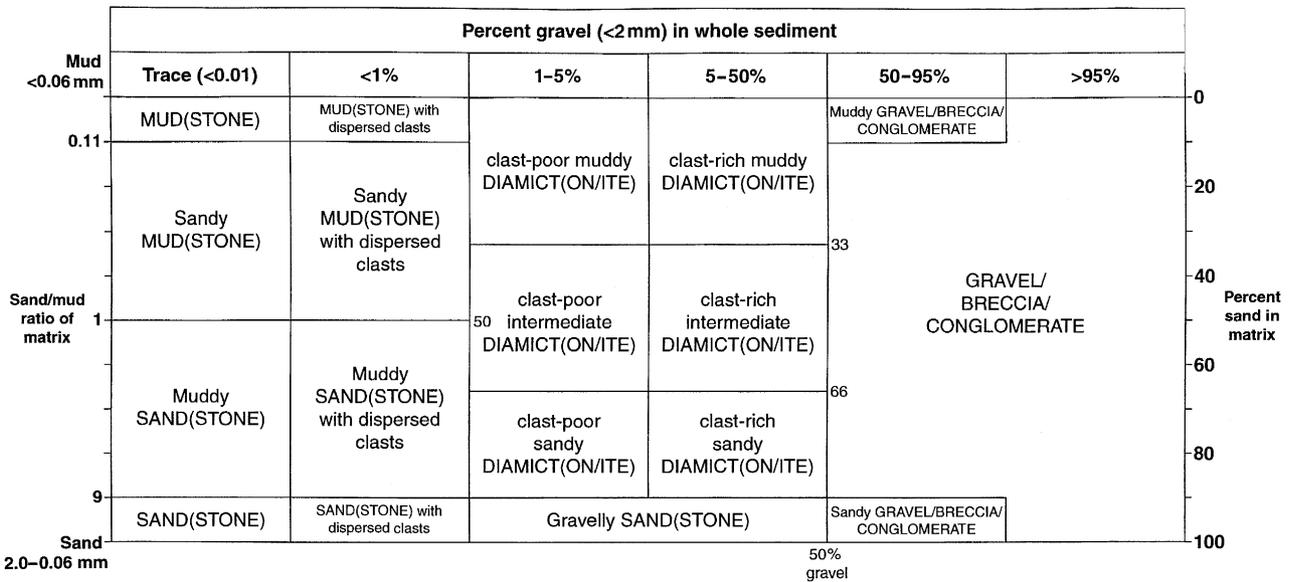

Table G11 Genetic classification of terrestrial glacial sediments (adapted from Dreimanis, 1989). The vertical columns are independent of each other and no correlation horizontally is implied. Not all combinations are feasible

Release of glacial debris and its deposition or redeposition			Depositional genetic varieties of till		
I Environment	II Position	III Process	IV By environment	V By position	VI By process
Glacioterrestrial	Ice-marginal Frontal Lateral	<i>A. Primary</i> Melting out Lodgement Sublimation	Terrestrial	Ice-marginal till Supraglacial till	<i>A. Primary till</i> Meltout till Lodgement till Sublimation till
	Supraglacial	Squeeze-flow Subsole drag	non-aquatic till	Subglacial till	Deformation till Squeeze-flow till
	Subglacial Substratum	<i>B. Secondary</i> Gravity flow Slumping Sliding and rolling			<i>B. Secondary till</i> Flow till

granulometry and particle-size distribution of the parent ice, so may be massive or layered, commonly with a strong clast orientation parallel to flow.

Lodgement till: deposited by “plastering” of glacial debris from the sliding base of a moving glacier by pressure melting or other mechanical processes. This process also normally produces a massive diamicton, although sometimes with anastomosing planar discontinuities resulting from shear (Figure G15(A)). A consistent flow-parallel clast orientation is evident in lodgement tills.

Basal till: embraces both the above.

Sublimation till: is released by sublimation direct from debris-rich ice in sub-zero temperatures. Texturally, this is a diamicton, but is a rare deposit, only found in a few arid parts of Antarctica.

Deformation till: comprises weak rock or unconsolidated sediment that has been detached by the glacier at its source and

subsequently deformed or disaggregated, and some foreign material admixed. Texturally, this is variable, often breccia-like; rafts of rock or sediment may be many meters in length.

Flow till: till which has been remobilized by gravity flowage, although better known as a *glacial sediment flow*. A degree of sorting into gravel-rich and gravel-poor components accompanies this process, and the clast fabric is weak and highly variable.

The above discussion refers primarily to terrestrial glacial sediments. There is no agreed genetic classification for glaciomarine sediments. The following terms, however, are commonly used:

Ice-proximal glaciomarine sediment: sediment that is released either from floating basal glacier ice or by continuous rain-out from icebergs, without subsequent winnowing by currents and waves; this embraces the term waterlain till which is no longer favored. Typically, this is a diamicton, either massive where

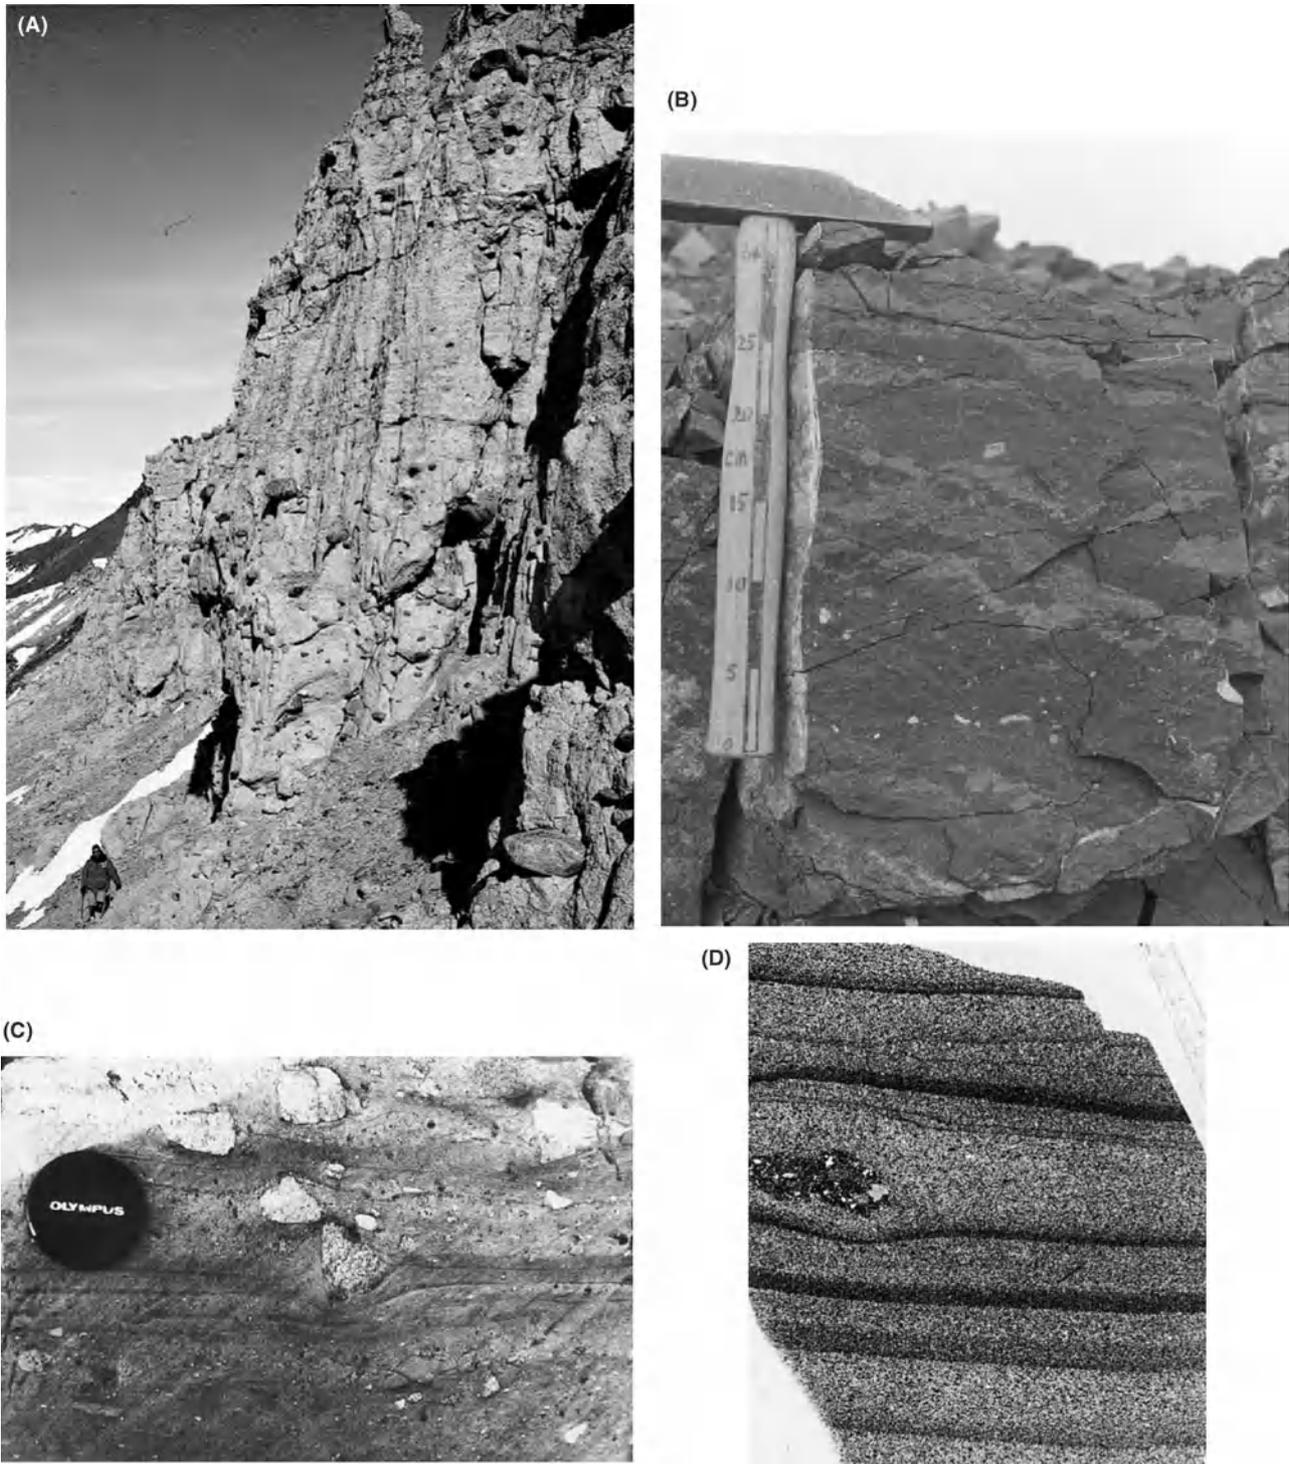

Figure G15 Some typical lithofacies from glacial environments: (A) Clast-rich massive diamicton interpreted as lodgement till, overlain successively by stratified diamicton of glaciolacustrine origin, and more massive diamicton, Sirius Group (Neogene), Shackleton Glacier, Transantarctic Mountains. (B) Clast-poor weakly stratified diamicton, interpreted as proximal glaciomarine sediment, Wilsonbreen Formation (Neoproterozoic), Backlundtoppen, Spitsbergen. (C) Dropstone-laminite, interbedded with diamicton from Paleoproterozoic Gowganda Formation, Whitefish Falls, Ontario; interpreted as cyclopsams and cyclopels (tidal), and subaquatic debris flows. (D) Thin section of laminated clay (dark) and sand/silt (light) with dropstone, Neoproterozoic Petrovreen Member, NE Spitsbergen; these couplets are typical of glaciolacustrine sediments, each pair formed in one year (a varvite).

iceberg rainout is dominant and continuous, or has a faint wispy stratification (Figure G15(B)). Clast fabrics are weak or random.

Ice-distal glaciomarine sediment: sediment that is released from icebergs, but subject to winnowing, and admixed with other marine sediment, including biogenic components. Texturally, this facies is sandy mud or muddy sand with dispersed stones, and in modern environments often rich in diatoms.

Iceberg turbate: sediment deposited on the seafloor that is subsequently reworked by grounded icebergs. The end product is commonly a massive diamicton with a heavily grooved upper surface.

Cyclopls (silt/mud couplets) and *cyclopsams* (graded sand/mud couplets): rhythmically laminated sediments derived from turbid overflow plumes from subglacial discharge, especially in fiords, typically producing two couplets a day according to the tidal cycle. If deposition is accompanied by ice-rafting, dropstone structures may be evident (Figure G15(C)).

Glaciolacustrine facies are similar to those in glaciomarine environments. In addition, lakes commonly have rhythmically laminated sands and muds called *varves* (or *varvites* if lithified), similar to cycloplsams and cyclopels, but with each couplet forming over one year. Sand laminae represent input to the lake during summer, and silt/clay represent settling out from suspension in winter. Iceberg debris, in the form of dropstone structures, may disrupt the laminae (Figure G15(D)). Other laminated sediments in lakes or the sea may be deposited from turbidity currents and also include dropstone structures. Differentiation of the processes responsible for the formation of laminated facies is challenging.

Facies analysis of glacial facies

The facies approach

Compared with other sedimentologists, glacial geologists have been rather slow in adopting the *facies* approach. However, it is now recognized that for objective treatment this approach must be used.

The first step is to describe the lithofacies found in a vertical section or core, using a wide range of criteria (texture, sedimentary structures, bed geometry and boundary relations, clast characteristics), and avoiding generic terms such as "till". Some authors use formal lithofacies codes (Eyles *et al.*, 1983), but this is thought by others (e.g., Hambrey, 1994; Miller, 1996) to be too inflexible and include interpretative elements. Here, we advocate that workers devise their own scheme to suit the distinctiveness of their sections. The next step is to group the lithofacies into facies associations that contain a set of attributes that will allow the depositional setting to be determined, such as glacioterrestrial or glaciomarine. On a regional scale, given sufficient three-dimensional exposure on land, or extensive seismic and borehole stratigraphy offshore, derivation of the *facies architecture* is a desirable aim, allowing one to address larger issues, such as basin evolution, ice sheet-scale fluctuations and sea-level changes. Representative facies associations from terrestrial, lacustrine, and glaciomarine settings are illustrated in Figure G16.

Glacial sediment/landform associations

The concept of *glacial sediment/landform associations* (the "landsystems" approach) is relatively new to glacial geology.

The approach rests on the assumption that at the large-scale it is possible to identify areas of land with common attributes, distinct from the surrounding areas, that can be related to the processes involved in their development (Benn and Evans, 1998). The landsystems approach was pioneered for glaciated terrain by Boulton and Paul (1976) in an attempt to identify tracts of land created by similar till-forming processes and therefore of similar geotechnical properties. The *glacial land-system* concept was then applied to former ice-sheet beds. Originally, three distinct landsystems were defined:

The subglacial landsystem, in which the dominant glacial sediment/landform associations are formed at the glacier bed.

The supraglacial landsystem, in which the dominant glacial sediment/landform associations are largely composed of a drape of supraglacial debris.

The glaciated valley landsystem, in which the dominant glacial sediment/landform association is that formed by mountain glaciation.

As the concept has developed, other landsystems have been added to this simple list. These include landsystems formed in proglacial and glaciomarine environments, as well as those found in settings where surge-type glaciers are common. It is also possible to relate landsystems to glacier thermal regime. Thus we can identify landsystems related to warm-based ("temperate"), polythermal and cold-based ("polar") glacier margins. A criticism of the landsystems approach is that it takes no account of spatial patterns of ice-sheet erosion and deposition, and how these vary during ice-sheet growth and decay. Elucidating these links remains a challenge for glacial geologists.

Glacial sediments in the geological record

Identification of glaciation in the geological record

The recognition of glacial facies in the rock record is of fundamental importance to paleoclimatological and paleo-environmental reconstruction. Even where exposure is good, evidence for glaciation may be equivocal as, for example, in alpine regions where mass-movement and fluvial processes may overprint direct evidence for glacial deposition, or in those areas where tectonic deformation has overprinted depositional features. However, detailed analysis may yield sufficient criteria that, taken together, could form the basis of a glacial interpretation. Table G12 lists the principal criteria for establishing the glacial origin of a diamict-bearing succession.

Preservation potential of glacial successions

Tectonic setting is the principal control on whether a glacial succession is preserved. Eyles (1993) has provided a detailed review of the wide range of tectonic settings suitable for preservation. Intracratonic basins, rifts, forearc and backarc basins, and subsiding continental shelves are particularly suitable receptacles for preservation of a glacial record, especially if those sites are first buried and later uplifted and exposed. Except for deposits of Quaternary age, land areas are less likely to preserve glacial sediment, as continued erosion tends to remove traces of glaciation. There are, however, notable exceptions in the geological record.

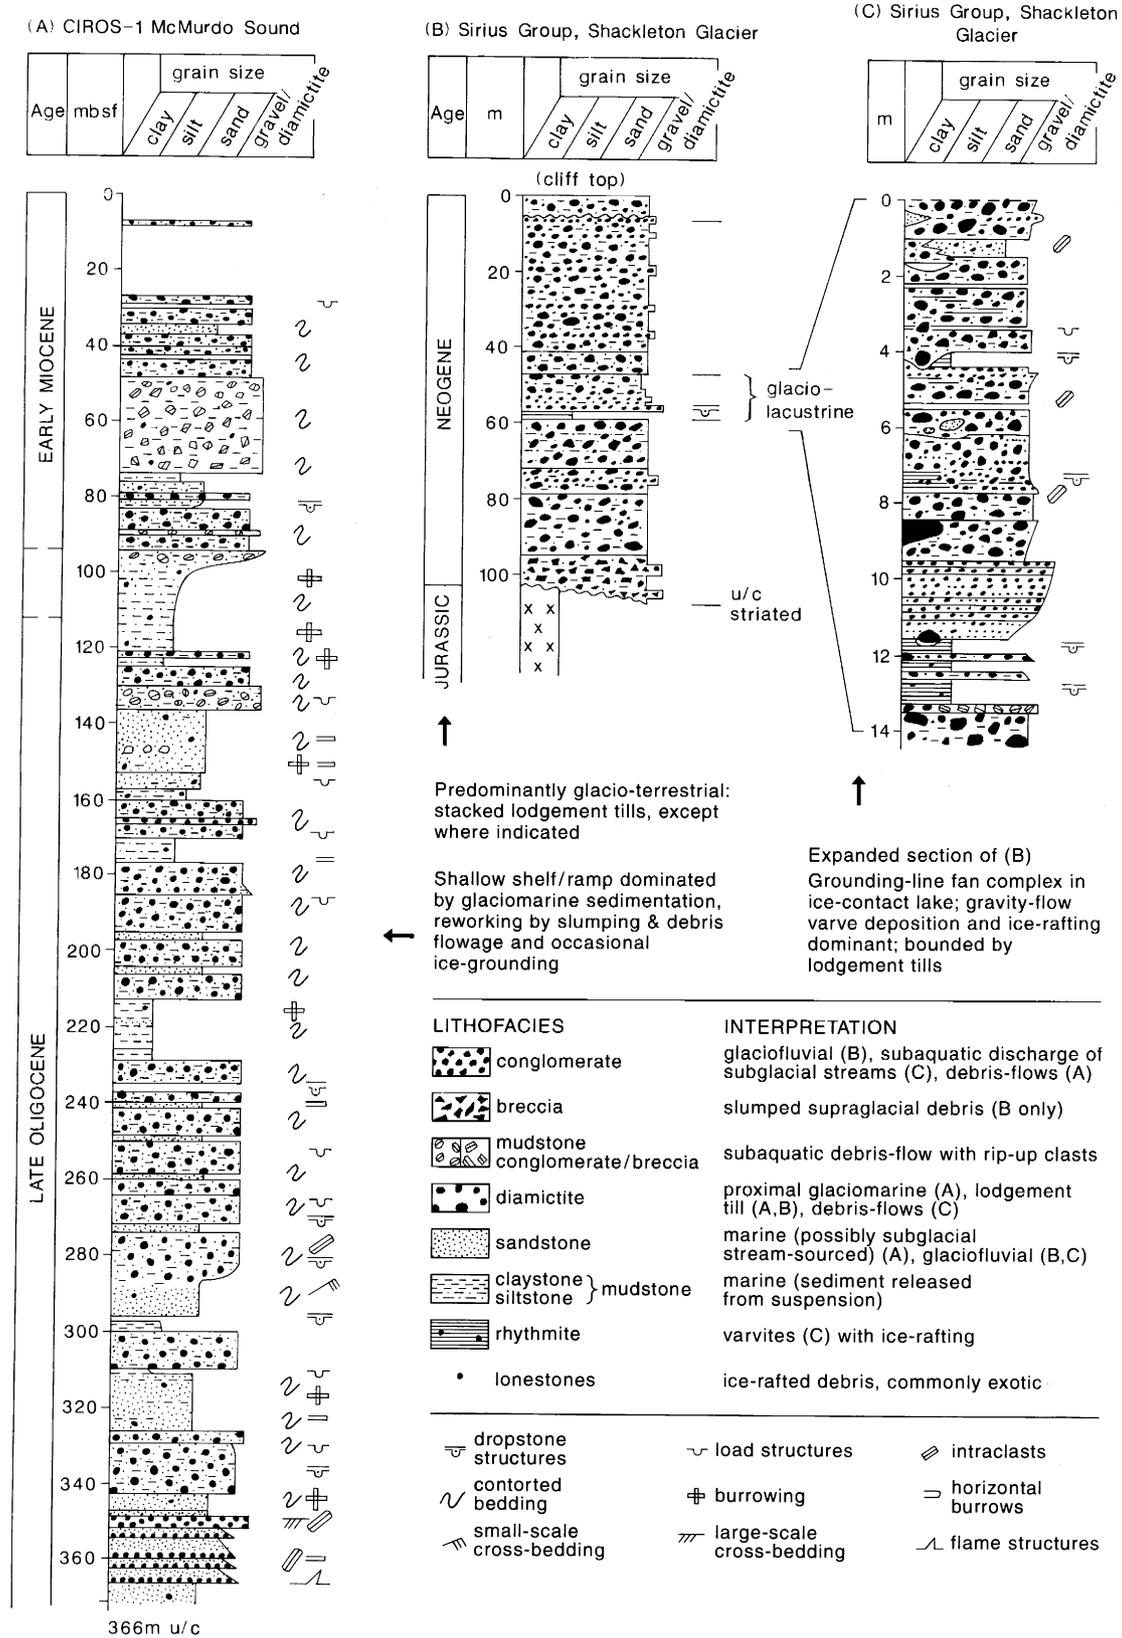

Figure G16 Characteristic facies associations from: (A) Late Oligocene-Miocene proximal continental shelf facies association, upper part of CIROS-1 drill-core, McMurdo Sound, Antarctica, illustrating deposition in a subsiding rift-basin, with occasional ice-grounding events (data from Barrett, 1989). (B) A terrestrial setting dominated by repeated lodgement till deposition, represented by stacked diamictites; Sirius Group (Neogene), Shackleton Glacier, Transantarctic Mountains (cf. Figure G15(A)). (C) Glaciolacustrine association in middle of section shown in B, illustrating ice-proximal deposition dominated by slumping and debris-flowage of rain-out diamicts and varve-sedimentation.

Table G12 Criteria for establishing a glacial origin of diamict-bearing successions for different environments (from Hambrey, 1999)

(a) Evidence for terrestrial glaciation

Abraded surfaces

- Grooved striated and/or polished surfaces
- Crescentic gouges, friction cracks, chattermarks
- Striated boulder pavements
- Roches moutonnées
- Nye channels, “p-forms”

Diamict and muddy boulder gravel beds with:

- Little or no stratification
- Irregular thickness, typically several m (but may be up to 10s of m)
- Preferred clast orientation
- lenses of sand/gravel (glaciofluvial)
- Shear structures parallel to depositional surface

Depositional landforms

For example, moraines, eskers, but rarely recognisable in pre-Quaternary successions

Association with extensive sheets of sand and gravel—inferred glaciofluvial origin

(b) Evidence of glaciomarine/glaciolacustrine deposition

- Massive or stratified diamicts, often tens to hundreds of m thick, with gradational boundaries
- Dropstones in stratified units
- Random clast fabric
- Slight sorting or winnowing at top of beds, to give lag deposits
- Association with *in situ* fossils
- Association with rhythmites (varves in lakes; tidal rhythmites in fjords; turbidites in both)
- Association with resedimented deposits (subaquatic gravity flows)

(c) Evidence common to both environments

Clasts

- Range in size up to a few meters
- Range in lithologies, reflecting terrain over which ice flowed
- Constant mix of clasts over wide area common
- Range in shape from very angular to rounded (e.g., subangular to subrounded predominant in subglacial debris), sometimes influenced by prior transport history
- Surface features include facets and striations from transport within the basal ice zone, and flat-iron or bullet-nosed shapes from persistent glacial transport
- Fragile clasts survive well
- Calcareous crusts in some deposits

Grains

- Surface of quartz grains show typical fracture characteristics
- Surface of quartz grains show chattermarks
- Unstable (ferromagnesian) minerals remain relatively unweathered

(d) Other evidence of cold climate

- Ice wedge casts
- Sorted stone circles, polygons and stripes
- Solifluction lobes
- Association with lithified loess (loessite)

been undertaken (e.g., Eyles, 1993; Deynoux *et al.*, 1994; Crowell, 1999). For the Quaternary Period there is a vast literature to chose from.

The oldest known glacial sediments are of late Archean age (2,600–3,100 Ma) from South Africa. Extensive Paleoproterozoic (2,500–2,000 Ma) tillites are known from South Africa, Australia and Finland. The most prolonged and globally extensive glacial era took place in Neoproterozoic time (1,000–550 Ma). Evidence for glaciation occurs on all continents, leading to the “snowball earth” hypothesis that envisages the Earth being totally ice-covered. Sporadic Early Proterozoic glacial events are best represented by the late Ordovician to early Silurian deposits and erosional features of Gondwana, notably in Africa. The most prolonged and extensive phase of glaciation during the Phanerozoic Eon spanned about 90 Ma of the Carboniferous and Permian Periods, affecting all Gondwana continents. Finally, after a phase of global warmth, with little evidence of ice on Earth, the Cenozoic glaciations began in Antarctica at the Eocene/Oligocene transition (35 Ma). Northern Hemisphere glaciation followed, with minor ice-raftering events recorded in the North Atlantic from late Miocene time, until full-scale glaciations began in late Pliocene time (2.4 Ma).

State-of-the-art and future prospects

Considerable strides have been made in the last three decades in understanding glacial processes, which, when combined with rigorous facies analysis, have led to well-founded reconstructions of past glacial environments (see, e.g. compilations and reviews by Dowdeswell and Scourse, 1990; Hambrey, 1994; Menzies, 1995, 1996; Bennett and Glasser, 1996; Benn and Evans, 1998). Major advances in recent years have included: (i) elucidation of oceanographic and sedimentary processes in the glaciomarine environment; (ii) the recognition of the importance for ice dynamics of soft, deformable beds (particularly beneath large ice streams in the Antarctic); (iii) the role played by glacier surges in terrestrial glacier sedimentation; (iv) linking deformation in glacier ice, for example, folding and thrusting, to facies and landforms in terrestrial settings; and (v) establishing the relationship between glacier fluctuations and climatic change. These advances have provided the means for enhanced evaluation of Quaternary and ancient glacial sequences, but there remain considerable opportunities to undertake such work. Several important questions and controversies remain: what determines the nature of the glacier bed; how do conditions at the bed influence long-term dynamics and stability of ice sheets; what is the role of glaciotectonics in the generation of landforms; how may proximal glaciomarine sequences, that may not provide clear indications of water-depth, be reconciled with sequence stratigraphy; and how do sediment facies associations vary according to climatic and topographic regimes?

Michael J. Hambrey and Neil F. Glasser

Earth's glacial record

Far more is known about the Quaternary glaciations than all previous glaciations put together, even though some of those earlier events were equally dramatic in terms of scale. Since the International Geological Correlation Programme compiled an inventory of all known pre-Quaternary glacial sequences (Hambrey and Harland, 1981), several detailed syntheses have

GLAUCONY AND VERDINE

Glaucony

Glaucony, a general term introduced by Odin and Létolle (1980) to represent a depositional facies, corresponding to sand-sized green glauconitic grains regardless of their mineralogical structure, consists of 2 : 1 layered, potassium and iron-rich, dioctahedral minerals with a high $\text{Fe}^{3+}/\text{Fe}^{2+}$ ratio. Glauconitic grains generally occur as light to dark green pellets.

Glauconitization is characterized by the formation of a glauconitic precursor, corresponding to a K-poor and Fe-rich smectite. Maturation includes progressive incorporation of potassium and iron and change of mineralogical structure toward an end member constituted by a non-expandable, K-rich glauconitic mica (Odin and Matter, 1981; Odin and Fullagar, 1988), namely glauconite (Burst, 1958; Hower, 1961). Common substrates of glauconitization include microfossil tests, carbonate grains, fecal pellets, and rock fragments.

Several types of glaucony can be identified based upon mineralogical structure and chemical composition. X-ray diffraction patterns from well-ordered, highly-evolved glauconite reveal sharp and narrow (001) reflections at 10Å (illite-type clay mineral). A predominantly ordered structure is also indicated by well shaped (111-) and (021) reflections, and high-intensity (112) and (112-) reflections of comparable size to the (003) peak. Poorly evolved glaucony is structurally disordered, with broad peaks between 12Å and 14Å, a small number of diffractions and low-intensity (112) and (112-) peaks.

Four stages of evolution of glaucony (nascent, slightly evolved, evolved and highly evolved), each reflecting specific morphological habits, can be differentiated on the basis of potassium content of the green grains (Odin and Matter, 1981). K_2O generally shows a direct correlation with other attributes, such as the color of grains. K-poor, nascent (K_2O = 2 percent to 4 percent) and slightly evolved (K_2O = 4 percent to 6 percent) glaucony generally has a pale to light green color, with a few exceptions, and generally shows obvious traces of the primary substrate of glauconitization. In contrast, evolved (K_2O = 6 percent to 8 percent) and highly evolved (K_2O > 8 percent) glaucony, where substrate has been completely dissolved, is green to dark green and display characteristic fractures (*craquelures* of French geologists) at grain surfaces. Incorporation of iron mostly predates any potassium uptake into the structure of glauconitic minerals, as shown by high (>15 percent) Fe_2O_3 values also in the least evolved, K-poor samples. However, the direct correlation between K_2O and Fe_2O_3 observed within evolved and highly evolved glaucony, combined with the characteristic higher paramagnetic susceptibility of the most evolved samples, indicate that additional

Fe₂O₃ can be incorporated as potassium begins to enter the smectite structure of glaucony.

Glauconitization typically occurs in submarine, low-energy conditions, under slow sedimentation rates, within confined microenvironments at the interface between oxidizing seawater and slightly reducing interstitial water. Typical depths for glauconitization are comprised between 50 m and 500 m, with temperatures below 15°C. In modern environments, authigenic glaucony typically develops on the outer margins of continental shelves and adjacent slope areas. Rapid burial limits sediment residence time in the appropriate sub-oxic redox regime, preventing glaucony evolution. The maturity of glaucony thus reflects mostly the duration of nondeposition before burial. Present-day forming glaucony is a poorly evolved (nascent to slightly evolved) glauconitic smectite. Glaucony can undergo more or less pronounced modifications due to changes in local subsidence, terrigenous supply, and other factors, such as availability and abundance of iron, pH/Eh, and size and composition of substrates.

Despite its importance, the origin of glaucony is not fully understood and considerable debate exists about both the nature of the chemical reactions involved and the parameters that control its development. The major models of glauconitization include the layer lattice theory of Burst (1958) and Hower (1961), the *verdissement* theory of Odin and Matter (1981) and the two-stage evolutionary model of Clauer *et al.* (1992). All these models involve derivation of the constituents ions from both parent sediment and seawater.

In common usage glaucony is depicted as an autochthonous constituent of marine sediments. Since the first half of this century, glaucony has been regarded as one of the most reliable indicators of low sedimentation rate in marine settings, and glaucony-bearing horizons have been considered as diagnostic of transgressions, because of their presence in lower parts of transgressive/regressive cycles. Glaucony has been commonly reported from condensed sections (Loutit *et al.*, 1988), in association with phosphate grains and abundant fossils. Glaucony may also occur as a coating and incrusting film facies, associated with hardgrounds or burrowed omission surfaces.

Despite the widely held concept that the accumulation of glaucony generally takes place in open-marine environments and far from zones of active sedimentation, preferably during long periods of sediment starvation due to relative sea-level rise (Odin and Fullagar, 1988), glaucony is commonly encountered within a variety of deposits in the rock record. Penecontemporaneous remobilization of the green grains by storms, tidal currents and waves, or reworking caused by subaerial shelf exposure during relative sea-level fall are likely to lead to important concentrations of allochthonous glaucony in a variety of environments poorly suited to glauconitization, such as nearshore, lagoonal, estuarine, incised-valley and turbidite systems, and even alluvial plains.

A reliable interpretation of glaucony-bearing deposits thus requires that spatial distribution, maturity, and genetic attributes of glaucony be determined. This implies the evaluation of autochthonous versus allochthonous glaucony, with a further division of allochthonous glaucony to parautochthonous (intrasequential) versus detrital (extrasequential). The integration of sedimentological, petrographic and mineralogical studies provides a comprehensive framework to differentiate autochthonous from allochthonous glaucony (Amorosi, 1997). Criteria that might be useful in recognizing

an allochthonous origin of glaucony include: (i) association with nonmarine deposits; (ii) selective spatial distribution of grains; (iii) high degree of sorting and roundness; (iv) absence of fractures in the most evolved samples, since such features represent zones of weakness that are likely to facilitate mechanical breakdown of grains in the case of prolonged transport or reworking.

The distinction between parautochthonous and detrital glaucony can be sometimes performed by radiometric dating. More commonly, it requires that compositional attributes of glaucony be matched against those of putative sources. The combination of factors that primarily control glaucony development is unique during each transgressive–regressive cycle, and glauconies from distinct parent rocks generally have different maturity and carry unique geochemical and mineralogical fingerprints.

Glaucony is a valid tool for the understanding of depositional cyclicity in the sedimentary record (Amorosi, 1995). Stratigraphically condensed intervals, interpreted to have formed during prolonged breaks in sediment accumulation at sequence scale, may include up to 90 percent autochthonous glaucony. Within these condensed sections, glaucony abundance may show rhythmic fluctuations, with maximum concentration near the base of each cycle and a systematic upward decrease. In these instances, the burrowed, glaucony-rich cycle boundaries correspond to marine flooding surfaces, and the vertically stacked cycles reflect short term sea-level fluctuations, at the scale of parasequences or parasequence sets (Amorosi and Centineo, 2000). Although autochthonous glaucony is most commonly associated with condensed sections and marks the major marine flooding surfaces within the transgressive systems tract, the green grains may be present at any site of the third-order depositional sequence. Parautochthonous glaucony can be widespread throughout the sequence, generally showing lower concentration and maturity than its autochthonous counterpart. Detrital glaucony is present mainly within falling-stage and lowstand deposits, its concentration and composition depending on the characteristics of the source horizon.

Radiometric dates of K-rich glauconies have been widely used to determine the depositional age of sedimentary rocks, and have provided numerous age constraints for the calibration of the relative time scale in strata lacking reliable high-temperature chronometers (Odin, 1982). Although glaucony supplies 40 percent of the absolute-age database for the geological time scale of the last 250 million years, radiometric dating of glaucony often presents large practical limitations, because glaucony can be affected by tectonics, alteration and diagenetic effects, and K-poor glauconies and (to some extent) evolved glaucony are likely to provide apparent ages that are significantly different from the actual age of glaucony.

Verdine

Verdine is a 1 : 1 layered, trioctahedral, 7Å iron-rich silicate, known for long under the name berthierine, but also referred to as phyllite V or odinite. In terms of color and morphology, the verdine facies is similar to and often visually indistinguishable from the glaucony facies. Verdine minerals, however, differ from glauconitic minerals in their mineralogical structure (major peaks at 7.2Å and 14Å) and chemical composition (contain significantly less K₂O than glaucony).

As with glauconitic minerals, minerals of the verdine facies form in marine settings near the sediment–water interface, under conditions of low sedimentation rates and iron availability (they contain iron in both its reduced and oxidized states). The environment of verdine formation, however, is different than that for glaucony, corresponding to warmer, tropical (low-latitude) settings, with water temperature near or greater than 25°. Verdine is abundant at shallower depths than glaucony (15 m to 60 m), and has been observed to replace glaucony on present continental shelves at about 60 m depth (Thamban and Rao, 2000). Verdine generally occurs in proximity of river mouths, which largely contribute the iron needed for verdine formation (Odin and Sen Gupta, 1988).

Verdine is a newly distinguished facies that has been reported from less than 20 locations in the world (Rao *et al.*, 1995). However, most of the occurrences are restricted to Holocene deposits from tropical oceans, and verdine is very rarely present in the rock record. Similarly to glaucony, verdine is abundant in coincidence with condensation intervals. To date, the only sequence stratigraphic interpretation for verdine deposits is the one by Kronen and Glenn (2000). More work thus is needed to constrain the range of occurrence of verdine in the stratigraphic record.

Summary

Glaucony is one of the most reliable indicators of low sedimentation rate in marine settings and is a potentially powerful tool for basin analysis and stratigraphic correlations, because of its occurrence within stratigraphically condensed intervals formed during major transgressive events. However, the presence of glaucony in the record is not diagnostic *per se* of sediment starvation and transgression.

Glaucony can provide useful information only if the variability of its physicochemical properties and spatial/temporal characteristics are taken into account. This approach requires that the following types of grains be differentiated: (i) low-maturity (K-poor) versus mature (K-rich) glaucony; (ii) autochthonous versus allochthonous glaucony; (iii) intra-sequential versus extrasequential glaucony. Glaucony characterization should be performed by integrated mineralogical and geochemical investigations. Caution should be taken when interpreting glaucony-rich deposits based upon visual estimates of the green grains.

Verdine is visually indistinguishable from glaucony, but can be easily identified by its peculiar mineralogical structure and chemical composition. As with glaucony, verdine is concentrated in relatively condensed sections, although it appears to form at shallower depths (<50 m) than glaucony (50 m to 500 m), under strongly river-influenced conditions. The geological significance of the verdine facies is not fully understood, due to its extremely low abundance in the rock record.

GRADING, GRADED BEDDING

Graded bedding (Bailey, 1930) characterizes a clastic sedimentary deposit if there is a progressive upward change in the mean, maximum, or modal grain size. If the particle-size variation is repetitive rather than progressive, then the deposit is *stratified* (>1 cm scale) or *laminated* (<1 cm scale), but not necessarily graded. Stratified or laminated beds may also be

graded if the average particle size changes progressively upward at a scale exceeding that of single laminae; this is the case in graded turbidites containing *Bouma sequences*. Graded beds range in thickness from ~1 cm to many meters. The thickest graded beds are so-called “megaturbidites” which may be thicker than 100 m (Labaume *et al.*, 1985). Thick graded beds may be composed of gravel and sand or predominantly mud (Weaver and Rothwell, 1987). The term “grading” should not be used to describe gradual changes in rock type across-bedding planes. Instead, it is better in such cases to refer to *gradational bed contacts*.

Graded bedding may be *normal*, with an upward decline in particle size, or *reverse* (sometimes called *inverse*) if there is an upward increase in particle size. In some conglomerates, reverse grading at the base of a bed passes upward into normal grading (Walker, 1975). Graded bedding must be distinguished from so-called *upward fining* or *upward coarsening* successions, which involve many beds and generally more than one facies (Nichols, 1999, pp. 42–43). Because normal grading is much more common than reverse grading, its presence is often used for *way-up determination*.

Graded beds are commonly the result of deposition from short-lived *events* that introduce sediment by downslope transport, offshore transport, or flooding. Examples are *turbidity currents*, storms on shallow-marine shelves, and overbank flooding of rivers. If the energy available for transport increases during the depositional event, then reverse grading may result. Alternatively, reverse grading may result from *grain interaction* (i.e., collisions and near-collisions) in a basal grain-rich layer sheared along by the overriding current (Bagnold, 1956), or by downward percolation of finer particles through coarser fractions during near-bed shearing (Allen, 1984, p. 157).

The normal grading that characterizes most turbidites (Allen, 1984, p. 404) has been interpreted to result from a progressive decline in the carrying capacity of the current for all size fractions initially suspended in the flow (Hiscott, 1994). This decline in capacity occurs at each point along the transport path, and is ascribed to the temporal deceleration of a waning flow (Kneller, 1995). Alternatively, depositing turbidity currents can produce normally graded beds as they pass over a fixed point if there is a lateral size grading from the front to the rear of the flow (Walker, 1965). The lateral grading of the suspended load develops because the body of turbidity currents moves faster than the head of the flow on basin slopes. The head does not grow unchecked as suspension from the body of the current overtakes it. Instead, the rate of body flow into the head region is balanced by loss of suspension from the wake at the back of the head. This ejected material settles back into the flow top according to fall velocity, with the coarsest grains settling into the body nearest the head and the finest grains returning far behind the head, leading to lateral size grading in the flow.

Kneller (1995) modeled the development of grading in turbidites depending on whether flow velocity at a single site decreases, remains steady, or increases with time (temporal deceleration and acceleration); and whether velocity decreases, remains uniform, or increases along the transport path (spatial deceleration and acceleration). Five combinations of spatial and temporal acceleration and deceleration are predicted to generate deposits with distinctive grading profiles (Figure G17). This theoretical treatment applies whenever transport velocity changes systematically through time or along the transport path, and is not limited to turbidites.

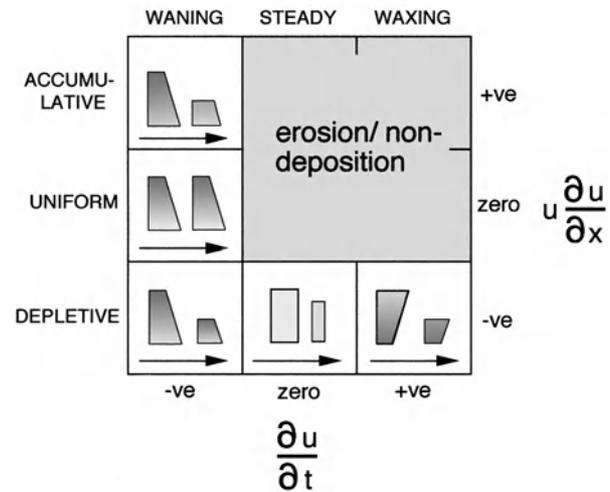

Figure G17 Acceleration matrix where u/t is temporal acceleration at a fixed point, and $u \cdot \partial u / \partial x$ is spatial acceleration in the downflow direction. Three combinations of these variables produce normal grading, and one produces reverse grading. Arrows point downflow. Reproduced by permission of Ben Kneller (Kneller, 1995).

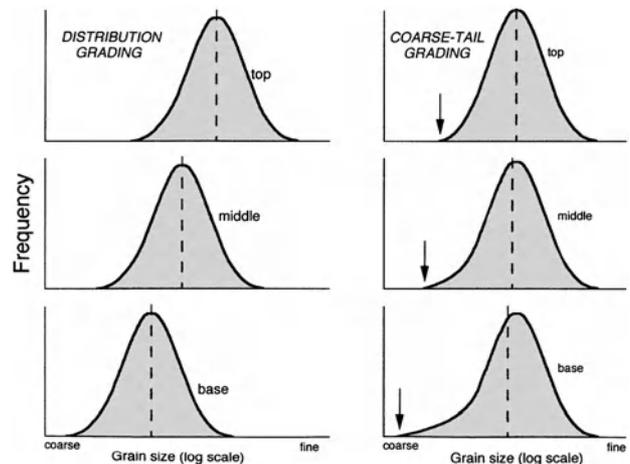

Figure G18 Vertical changes in grain-size distributions for beds showing *distribution grading* (left) and *coarse-tail grading* (right). The dashed lines indicate the mean size. An alternative type of coarse-tail grading would have a symmetrical (bell-shaped) basal sample with no tail of coarse material, and overlying size distributions truncated at their coarse end.

Normal grading can involve the entire size population (*distribution grading*) or only the coarsest 1 percent to 5 percent of the population (*coarse-tail grading*; Middleton, 1967). In distribution grading, there is a progressive shift to finer sizes, so that central measures like mean and modal size clearly reflect the grading (Figure G18). In coarse-tail grading, the percentage of the coarsest grains, and the maximum size, both decrease upward. However, the mean size decreases only very slightly and the mode remains unchanged. Coarse-tail grading is best developed in the deposits of high-concentration turbidity currents.

Although graded bedding is generally used to describe upward changes in grain size, it is permissible to extend the concept to compositional grading, for example in pyroclastic deposits (Cas and Wright, 1987, p. 194). White *et al.* (2001) describe reverse grading in marine pyroclastic deposits, formed because larger pumice takes longer to become saturated with water (and sink) than smaller particles.

The term “grading” is generally used to describe vertical changes in average grain size. However, it is acceptable to refer to *lateral grading* if the grain size changes systematically along or across the transport path.

GRAIN FLOW

Perhaps the most familiar example of a granular material is the sand on a beach, which by itself clearly illustrates the dual solid/fluid nature of a granular material. When walking on the beach the sand easily supports your weight like a solid material. Yet, a handful of sand will run out your fingers as if it were a liquid. As it runs out, the same sand will form a pile with sloping sides that shows that material can support weight (at least up to a point) and thus has once again, assumed a solid behavior. Granular flow concerns this intermediate fluid-like movement of a material consisting of solid particles that in other circumstances will behave as a solid. This fluid-like behavior is completely a result of the particulate nature of the material. While the interstitial space between the particles is filled with some sort of fluid such as air or water, there are many situations for which the fluid has no significant effect on the flow behavior.

The particles interact by the elastic deformation of frictional contacts between each particle and its neighbors. The area of these contacts is a very small fraction of the surface area of the particles and as a result the bulk granular material will be much softer than the material that makes up its constituent particles. Any force applied to the bulk material is distributed between the particles and supported across the contacts. However, the force will seldom be distributed evenly. Instead, networks of highly loaded particles known as *force chains* will support the majority of the force, while neighboring particles will experience little or none of the force. Force chains were first observed by Drescher and de Josselin de Jong (1972).

When will the material behave like a solid and when will it behave as a fluid? First of all, a fluid is classically defined as a material that cannot withstand a shear force, hence a classical fluid-like movement is a shear motion (one with velocity gradients) that comes about in response to a shear force. Imagine now that a force is applied to the material, such as the weight of your foot or gravity which makes the material run out between your fingers. Basically, if the particle contacts can support the force, the granular material will behave as an elastic solid and if not, the contacts will break and the material will flow. But it is not simply a function of the magnitude of the applied force as clearly a much larger force is applied by walking on a material than is applied by gravity as the same material flows from your hand. The difference between the two cases lies in their different configurations. When resting on the beach the sand distributes your weight to the particles beneath it. Between your fingers nothing supports the weight and it flows freely.

To induce flow, it is usually necessary to first decrease the particle concentration or to move the particle centers apart increasing the interstitial void space. This process is known as *dilatation* and can be observed while walking on a wet beach; even though the sand still behaves as a solid, it will dilate under the pressure of the footfall which will suck water into the increased pore space, causing an easily seen local drying of the surface in the area around the foot. The first step in inducing flow is to force this dilatation which generally requires doing work against the applied forces. Thus, unlike a normal fluid, one must first force a granular material to yield before flow can occur. This yield determines the slope of the sides of a granular

pile which is known as the *angle of repose* ($q.v.$); steepening of the slope beyond the angle of repose will cause yield and the surface material will flow until the slope is equal to or slightly gentler than the angle of repose.

When static, the majority of the force is carried by force chains and when the material begins to flow, the particles in the force chain will move as a unit. In this way, flow is possible while particles remain locked at the same relative positions to their neighbors in the chain. This flow state is particularly likely at large concentrations and for particles with angular shapes whose protrusions may lock together giving extra strength to the chain. But even spherical particles can be held together by frictional forces and flow in the same manner. The life cycle of a force chain in a shear flow may be likened to that of a pole-vaulter's pole. The chain is formed as the shear flow forces particles together. It will start nearly horizontal, and be compressed by the shear motion initially generating horizontal forces. However, the shear motion will cause the chain to rotate until it is oriented vertically and exerts a nearly vertical force. Rotating beyond the vertical eventually causes the chain to collapse. A new chain then forms and the cycle repeats. As the direction of force rotates with the chain, both shear and normal forces are generated. Now, the average force generated depends on the degree to which the chain is compressed which is largely a function of the particle concentration and in particular, does not depend on the shear rate. The rate at which chains are formed is proportional to the shear rate but the duration of the chain is inversely proportional to the shear rate so that the product of the two is shear-rate independent. Thus, the resultant stresses are shear rate independent or *quasistatic*.

Quasistatic flows have historically been modeled using techniques borrowed from metal plasticity by incorporating a Mohr-Coulomb failure criterion. Such techniques were originally used in the Civil Engineering science of soil mechanics, which describes how granular soils support buildings. However, in that field the concern stops at the initiation of flow, after which time the foundation fails and the building falls down. Plasticity models are less successful in predicting flow behavior, partially because they generally assume that the ratio of maximum shear to normal stress is a constant material property known as the "internal angle of friction." However, computer simulations have shown that the ratio is far from a constant.

At lower concentrations (just how low depends on particle shape and frictional properties) it is possible to have flows in which the individual particles are not locked into chains but can move independently of their neighbors. In an extreme case, the flow shears so rapidly that, except during collisions, the particles lose contact with their neighbors and move freely with a random motion reminiscent of the thermal motion of molecules in a gas. This is the *rapid-flow* regime and is typically modeled using techniques borrowed from the kinetic theory of gases (see Campbell, 1990). Forces in this regime must be small as they are carried by the inertia of the particles and imparted by impact; large forces would require such large thermal velocities and such strong impacts that particles would shatter. Furthermore, very large shear rates (of the order of 100 inverse seconds) are required to generate such flows under Earth gravity. As a result there are essentially no rapid granular flows of geological importance as geological forces are large and the corresponding shear rates small. The more common regime where particles remain in nearly perpetual

contact with their neighbors but still move freely, is not well understood. However in this case, the stresses are generated inertially and dimensional analysis dictates that the stresses must vary as the square of the shear rate. But as the stresses are inertial, it is again unlikely the shear rates will ever be large enough to support the large forces encountered in geological applications. Consequently, most geological flows will fall into the quasistatic flow regime. The various flow regimes, the transitions between them, including the many orders of magnitude changes in the stresses that accompany transition are discussed in Campbell (2002).

But even when flowing as a liquid, a granular material retains some of its solid character. One example already mentioned is that a granular material must yield before flow can begin. But also, when confined in a vertical tube, the friction contacts between the granules and the walls will help support the weight of the particles. Beyond a certain height, all of the remaining particle weight will be supported by wall friction so that the force on the material on the bottom of the column is independent of the height of material above it. (This result is due to Janssen, 1895, and is one of the earliest engineering treatments of granular materials.) For this reason, sand is used to fill an hourglass. Were the hourglass filled with a fluid, the pressure at the opening and thus the flowrate depend on the height of liquid above it, making it difficult to predict the time required to empty the glass. But this calibration is simple for a granular material, as the pressure at the opening and thus the flowrate are height independent so that doubling the amount of material in the glass simply doubles the emptying time.

GRAIN SETTLING

Pebbles settle faster in water than do grains of sand, and any particle settles more slowly in a viscous fluid such as oil. An understanding of grain settling is important in analyzing sediment transport and deposition. The turbulent eddies of flowing water in a river or ocean current lift sediment particles above the bottom and transport them in suspension. This

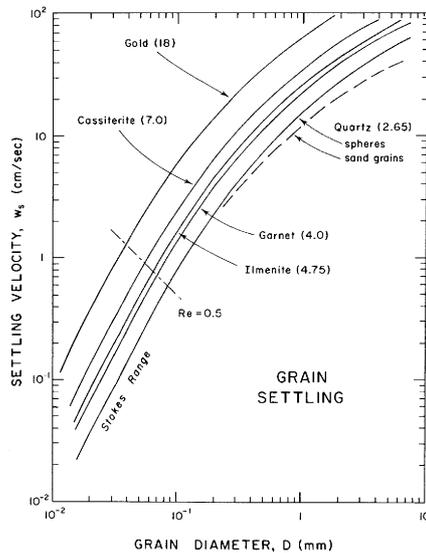

Figure G19 Curves for the settling velocities of spherical grains having densities that range from quartz (2.65 g/cm^3) to gold (18 g/cm^3). The dashed curve is for the settling of natural sand grains as measured by Baba and Komar (1981), giving some indication of the importance of the grain's nonsphericity on its settling velocity.

process depends on the settling velocities of the grains, the lower their settling rate the higher the grains are lifted above the bottom and the greater their concentration. As the strength of the current wanes, the grains are deposited on the bed at rates that depend on their settling velocities.

A number of studies have been conducted to measure settling velocities of sediment grains, with the analyzes relating the settling to the sizes and densities of the grains. Such measurements are usually made in a cylindrical tube filled with water. When the grain is released in the water, it initially accelerates, increasing in velocity until a balance is reached between the immersed weight of the grain in water, which is the net downward force causing it to settle, versus the drag force produced by the friction of the water that resists the grain's movement. When a balance is achieved between these opposing forces, the grain settles at a constant velocity, its *terminal velocity*. It is this terminal velocity that is measured in settling-tube experiments, and used in most applications.

Equations can be derived for the prediction of this terminal velocity by balancing relationships for the immersed weight of the grain and fluid drag. If one considers a spherical grain with a diameter D and density ρ_s , its immersed weight is equal to the difference between its density and that of the fluid, ρ , times the acceleration of gravity g , and the volume of the sphere, giving $(\rho_s - \rho)g(\pi D^3/6)$. For small particles settling at a slow rate, Sir George Stokes derived a relationship for the fluid drag, equal to $3\pi\mu D w_s$, where μ is the fluid's viscosity and w_s is the settling velocity. If the force of drag is equated to the immersed weight and then solved for w_s , one obtains

$$w_s = \frac{1}{18} \frac{1}{\mu} (\rho_s - \rho) g D^2$$

the Stokes settling equation. It is seen that in the Stokes range the settling velocity of a sphere depends on the square of its diameter, the density difference between the grain and fluid,

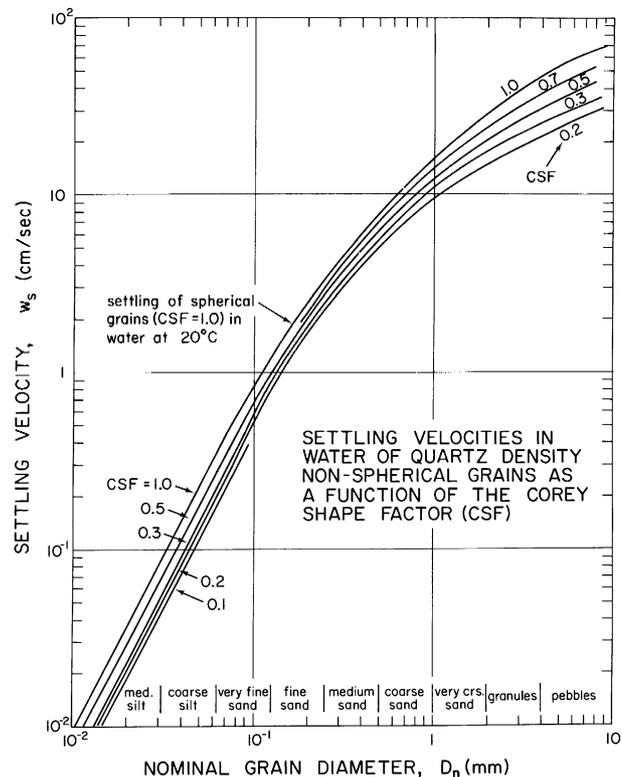

Figure G20 Curves for the settling of particles having the shape of a triaxial ellipsoid, with the nominal diameter being that of an equivalent sphere having the same volume and weight. The settling velocity depends on the Corey Shape Factor (CSF), a measure of the grain's sphericity. After Komar and Reimers (1978).

and is inversely proportional to the viscosity of the fluid. Application of this equation is limited to values of the *Reynolds number*, $Re = \rho D w_s / \mu$, that are less than about 0.5, that is to small combinations of D and w_s . For quartz-density spheres settling in water, this limits its use to particles of diameter less than about 0.08 mm, that is primarily to silt and clay. For large particles that settle at high velocities (pebbles), the drag becomes proportional to the square of the velocity. The derived relationship for the terminal velocity is then proportional to \sqrt{D} . The relationship for the settling of large particles is also complicated by the inclusion of a drag coefficient that must be evaluated from empirical curves that are based on actual measurements of settling spheres.

Curves of settling velocities in water versus grain diameters are given in Figure G24 for a range of sediment grain densities, from quartz ($\rho_s = 2.65 \text{ g/cm}^3$) through the range of common heavy minerals, and including native gold with its very high density of 18 g/cm^3 . As expected, for a given grain diameter the denser the mineral the higher its settling velocity. The cut-off Reynolds number $Re = 0.5$ for application of the Stokes equation is shown in the diagram. In the Stokes range of small particles, the increase in w_s is proportional to D^2 ; the proportion to \sqrt{D} does not occur for quartz-density grains until the diameter is on the order of 10 mm. There is a zone of transition, which unfortunately in the case of quartz-density

grains corresponds to diameters in the sand-size range, making it more difficult to evaluate their settling velocities.

The curves in Figure G19 are for the settling of perfect spheres. Most sediment grains are not smooth spheres, so the effects of particle shape (sphericity and angularity) must be considered. The dashed curve in Figure G19 for natural sand grains is based on the measurements by Baba and Komar (1981) relating the terminal settling velocities to the intermediate axial diameters of the natural grains whose overall shapes are roughly that of a triaxial ellipsoid so the intermediate diameter is representative of the grain's overall size. The resulting curve is seen to be at lower settling velocities than the curve for quartz spheres, since the nonsphericity and angularity of the natural grains increases their drag and thereby reduces their settling velocities.

Experiments have been conducted on the settling of regularly shaped but nonspherical grains, such as perfect triaxial ellipsoids or cylinders. Curves based on experiments by Komar and Reimers (1978) with triaxial ellipsoids are given in Figure G25, with each curve depending on a value of the Corey Shape Factor

$$CSF = \frac{D_c}{\sqrt{D_a D_b}}$$

where D_a , D_b , and D_c are respectively the longest, intermediate and shortest axial diameters of the triaxial ellipsoid. This shape factor evaluates the degree of departure from a sphere, which has a value $CSF=1$, the greater the departure the smaller the value of CSF . The series of curves in Figure G20 is seen to depend on CSF , progressively shifting to reduced settling velocities compared with the curve for perfect spheres as the value of CSF decreases and the grains become less spherical. Although the natural sand grains employed by Baba and Komar (1981) in their experiments, yielding the dashed curve in Figure G19, were not perfect triaxial ellipsoids, the degree of departure of the measured settling velocities from the curve for perfect spheres was still found to depend in large part on CSF .

The extreme case of particle shape affecting settling occurs for flat mica plates. Experiments have been undertaken with some success by Komar *et al.* (1984) to measure settling velocities of mica and to relate them to the grain's degree of flatness (the ratio of the thickness of the plate to its average two-dimensional diameter). However, the analysis of mica settling can be complex due to the oscillations they sometimes undergo, particularly for larger mica plates (Berthois, 1962).

The degree of angularity or roundness of the grain can also have some effect on its settling velocity. However, grain roundness has been found to be less important than sphericity (Dietrich, 1982).

While most applications involve assessments of the settling velocities of silt and sand grains, there is also interest in the settling of clay, which is complicated by its tendency to form low-density flocs, the density of which often decreases as the sizes of the flocs increase (Kajihara, 1971). Another application is to the settling of fecal pellets and shells of organisms such as foraminifera, important to deep-sea sedimentation. Fecal pellets are commonly elliptical or cylindrical in shape, and measurements of their settling velocities have been shown to agree with equations for the settling of such particle shapes (Komar *et al.*, 1981).

GRAIN SIZE AND SHAPE

Introduction

Size and shape are conceptually distinct properties of sedimentary grains. The former derives from reference to an external metric to determine the absolute magnitude of a grain, while the latter represents relative measures of the grain to establish its geometry. In practice, the two are related, first by the means that are customarily employed to establish the size of a grain, and second by the fact that grain shape in a sample might vary systematically with grain size. Size and shape of constituent grains are component properties of the texture of granular aggregates. Most grains originate by disintegration of bedrock, so size and shape are set initially by characteristics of the rock and by the disintegration process. Grains may also be formed by chemical precipitation or by cementation of previously existing grains, whence the initial properties are set by the endpoint of those processes. Size and shape are subsequently modified in the surface environment by weathering and by the damage imposed by processes of sediment transport.

Size and shape are fundamental properties of clastic sediments. The distributions of size and shape in sediment deposits influence and index other important physical properties of the sediment, such as porosity, permeability, and surface roughness, they carry important information about the origin of a deposit, they affect the stability of the deposit, and they influence habitat quality for small organisms. In this article we first examine conceptual and operational measures of grain size and shape. We then consider sampling procedures for determining representative size and shape in sedimentary deposits, since sampling places some constraints on the information that practically can be had. Finally, the distributions of size and shape properties of sedimentary aggregates are considered. A more extended review is given by Pye (1994),

while the classic work on sampling and analysis of sediment properties remains that of Griffiths (1967).

Grain size

The size of a compact, three-dimensional object such as a sedimentary grain might be indexed by some measure of its volume, or by some linear measure of its geometry. For geometrically regular objects, either carries equivalent information. For irregular objects, including sediment grains, they do not. Both approaches have been used for characterizing grain size. Conceptually, the most thorough measure is provided by grain volume, or by the equivalent linear measure $\sqrt[3]{V}$. The most common explicit measure, however, is the notional length of the second principal axis (b -axis) of the grain (see Figure G21). This measure gains its prominence from the operational method for sizing grains by washing or dry passage through a sequence of sieves with defined openings (DIN 18123, 1983; BS812-103, 1985; ASTM D422-63, 1990; D75-87, 1992) It is always possible for the a -axis to pass through on end, so grain size is determined by the b -axis length.

Sieves with round openings gauge the b -axis accurately, but square-mesh screen sieves are customarily used. Passage through a square opening depends jointly on b - and c -axis dimensions of the grain (Figure G21), so the measure is biased in comparison with a caliper measurement. The sieve opening, D , is customarily accepted as the practical measure of grain size. This technique is commonly applied down to 0.063 mm (63 μm), the lower limit of sand sizes, but the dry technique is inefficient below 125 μm . Size determination in this manner is in fact a classification procedure: sizes are determined only to within the limits established by successive sieves. The conventional classification scale is a geometric progression with ratio 2, known as the Udden-Wentworth scale (Table G13, which includes the equivalent ϕ -scale employed by sedimentologists). In research practice, clasts larger than about 64 mm commonly are measured individually using a ruler or calipers (usually without bias correction for D), although grains up to boulder size may be classified through screens in industrial operations.

Very small grains defy efficient size separation by screens. Two methods dominate size determination of fine materials. The traditional method entails particle settlement in water. The density of an aqueous suspension of particles is periodically measured, traditionally, by pipette withdrawal or hydrometer (BS3406-2, 1984; ASTM D422-63, 1990), but in modern methods by optical or X-ray beam transmission. The limit of sizes that have cleared the measured suspension or the beam path at the time of measurement is determined from Stokes' Law,

$$v_t = g(\rho_s - \rho)D^2/18\eta \quad (\text{Eq. 1})$$

in which v_t is the terminal fall velocity of a spherical grain in the laminar regime, g is the acceleration of gravity, ρ_s and ρ are respectively the solid and fluid densities, and η is the dynamic viscosity of the fluid. The notional grain size assigned by this technique is the diameter of a sphere settling in still water in the laminar regime at the same rate as the observed particle (the *nominal* or *settling diameter*). Stokes Law holds (i.e., the settling regime is satisfactorily laminar) for grains finer than 50 μm in suspensions more dilute than about

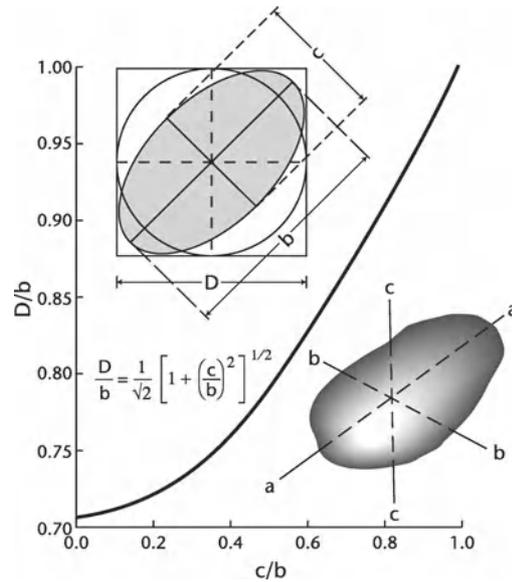

Figure G21 The ratio of square sieve opening (D) to b -axis length as a function of clast flatness, c/b . D/b gives the bias between commonly employed measures of grain size, and is the correction factor required to convert the caliper-determined b -axis to the equivalent square sieve opening. c must be measured to calculate it. Insets: 1. definition of principal axes of a grain; 2. Geometry of a grain in a square mesh opening.

1 percent. The practical lower limit of size determination by settling is around 0.5 μm , below which Brownian effects dominate the settling behavior. A similar technique can be used to determine the settling diameter of sands (USFIASP, 1957) but, in this case, terminal velocities fall in a transitional region between laminar and fully turbulent settling

In settling techniques, the actual grain size of the irregular particles is nearly always different than the settling diameter. The assigned grain size is no longer simply related to particle geometry at all (Figure G22). The measure is nonetheless convenient since, in sedimentology, the settling behavior of the grain in water is often a critical element of interpretation. Hallermeier (1981) presented empirical functions for the settlement of natural quartz grains and Dietrich (1982) presented generalized functions for settling velocity that subsume variations in size, density, shape and roundness, while Komar and Cui (1984) have systematically studied the variation between geometrical diameter (b -axis) and the measures realized by sieving and settling methods (see *Grain Settling*).

A modern technique for determining the size of fine grains entails the measurement of laser or optical beam interruption intervals induced by a suspension pumped through the beam (BS3406-7, 1998). This technique measures an arbitrary diameter or "cut" across the grain. The relation between the distribution of random cuts and the true diameter for grains of fixed shape is known for dilute particulate phases (Nicholson, 1970), and is used to derive a size distribution.

The methods for sizing grains are almost exclusively applied to aggregations of grains to return a frequency distribution of sizes in the aggregation. The size of individual particles is not distinguished. If individual sizes are of interest, they can be

Table G13 The Udden-Wentworth scale for classifying grain size, with ϕ -equivalents^a

Size of squared opening		U.S. Standard/ASTM		Size class
millimeters	micrometers	ϕ^b	sieve mesh no. ^c	description ^d
4,096		-12		Very large boulders
2,048		-11		Large boulders

^a A comprehensive chart of grain size scales is given by Truesdell and Varnes (1950).

^b $\phi = -\log_2 D$, where D is the assigned grain diameter in mm. (The minus sign was introduced so that sand sizes would have positive ϕ -numbers. Gravel sedimentologists today often ignore the minus sign and use $\psi = \log_2 D = -\phi$.)

^c Approximate mesh opening size (inches) or number of mesh openings per inch.

^d Terminology established by Wentworth (1922). Modified in modern usage.

^e Nominal diameter: usually analyzed by settling rate in fluid.

^f In certain classifications, the upper limit of clay sizes is 2 microns. Textural usage is not related to the mineralogical usage of the term "clay".

determined by the use of calipers, by tracking individual particles in a settling column (practical down to about 125 μm without special arrangements), or by examination of grains on a microscope stage. Particulate flocs—complex aggregations of fine particles that may include organic material—present special problems. Flocs commonly are open, porous structures. The most practical method that has been forwarded for sizing them is to make microphotographs of individual grains in a settling column or to deposit them on a filter or microscope slide and to analyze the photographs using image analysis techniques (BS3406-4, 1998). The complex shapes of such grains make ordinary linear measures of size relatively meaningless. Shape complexity of such grains has been measured by fractal analysis (Logan and Kilps, 1995).

There has also been substantial interest over the years to obtain grain size measurements from photographs. Either grains are actually measured on the photographs, or they are counted and correlated with mean or median diameter using a calibration curve constructed from several photos for which there are corresponding field measurements. The results vary with grain shape, packing and characteristic attitude. For the case when the grains are essentially flat lying (i.e., lying in the principal axis, or *ab* plane), unbiased distributions and summary statistics may be recovered for a truncated range with lower cutoff corresponding with the practical limit to resolve grains in the photo. When grains are not consistently oriented, the photo view amounts to a sequence of random cuts through the grains. The situation is similar to that encountered in beam interruption methods, but the grains are

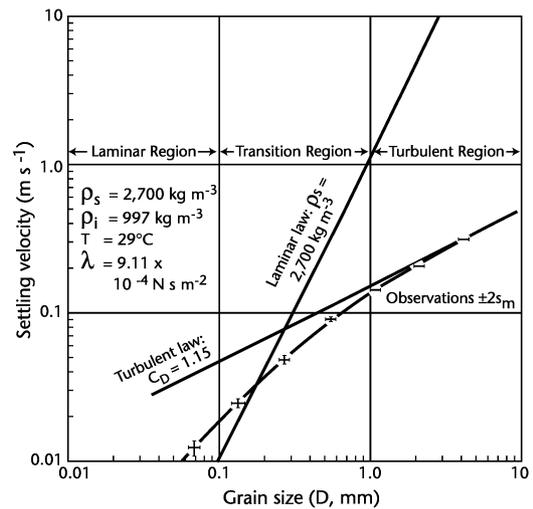

Figure G22 Settling diameter of grains compared with D , determined by sieve classification. Note that the observed results (crosses defined by error bars, derived from many experiments in a large settling cylinder) depart systematically from those predicted for spheres with diameter D . The difference is mediated by the irregular shapes of natural grains, which means both that D is a biased measure of equivalent spherical diameter and that the grains adopt complex settling trajectories in water.

not now dispersed. Kellerhals *et al.* (1975) made a detailed study of this situation (which is analogous to grains on a thin section) by making numerical trials on ellipsoid shapes and found that the measured a -axis closely estimates the true b -axis, and that the measured b -axis closely estimates the true c -axis. Krumbein (1941) found that an ellipsoid generally provides an acceptable approximation of actual grain shape, so the results of Kellerhals *et al.* appear to be robust. However, most deposits of clastic grains possess some preferred fabric, which would render the result invalid. The methods discussed in this paragraph are under renewed scrutiny now as modern image analysis techniques promise automation of what has been a tedious problem (Butler *et al.*, 2001).

Grain shape

Measures of grain shape may be divided into two distinct categories; ones which seek to express surface curvature or smoothness, and ones which seek to represent the overall shape or bulkiness of the grain.

Measures of surface “smoothness” or *roundness* are, in effect, measures of grain wear in the surface environment. A number of measures have been proposed, all related to the ratio between the minimum radius of curvature over some part of the grain surface and some measure of the overall grain diameter (Figure G23); that is,

$$R = 2r_{min}/a \quad \text{or} \quad R = 4r_{min}/(a + b) \quad (\text{Eq. 2})$$

where r_{min} is the minimum radius of curvature. For grains larger than a few millimeter in diameter, the measurements are conventionally made in the principal axis plane. The two quoted measures differ only insofar as the second averages the reference diameter of the grain over two principal axes. The range is $0 \leq R \leq 1$, the limits being represented by a grain with a sharply broken corner ($r_{min} \rightarrow 0$) and a circle or sphere.

Ratios of the principal axes represent elementary measures of grain shape. Grain *elongation* (E) may be represented by the ratio a/b , and grain “flatness” by the measure cb . Other measures of flatness include $F = 2c/(a + b)$, and $C = c/(ab)^{1/2}$, the *Corey Shape Factor*. Elongation is an open-ended measure with minimum value 1. It has proven useful for identifying grains suitable for *in situ* orientation measurements (various investigators specify $E > 3/2$ or $E > 2$ for such measurements). Zingg (1935) inverted E and used the axial ratios b/a and c/b to define a two-parameter description of grain shape. He defined four characteristic shapes on the basis of these ratios (Figure G24) which have proven useful because they reflect well the relative mobility of grains in traction under fluid shear.

Krumbein (1941) observed that grain shape is fundamentally expressed as the ratio of grain surface area to surface volume. Nondimensional measures of grain shape or bulk might logically be based on reference to some ideal or limit shape, e.g., $\sqrt[3]{V/V_{sc}}$, in which V_{sc} is the volume of the smallest circumscribed sphere (the sphere with diameter a). For small grains, this quantity is difficult to measure, so alternatives include $\sqrt{A/A_{sc}}$, in which A is grain surface area, or projected area in the principal axis plane, and A_{sc} is the area of the smallest circumscribed circle, or simply the axial ratio b/a or $2b/(a + b)$. Wadell (1933) adopted an alternative definition A_s/A , in which A_s is the surface area of a sphere with the same volume as the given particle. The ratio is inverted with respect to the previous suggestions in order to preserve the limited range [0,1]. This proposal is rational, but the measurement is tedious.

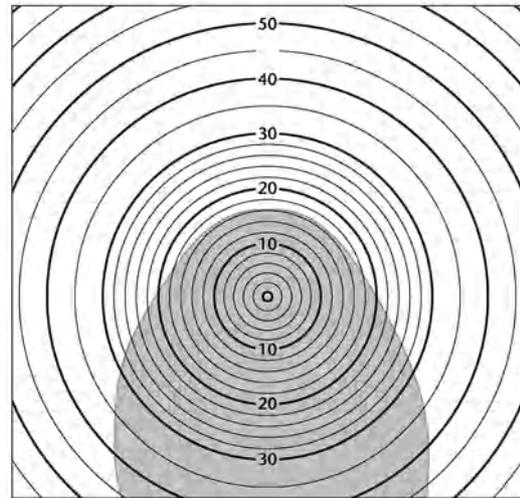

Figure G23 Illustrating the principle of a measure of smoothness or roundness of a grain. By convention, radii created by individual mineral asperities on the grain surface are ignored (since they may reflect varying mineral hardness rather than overall wear).

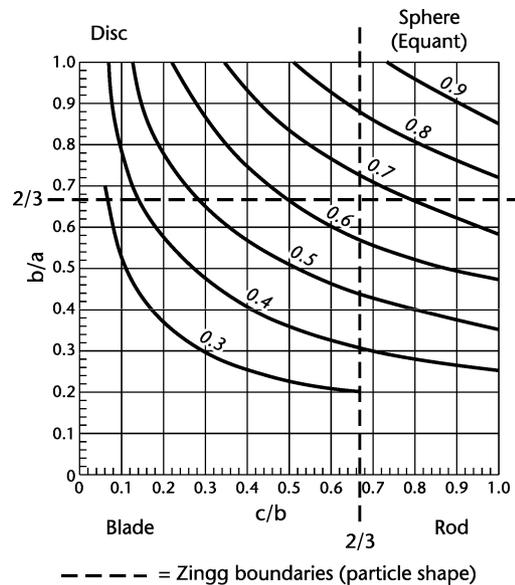

Figure G24 Zingg grain shape diagram, including Krumbein intercept sphericities.

Accordingly, Krumbein (1941) introduced *intercept sphericity* as a close approximation of Wadell's measure: $S = \sqrt[3]{bc/a^2}$. The quantity under the surd is the ratio of the volume of the approximating ellipsoid to the volume of the circumscribing sphere. Sneed and Folk (1958) proposed *maximum projection sphericity*, $\Psi = \sqrt[3]{(c^2/ab)} = C^{2/3}$, noting that this measure represents the ratio of maximum projected areas of a sphere of equivalent volume and of the particle, hence is a rational measure of the effect of particle shape on settling velocity. This justification accounts for the wide use of Ψ and C in studies of clastic sedimentation.

Sampling grains

Sampling enters into the definition of grain size because, in most instances, grains are collected and sized in aggregate (such as by sieving), so that a distribution of sizes is obtained. Grains are not measured individually. To the extent that the sampling procedure biases the selection of grains, it influences the observed results. For example, point (grid), linear, areal and volumetric methods for selecting material predetermine 0, 1, 2, and all 3 dimensions, respectively, of the sample volume, whilst number and weight as bases for assigning frequency to separated size classes also vary by a factor L^3 . Kellerhals and Bray (1971) presented a formal conversion procedure based upon the dimensions of a sample that are predetermined by the sampling and analysis techniques so that observed results can be represented in terms of any preferred measurement conventions. The general conversion formula is

$$f_{ci} = f_{oi} D_i^x / \left[\sum f_{oi} D_i^x \right] \quad (\text{Eq. 3})$$

in which f_{oi} is the observed frequency, D_i is mean grain size for size class i , x is the integer dimension required for the conversion, n is the number of classes, and the sum effects a renormalization of the distribution to yield the converted frequencies f_{ci} . Table G14 gives the dimensions for conversions amongst any usual combination of sampling and frequency assignment methods. For the conversion grid-by-number (the usual means to select and analyze individual grains from outcrop or surface) to volume-by-weight (classified bulk samples), $x = 1$; these two standard procedures are equivalent in principle. Photographic samples are area-by-number samples, for which the conversion factor to equate the result with standard analyzes is $x = 2$. A number of subsequent analysts have criticized the Kellerhals–Bray procedure on the grounds that the simple packed cubes model employed by Kellerhals and Bray to illustrate their concept is defective since it does not realistically model the porosity or grain arrangements in real earth materials. It should be emphasized that the formal model does not depend upon the illustration at all. Properly conducted tests (Church *et al.*, 1987) confirm the efficacy of the formal conversions.

Counts are used to establish frequency by size of grains when relatively small numbers or comparatively large grains are selected from outcrop or a sedimentary surface, and when grains are selected on a microscope slide. They would normally be selected on a grid or by application of randomly drawn coordinates (see, for example, Wolman, 1954). Weights are

recovered when large numbers of grains are sorted in sieves, and when settling methods are used. An important distinction in the quality of the information in these two cases is that number counts constitute legitimate quantities for statistical manipulation; frequencies derived from weights do not. Knowledge of grain size, packing and mineral density make the derivation of approximate grain number equivalents feasible but, in practice, the numbers become so large for fine materials that no useful statistical resolution may be gained anyway.

The question arises how large must a sample be in order to obtain an unbiased representation of sizes, or an estimate of some summary measure—such as the mean size—to within some desired level of precision. For samples in which frequency is assigned by enumeration (typically, grid-by-number samples—commonly known as “Wolman samples”), these are statistical questions that have been considered by many analysts. Table G15 summarizes some results.

Frequency is assigned in a bulk sample by relative weight, so the numbers of grains present in one size class influences the observed frequency in all other classes. The critical class is that which contains the largest grains, since these will be the least numerous in comparison with their aggregate weight. One requires a sample large enough to ensure that this class is adequately represented. The requisite weight for a given maximum grain size is the subject of several standards (ISO 4364, 1977; ISO 9195, 1992; ASTM D75-87, 1987; BS3680-10C, 1996; BS3680-1-E, 1998). In the sedimentary literature, Church *et al.* (1987) and Milan *et al.* (1999) have pursued the question of adequate sample size for gravels. Church *et al.* determined that the largest grain should not constitute more than about 0.1 percent of the sample weight in order to obtain a reliable analysis. The criterion is not conservative (compare ISO criteria, based on the D_{84} size: Figure G25), but it nevertheless leads to sample sizes that are impractical for manual sampling of material coarser than gravel. Ferguson and Paola (1997) have estimated by numerical simulations the bias and precision of percentile estimates in bulk size distributions. Their results show that, if only information about relatively central measures is required, then substantially smaller samples are tolerable than those suggested for characterizing the full distribution, and that results depend upon the gradation (range of sizes) of the material.

There remains the additional sampling question raised by the probability that the sampled materials are inhomogeneous over the sampling surface or volume. If one is interested only in average measures of the material, it is far more convenient to sample over the variability than to attempt to identify and sample each homogeneous subunit (which may be very difficult to identify in some circumstances). Wolcott and Church (1991) and Crowder and Diplas (1997) have addressed this question for bulk and surface sampling, respectively. A special problem presented by fluvial gravels and by some other deposits is that the surface is characteristically different than the subsurface because of the loss of fines from the surface by settling or by winnowing (armoring). Consequently, surface (by point, linear or areal means) and subsurface sampling (by volumetric means) are customarily conducted separately in coarse materials with evident segregation.

Because the distribution of grain sizes in a deposit may be very wide (possibly surpassing five orders of magnitude), so that it may not be feasible to use a single technique to sample or analyze the entire range of sizes that occur, and because

Table G14 Weighting factors for conversion of grain size frequency distributions^a

Conversion from	Conversion to sieve by weight	Grid by number	Grid by weight	Area by number	Area by weight
Sieve by weight	1	1	D^3	D^{-2}	D
Grid by number	1	1	D^3	D^{-2}	D
Grid by weight	D^{-3}	D^{-3}	1	D^{-5}	D^{-2}
Area by number	D^2	D^2	D^5	1	D^3
Area by weight	D^{-1}	D^{-1}	D^2	D^{-3}	1

^a After Kellerhals and Bray (1971, their table 2).

Table G15 Criteria for grid-by-number sample size^a

Authority	Basis of recommendation	Parameter	Recommendation
Wolman (1954)	9 replicate samples	median	100 grains
Hey and Thorne (1983)	Operator variance	mean	100
Mosley and Tindale (1985)	Cumulative histogram	mean	70
Church <i>et al.</i> (1987)	Statistical theory	Precision of the mean	Variable
Fripp and Diplas (1993)	Binomial theory	Percentiles	200–400
Rice and Church (1996)	Bootstrap analysis	Percentiles and size distribution	400

^a Mainly after Rice and Church (1996).

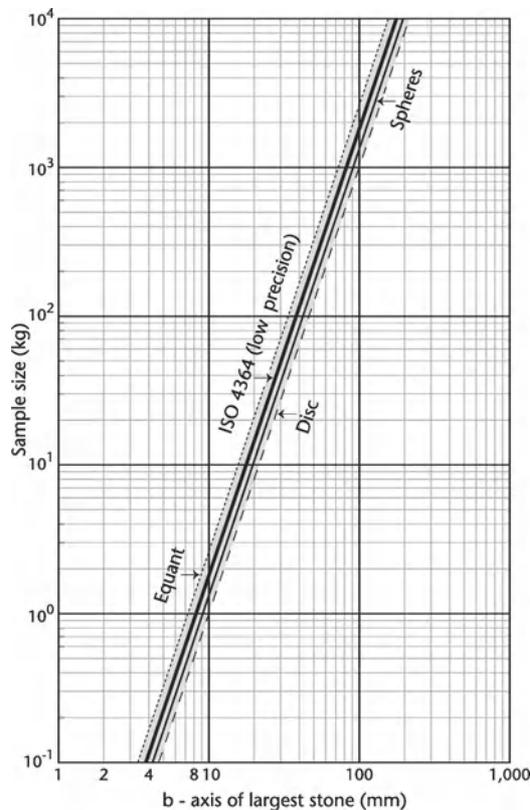

Figure G25 Bulk sample size standards based on the largest grain constituting 0.1 percent of the total sample weight (after Church *et al.*, 1987; Milan *et al.*, 1999). ISO 4364-1977(E), based on the D_{84} , is shown for comparison.

sampling requirements may become unrealizable for deposits that include very large materials, samples often represent only a portion of the entire size distribution. The sample may still contain significant information (as, e.g., when it is of interest to sample the matrix materials in a diamict sediment). Because frequencies are assigned on a relative basis, it is important to constrain comparisons between samples to the common range of analyzed sizes. Such samples may be regarded as truncated

or censored samples of the entire size distribution. Combining data from different sampling techniques may require adjustment of the assigned sizes in one or the other portion of the range, as the consequence of the nonequivalence of size assignments amongst different techniques (Komar and Cui, 1984). The most frequent example of this problem arises in the joining of sieve data of sands with the data of silts derived by settling methods.

The distribution of grain sizes

The distribution of grain sizes arrived at by enumeration is a statistically valid distribution, but the distribution of sizes arrived at by weights is not. Since the relation between the two bases goes as D^3 , frequency by weight represents a nonlinear transform of frequency by number. Despite the ill-conditioned nature of distribution by weight, sedimentologists have long used mathematical functions to approximate grain size distributions (GSD). The procedure is essentially descriptive, and no rigorous goodness of fit tests are available for comparing distributions with data or with each other. Analysis is characteristically conducted in ϕ -space, since the logarithmic transform is necessary to homogenize the variance of grain size data.

Two distributions dominated classical thinking about GSD: the so-called *Rosin distribution* (see Kittleman, 1964) which is, in fact, the two-parameter Weibull distribution, and the *log-normal distribution* (Krumbein, 1938), both customarily applied to GSD by weight. The former is justified on the basis of the size distribution of crushed material (Bennett, 1936; see also Turcotte, 1992), whilst Inman (1949) and Middleton (1970) have found justifications for log-normal distributions on the basis of sediment sorting in transport. The Rosin–Weibull distribution has been successfully applied to a range of naturally broken materials, but mostly with $D_{max} < 32$ mm ($\phi > -5$). Exceptions exist, but a plausible reason for an upper size limit is that the size of larger “broken” grains will almost always reflect primary jointing and bedding planes at outcrop, which are often not random. Ibbeken (1983) gave a review of empirical results. The log-normal distribution appears to describe tolerably well a wide range of sedimentary materials, but it often has been adopted without critical analysis as a matter of descriptive expediency.

In recent years, additional distributions have been proposed to describe transported sediments, including the log-hyperbolic

distribution and the log-skew-Laplace distribution. Both are related to the normal distribution (the hyperbolic distribution being the most general). Fieller *et al.* (1992) give a brief but comprehensive description of the application of distribution functions to describe GSD.

Many GSD are clearly not simple. Bimodal or multimodal distributions have been described using mixture distributions. However, insofar as multiple modes usually signify sub-populations that have been influenced by distinctive processes, it seems most sensible to partition the distribution into unimodal components and to study each one. The partition procedure, formerly tedious, is easy today using algorithms designed for this purpose (which usually require that the characteristic distribution be specified).

In the past, GSD have customarily been summarized by statistics, usually the first three moment statistics or graphical approximations of them. Approximate moments based on ϕ -percentiles have been advocated (Inman, 1952; Folk and Ward, 1957) and have the advantages that their consistent interpretation does not presuppose a particular distribution function, nor a complete expression of the distribution function (the extreme tails often remaining poorly sampled or unknown in sediment analysis), or a statistically valid description of the distribution. Strenuous efforts have been expended to associate moment domains with particular depositional environments, which implicitly supposes that some characteristic GSD is associated with an environment. Whilst some general associations were recognized the project did not identify clean discriminations and is not now much pursued.

Distributions of grain shape

The distribution of shape characteristics has received much less attention. A significant issue is the definition of a homogeneous population of grains for consideration, since shape variations may systematically be affected by grain size and by grain lithology. Shape measures have mainly been studied in terms of changes in median or modal values along sedimentation gradients. No general distributions have been proposed and there appears little reason to expect any, in homogeneous samples, beyond normal or log-normally distributed random variations.

GRAIN THRESHOLD

As the velocity of flowing water progressively increases over a bed of sediments, a condition is eventually reached when individual grains are dislodged and begin to be transported. This condition of first grain movement is called the *threshold of sediment motion*, or more concisely, *grain threshold*. It is the first stage in producing a transport of sediment, and in that context equations have been developed to correlate the quantity of sediment being transported to the difference between the measured flow strength (velocity, discharge, or mean stress) and that required to initiate sediment motion, thereby predicting zero transport prior to the threshold condition. In another application geologists have employed evaluations of grain threshold in interpretations of modern and ancient sedimentary deposits, for example to assess discharges of extreme floods from the maximum sizes of cobbles or boulders that were moved.

It might appear that the analysis of sediment threshold is a simple problem that can be solved through a series of

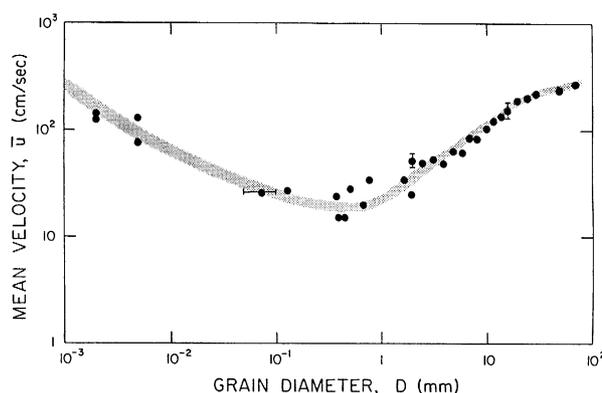

Figure G26 The threshold curve developed by Hjulström (1939), but with the data he used included.

laboratory flume experiments, each using a different grain size. A number of such experiments have been performed, usually with sediments having nearly uniform grain sizes, each experiment being conducted with a single sieve fraction. However, natural deposits of sediments contain ranges of particle sizes, and often include minerals that have different densities. Selective grain entrainment can then be important, for example involving the movement of various sizes of cobbles in a stream by floods having different discharges, or the formation of heavy-mineral placers in sands when the light minerals are selectively entrained and transported away, leaving behind the heavy minerals.

The earliest and still best known attempt to quantify the grain-threshold condition was that of Hjulström (1939), yielding the graph in Figure G26. Hjulström compiled the threshold measurements in the sand-size range, obtained by previous investigators in flume experiments, and data on flow velocities required to erode cohesive clays and silty soils. An interesting result seen in his grain-threshold curve is the presence of a minimum at a grain diameter of about 0.5 mm to 1 mm, a minimum threshold velocity of about 20 cm per second. Accordingly, it would be easiest to erode fine sand, whereas silt and clay, as well as coarser sand and gravel, require greater velocities for grain movement. The increased velocity needed to transport coarser grains is what one would expect. That it takes higher velocities to erode the fine-grained clays and silts results from cohesion binding the particles.

Although the Hjulström curve is reproduced in many textbooks, generally it should not be used in applications. This is because the evaluated threshold velocity is the average velocity as might be measured in a river, related to the river's discharge. It has no reasonable counterpart to a current in the ocean, which is characterized by a bottom boundary layer of increasing velocities with distance above the seafloor. In such a case it is necessary to relate the grain threshold to the velocity measured at some specified level above the bottom. In their review of the available threshold data, Miller *et al.* (1977) present such a threshold graph where the mean-flow threshold velocity is measured at 1 m above the bottom.

Rather than using a measure of the current's velocity, generally it is preferable to express the grain-threshold condition in terms of the mean stress exerted by the current on the sediment, the force per unit area. This stress is related to the gradient of increasing flow velocities above the bottom,

and thus to the frictional drag coupling the water flow and seafloor, representing in part the forces that are exerted on the individual sediment grains. The curve derived by Miller *et al.* (1977) for the threshold flow stress, τ_t , is shown in Figure G27. Of interest is the absence of a pronounced minimum like that seen in the Hjulstrom curve. This is because Miller *et al.* (1977) utilized only laboratory flume data extending down through silt grain sizes, where the cohesive effects of clay and organic matter were excluded. Even without the presence of cohesion to produce a distinct minimum in the curve, there still is an inflection with different slopes to either side. This is attributed to the changing character of the water flow immediately above the bed of sediments. With small grain sizes and generally reduced flow strengths required for their movement, there may be a viscous sublayer at the bed which has a reduced level of turbulence that acts to move the grains. In contrast, with larger grains and the absence of a viscous sublayer, individual particles shed eddies and absorb more of the drag. Such relationships between the nature of the flowing fluid in close proximity to the sediment bed and its importance to the initiation of grain movement were initially investigated by the German engineer Albert Shields in 1936, and more recently by Yalin and Karahan (1979). Of importance, such considerations led to the development of dimensionless graphs for the presentation of grain-threshold data, where the sediment grains might be composed of magnetite or some other mineral, and the experiments included viscous fluids such as glycerin and oils, as well as water. The result is a "universal curve" that is applicable to various combinations of grain densities and fluids, contrasting with the curves of Figures G26 and G27 that are limited in applications to the threshold of quartz-density grains in water.

Figure G27 reveals a considerable degree of data scatter above and below the threshold curve, perhaps surprisingly so in that the measurements were obtained in the controlled conditions of laboratory flumes. Furthermore, systematic differences are found between the data derived from different studies, evident in Figure G27 by the plotting position of the gravel threshold measurements obtained by Neill (1968). This scatter is due largely to the rather subjective nature of sediment threshold determinations, it being the experimenter's

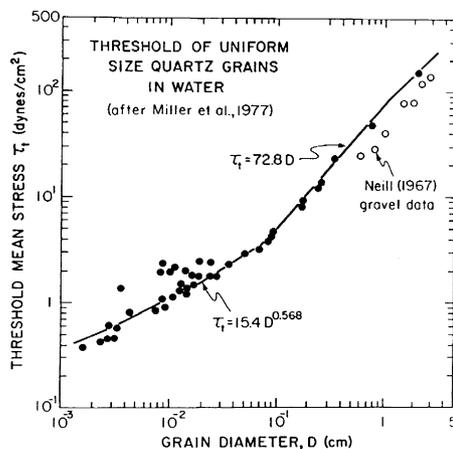

Figure G27 The flow stress τ_t required for the threshold of quartz-density grains of diameter D in water, based on the data compilation of Miller *et al.* (1977).

judgement as to just how much grain movement constitutes "threshold". The condition has been variously taken as "weak movement", "general bed movement", and for a single stone to be "first displaced" or to experience "scattered movement". This subjectivity in the determination of the grain-threshold condition needs to be recognized in applications where Figure G27, or any other threshold curve, is used. In addition, the idealized conditions of the flume experiments must be recognized, which excluded grain cohesion, represented experiments with only a narrow range of grain sizes (a sieve fraction), and where the bed of sediments was carefully smoothed in order to avoid irregularities that might affect the results. Smoothing the sediment of course eliminated the effects of bedforms such as previously formed ripple marks, which can affect the grain-threshold condition in natural environments.

The use of a narrow range of grain sizes in the experiments also departs from most natural sediments where there can be large ranges of sizes available for transport, and also different grain densities. This leads to the occurrence of *selective grain entrainment*, where with increasing flow velocities and stresses, progressively larger and more dense grains can be moved. Laboratory and field measurements have been undertaken to document this process, and example results are given in Figure G28, compiled by Komar (1987). Shown is a series of selective-entrainment curves that obliquely cross the threshold curve (dashed) for uniform grain sizes, the same curve given in Figure G27. The data of Milhous and Carling are for gravel entrainment in streams, while that of Hammond is from the observed movement of gravel on the continental shelf. The experiments of Day were undertaken in laboratory flumes, using various gravel-size mixtures. Each curve represents the largest gravel particle that is moved at a particular flow stress. Such an assessment is referred to as *flow competence*, with one important application being to evaluate the magnitudes (stresses, velocities and discharges) of extreme floods from the maximum sizes of the cobbles and boulders that were

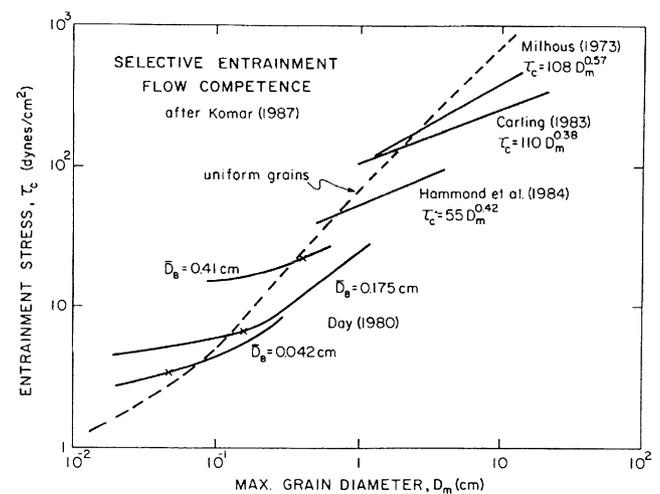

Figure G28 A series of selective entrainment or flow-competence threshold curves for the flow stress that moves the maximum grain diameter D_m within a deposit of mixed grain sizes. The dashed curve is for the threshold of uniform sediments, the same as given in Figure G27 [after Komar (1987)].

transported. The curves shown in Figure G28 all demonstrate that with a mixture of grain sizes available for transport, the stronger the flow (the higher the value of the flow stress), the larger the maximum sizes of gravel particles moved. Each selective entrainment curve crosses the curve based on uniform grain sizes at approximately its median grain size, so in general the use of the curve in Figure G27 represents the threshold of that median size within the deposit of mixed sizes. A more detailed review of selective grain entrainment is provided by Komar (1996), including the presentation of curves and equations for flow competence evaluations, together with a review of grain sorting by particle density in the sand-size range, important to the formation of placers.

GRAVITY-DRIVEN MASS FLOWS

Introduction

Gravity-driven mass flows, also known as sediment gravity flows, include a spectrum of phenomena in which more-or-less coherent mixtures of grains and intergranular fluid flow down slopes. At one end of this spectrum are dilute flows in which momentum is transferred mostly by fluid forces and sediment is largely a passive cargo that increases the effective fluid density. These dilute mass flows are part of a larger class of fluid dynamical phenomena known as gravity currents (Simpson, 1987; Bonnetcaze *et al.*, 1993). At the other end of the spectrum are concentrated mass flows such as granular avalanches and debris flows. Forces exerted by interacting

solid grains dominate momentum transfer in such flows, although fluid forces can mediate grain interactions (Savage and Hutter, 1989; Iverson, 1997).

A complete gradation of mass flows probably exists between the dilute (fluid-dominated) and concentrated (grain-dominated) end members of the spectrum. Most research emphasizes one end member or the other, but this article considers the full spectrum of mass flows and emphasizes unifying physical principles that help explain similarities and differences among flows with diverse origins, compositions, and modes of deposition. A fully unified physical theory applicable to all gravity-driven mass flows does not yet exist, however.

A variety of nomenclature is commonly used to describe and categorize gravity-driven mass flows that occur in subaerial, subaqueous, and volcanic environments (Table G16). This article does not emphasize nomenclature, because nomenclature is less important than is understanding the phenomena that govern flow behavior and sedimentation.

Macroscopic dynamics: unsteady flow with a free surface

All gravity-driven mass flows share some macroscopic traits that are largely independent of sediment concentration and the detailed behavior of solid and fluid constituents. One universal trait is unsteady, nonuniform motion—that is, motion that changes with time and position. Unlike ocean currents and river floods, gravity-driven mass flows typically have distinct starting and ending points in space and time. Most flows originate from static rock or sediment masses in steeply sloping source areas, accelerate and elongate as they move downslope, and then decelerate on flatter slopes, where they eventually form deposits. The character and composition of mass flows can evolve as changes in mass and momentum distributions occur during various stages of motion.

Another universal feature of gravity-driven mass flows is an unbounded upper surface that is free to change its shape. The presence of this deformable free surface fundamentally distinguishes gravity-driven mass flows from flows in pipes or other containers and also from rigid landslides that translate down slopes. The free upper surfaces of mass flows evolve rapidly after motion commences; most flows quickly develop blunt heads or snouts and tabular bodies with horizontal dimensions much greater than their thicknesses (Figure G29).

The tabular geometry of gravity-driven mass flows allows their macroscopic motion to be analyzed using shallow-flow theory. This well-known theory results from applying the principles of mass conservation and momentum conservation (Newton's laws of motion) to a deformable body flowing down a slope, and from using approximations that are generally suitable if the thickness of the body is much less than its areal extent. Vreugdenhil (1994) and Gray *et al.* (1999) provide detailed derivations of shallow-flow theory for water floods and granular avalanches, respectively, and Parker *et al.* (1986) and Iverson and Denlinger (2001) provide derivations for dilute and concentrated grain-fluid mixtures, respectively.

The equations of shallow-flow theory express the effects of macroscopic mass and momentum conservation on mass-flow behavior. A simple but instructive form of the equations that

Table G16 Names and attributes of some common gravity-driven mass flows. “Ambient fluid” is the fluid surrounding the flow. “Intergranular fluid” is the fluid within the flow. “Sediment concentration” is high or low depending on whether grains or fluid dominate momentum transfer

Name of flow	Attributes of flow			
	Ambient fluid	Intergranular fluid	Sediment concentration	Predominant grain size
Rock avalanche	Air	Air	High	Sand and larger
Debris flow	Air or water	Water	High	Sand and larger
Mud flow	Air or water	Water	High	Sand and smaller
Lahar	Air (at volcano)	Water	High	Undifferentiated
Pyroclastic flow	Air (at volcano)	Air	High	Sand and larger
Ash flow	Air (at volcano)	Air	Low	Sand and smaller
Turbidity current	Water	Water	Low	Sand and smaller

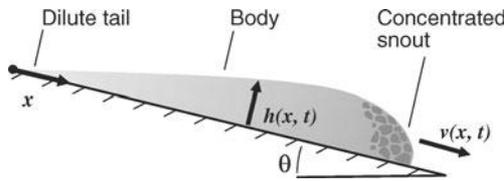

Figure G29 Schematic vertical cross section of a generic gravity-driven mass flow, with identification of morphological features and variables defined in the text. Vertical exaggeration is about 10–100×.

describe flow in one direction is

$$\rho \left[\frac{\partial h}{\partial t} + \frac{\partial(hv)}{\partial x} \right] = 0 \quad (\text{Eq. 1})$$

$$\rho \left[\frac{\partial(hv)}{\partial t} + \frac{\partial(hv^2)}{\partial x} \right] = (\rho - \rho_a)gh \left(\sin \theta - k \cos \theta \frac{\partial h}{\partial x} \right) - \tau \quad (\text{Eq. 2})$$

in which the independent variables are time, t , and downslope distance, x , and the dependent variables are the flow thickness $h(x, t)$ and velocity $v(x, t)$ (Figure G29). Parameters in the equations include the mass density of the flowing mixture, ρ , the mass density of the ambient fluid through which the mixture flows, ρ_a , the magnitude of gravitational acceleration, g , the slope angle, θ , and a lateral stress coefficient, k (equal to 1 if the mass flow behaves as a fluid but varying from about 1/5 to 5 if grain-contact stresses are important (Iverson, 1997)). All of these parameters can be measured or estimated with fair accuracy, and all are assumed to be constants in equations 1 and 2. A more enigmatic quantity in equation 2 is the resisting shear stress, τ , which can vary greatly depending on whether solid or fluid forces are dominant. Before considering the differing effects of solid and fluid forces, however, it is important to assess the terms in equations 1 and 2 that are universal and responsible for strong similarities among gravity-driven mass flows.

Each term in the mass-conservation equation 1 involves the product of ρ (mass per unit volume) and a velocity that describes the rate at which mass is redistributed within a deforming flow. The velocity $\partial h / \partial t$ expresses the change in the free-surface height due to movement of mass normal to the bed, and the velocity $\partial(hv) / \partial x$ expresses mass redistribution parallel to the bed. A term can be added to equation 1 to

express the velocity at which erosion or deposition normal to the bed adds or subtracts mass from the moving flow, but this term is omitted for the present because it significantly complicates the accompanying momentum equation 2.

The momentum-conservation equation 2 includes terms in brackets that are like the terms in brackets in the mass-conservation equation 1, except the terms in equation 2 contain an additional v . This relationship between mass-conservation and momentum-conservation terms is no accident, as the additional v 's in equation 2 reflect the definition of momentum: mass times velocity. Overall, the terms in brackets on the left side of equation 2 express the rate at which a segment of the deforming flow accelerates in response to the evolving balance between driving and resisting stresses. These inertial terms represent the “ ma ” term in Newton’s famous equation, “ $F = ma$.” Inertial terms play a crucial role in mass-flow dynamics, and they cannot be neglected in efforts to understand mass-flow deposition.

The terms on the right side of equation 2 represent the “ F ” term in “ $F = ma$,” and they express the balance of stresses that drive and resist mass-flow motion. The first term, $(\rho - \rho_a)gh \sin \theta$, is the driving stress due to the component of gravity that pulls the mass downslope. The gravitational pull is effectively reduced by the presence of ambient fluid with density ρ_a , because the ambient fluid exerts an upward buoyancy force on the flowing mass. However, this buoyancy force is negligible in concentrated subaerial flows, which typically have $\rho / \rho_a > 1,000$. The second term on the right side of equation 2 is the longitudinal stress due to the buoyant weight of flowing material that pushes against adjacent material upslope and downslope, $-(\rho - \rho_a)ghk \cos \theta (\partial h / \partial x)$. This longitudinal stress resists motion if the flowing mass thickens in the downslope direction ($\partial h / \partial x < 0$), but it helps drive motion if the mass tapers downslope ($\partial h / \partial x > 0$). The third term on the right side of equation 2 is the resisting stress due to internal and basal shearing, $-\tau$. If the terms on the right side of equation 2 sum to zero, the mass is static or has constant velocity; otherwise the mass accelerates or decelerates.

Equation 2 reveals that evolution of gravity-driven mass flows into tubular forms is attributable to gravity itself. When a mass flow commences, the leading edge of the flow experiences more driving force than resistance as gravity pulls it downslope. (Otherwise it would not move!) Moreover, the leading edge is pushed forward by the weight of the mass behind it, because $\partial h / \partial x < 0$ necessarily applies in the tapered leading edge. Behind the tapered leading edge there necessarily

exists a region in which $\partial h/\partial x > 0$, and in this region the distribution of weight exerts a backward (upslope) force on the trailing mass, which causes it to lag behind. The flowing mass thereby flattens into a tabular body, and continued tapering of the leading edge persists until the mass begins to decelerate or additional forces locally increase resistance and produce a blunt front or snout.

Two distinct mechanisms produce blunt fronts or snouts at the heads of gravity-driven mass flows. In dilute flows the mechanism involves the ambient fluid (water or air) that is displaced by an advancing flow front (Simpson, 1987). Acceleration of the ambient fluid produces an inertial reaction stress approximately equal to $\frac{1}{2}\rho_a v_{head}^2$, where v_{head} is the velocity of the advancing flow front. The reaction stress pushes against the flow front and produces resistance in addition to that included in the momentum equation 2. However, this additional resistance plays an important role only if $\frac{1}{2}\rho_a v_{head}^2$ has a magnitude comparable to that of the internal stresses affecting the flow. As indicated on the right side of equation 2, internal stresses have magnitudes proportional to $(\rho - \rho_a)gh$. A useful criterion for evaluating the importance of the flow-front reaction stress compares the values of $\frac{1}{2}\rho_a v_{head}^2$ and $(\rho - \rho_a)gh$ by employing their ratio $Fr_{head}^2 = [\rho_a / (\rho - \rho_a)](v_{head}^2 / gh)$, where Fr is known as a *densimetric Froude number*.

Experiments have shown that $Fr_{head}^2 \approx 0.5$ is typical of advancing fronts of dilute mass flows (Middleton, 1993). For example, for a dilute subaqueous flow with a thickness of 1 m and a density 10 percent greater than that of the ambient water through which it flows, $Fr_{head}^2 \approx 0.5$ occurs when flow speeds reach about 0.7 m per second. Such speeds are readily attainable, and dilute flows can therefore develop blunt snouts solely as a consequence of the inertia of the ambient fluid.

Concentrated subaerial mass flows develop blunt snouts through an entirely different mechanism, which entails local thickening due to locally enhanced internal friction. Ambient fluid has negligible effect on concentrated subaerial flows, in which $\rho_a \ll \rho$ and $Fr_{head}^2 \ll 0.1$ are typical. However, intense grain interactions in such flows cause efficient grain-size segregation that almost invariably leads to a cumulation of coarse clasts at flow fronts (Iverson, 1997; Vallance and Savage, 2000). Commonly these coarse clasts are more angular than the smaller clasts in the flow, and they produce more internal friction (Pouliquen *et al.*, 1997). Coarse-grained fronts also dissipate pore-fluid pressures in liquid-saturated mass flows, thereby enhancing local resistance and growth of blunt snouts (Major and Iverson, 1999). Feedbacks involving grain-size segregation, pore-fluid pressure, and flow-front resistance indicate that micromechanics on the scale of individual grains can play a key role in macroscopic flow dynamics.

Concentrated subaqueous mass flows (such as submarine debris flows) constitute a hybrid case in which blunt fronts may develop through a combination of grain-size segregation and the inertia of ambient fluid. Such flows can begin to hydroplane on a thin film of water when flow is fast enough that $Fr_{head}^2 \approx 0.2$; in such instances the snout may detach from the mass-flow body and run out in advance of it (Mohrig *et al.*, 1998).

Micromechanics: steady uniform shear flows

Momentum transfer on the scale of individual grains and similarly small elements of fluid occurs differently in dilute and concentrated mass flows. In dilute flows viscosity and

turbulence of the fluid phase cause most micromechanical momentum transfer. In concentrated flows enduring grain contacts and brief grain collisions are more important, although fluid may mediate grain interactions. These diverse modes of micromechanical momentum transfer are not represented explicitly in macroscopic models of mass flow, but are instead represented by stresses. Thus, micromechanics provides a basis for assessing the factors that determine the resisting shear stress τ and the lateral stress coefficient k that appear in equation 2.

Micromechanics can be quantified most simply by focusing on ideal, steady, uniform, shear flows (Figure G30), which are called “rheometric” flows because exact knowledge of the macroscopic state of stress aids determination of rheological relationships between stress and deformation. Many investigations of mass-flow mechanics have emphasized ideal, rheometric flows (e.g., Bagnold, 1954; Lowe, 1976; Chen, 1987), but it is important to recognize that this idealization balances the driving stress $(\rho - \rho_a)gh \sin \theta$ against just one term (τ) in a general mass-flow momentum equation such as equation 2. Therefore, the following characterization of steady, uniform, shear flows provides limited insight about unsteady flows in which all the terms in equation 2 are important.

Sediment concentration and the strength of the effective gravitational force per unit volume $(\rho - \rho_a)g$, are the most obvious causes of differing styles of micromechanical momentum transfer in dilute and concentrated mass flows. Effects of volumetric sediment concentration (v_s) and gravitational forces can be quantified in a rudimentary way by evaluating the ratio of the buoyant unit weight of the flowing mixture to its total unit weight, which yields the normalized bulk density

$$\rho' = \frac{\rho - \rho_a}{\rho} = \frac{\rho_s v_s + \rho_f(1 - v_s) - \rho_a}{\rho_s v_s + \rho_f(1 - v_s)} \quad (\text{Eq. 3})$$

where ρ_s and ρ_f are the densities of the solid grains and intergranular fluid, respectively, and $\rho = \rho_s v_s + \rho_f(1 - v_s)$ is the bulk density of the grain-fluid mixture. The fundamental importance of ρ' is evident from the fact that this quantity appears as a governing parameter on the right-hand side of the macroscopic momentum equation 2 if the equation is normalized by dividing all terms by ρgh .

Unfortunately, no universal criterion exists for distinguishing concentrated, grain-dominated flows from dilute,

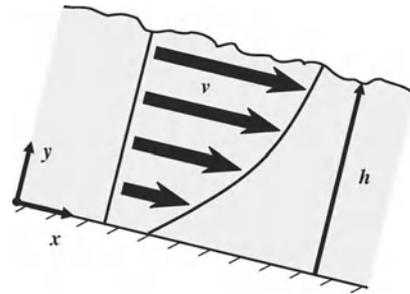

Figure G30 Schematic vertical cross section of a steady, uniform, gravity-driven shear flow with a hypothetical velocity profile. The mixture shear rate is related to the velocity profile slope by $\dot{\gamma} = dv/dy$ and is approximated by $\dot{\gamma} = \bar{v}/h$, where \bar{v} is the average velocity over the interval $y=0$ to $y=h$.

fluid-dominated flows solely on the basis of values of ρ' . For steady shear flows in which the ambient fluid is water and the solid phase consists of lithic grains with density $\sim 2,700 \text{ kg/m}^3$, flows are probably in the concentrated regime if $\rho' > 0.4$, and are likely in the dilute regime if $\rho' < 0.2$. Intermediate values of ρ' indicate a transitional regime that is neither concentrated nor dilute. If the ambient fluid is air, $\rho_a \approx 0$ and $\rho' \approx 1$ apply in most cases, and $\rho_s v_s / \rho_f (1 - v_s)$ is a more useful parameter than ρ' for distinguishing concentrated and dilute flows (Iverson and Vallance, 2001).

Concentrated flows

Large values (~ 1) of the dimensionless parameters ρ' and $\rho_s v_s / \rho_f (1 - v_s)$ indicate that solid grains are likely to dominate momentum transfer, but these parameters provide no information about the effects of flow size, the rate of deformation, or the vigor of grain interactions. Additional dimensionless parameters include these effects by including flow thickness, h , grain diameter, δ , fluid viscosity, μ , and mixture shear rate, $\dot{\gamma}$ in their definitions. These dimensionless parameters may be termed the *Savage*, *Stokes*, and *Bagnold numbers*, defined here as (cf. Iverson, 1997; Iverson and Vallance, 2001)

$$N_{Sav} = \frac{\rho_s \dot{\gamma}^2 \delta^2}{(\rho_s - \rho_f) g h} \quad N_{Sto} = \frac{\mu \dot{\gamma}}{(\rho_s - \rho_f) g h} \quad N_{Bag} = \frac{\rho_s \dot{\gamma} \delta^2}{\mu} \lambda^{1/2} \quad (\text{Eq. 4a,b,c})$$

where λ is the “linear concentration” of grains defined by Bagnold (1954). For spherical grains, the linear concentration is related to the volumetric concentration by $\lambda = v_s^{13} (v_*^{13} - v_s^{13})$, where v_* is the maximum concentration that is geometrically possible. The numbers defined in equation 4a,b,c take no account of fluid turbulence, which is assumed negligible owing to the high concentration of solid grains. (Although concentrated mass flows can be highly agitated when they move rapidly down rough slopes, agitation of the granular mass is not the same as fluid turbulence.)

The dimensionless parameters defined in equations 4a,b,c have the following physical significance: N_{Sav} estimates the ratio of grain-collision stresses to grain-contact stresses induced by gravity; N_{Sto} estimates the ratio of viscous fluid stresses to grain-contact stresses induced by gravity; and N_{Bag} estimates the ratio of grain-collision stresses to viscous fluid stresses if gravity-induced grain-contact stresses are negligible ($N_{Sav} \rightarrow \infty$; $N_{Sto} \rightarrow \infty$), as in the experiments of Bagnold (1954). Importantly, the parameters defined in equation 4 are interrelated by $N_{Bag} = (N_{Sav} / N_{Sto}) \lambda^3$.

Figure G31(A) illustrates a scheme for distinguishing modes of micromechanical momentum transfer in concentrated, steady shear flows on the basis of values of N_{Sav} , N_{Sto} and N_{Bag} . The figure indicates that flows with sufficiently small values of N_{Sav} and N_{Sto} generate stresses primarily through enduring, gravitational grain contacts that produce intergranular rubbing (i.e., Coulomb friction). The Coulomb friction regime is typical of relatively thick flows ($h > 1 \text{ m}$) with shear rates less than 10 per second, such as most rock avalanches and debris flows (Iverson and Denlinger, 2001). The Bagnold number of such flows is largely irrelevant, because gravity stresses dominate. On the other hand, if either N_{Sav} or N_{Sto} has a value that is of order 1 or larger—as may be true in thin, rapidly shearing flows—Coulomb friction is relatively

unimportant, and the Bagnold number distinguishes flow regimes in which grain collisions and fluid viscosity dominate momentum transfer. Boundaries between various concentrated-flow regimes are indistinct, and a combination of Coulomb friction, grain collisions, and fluid viscosity may be important in some circumstances. Moreover, transitions may occur between concentrated flow regimes and dilute flow regimes, particularly if the ambient fluid density ρ_a is similar to the intergranular fluid density ρ_f .

Dilute flows

Dilute mass flows occur most commonly where the ambient fluid and intergranular fluid are the same, a condition that facilitates fluid entrainment and sediment dispersal. Examples of such flows include subaqueous turbidity currents and subaerial volcanic ash flows. Buoyancy forces due to the ambient fluid are more important in dilute flows than in concentrated flows, and for dilute flows the parameter ρ' has correspondingly smaller values. [Equation 3 defines ρ' slightly differently than do some works on dilute, buoyancy-dominated mass flows, which use ρ_a rather than ρ in the denominator (e.g., Bonnetcaze *et al.*, 1993; Simpson, 1987). However, the two definitions differ negligibly if the ambient fluid and intergranular fluid are the same and the sediment concentration is small.]

Commonly, ρ' is multiplied by g to define a “reduced gravity,” $g' = \rho' g$, which appears in a densimetric Froude number applicable to steady, uniform flows,

$$Fr^2 = \frac{v^2}{g' h} = \frac{\dot{\gamma}^2 h}{g'} = \frac{\rho}{\rho - \rho_a} \frac{\dot{\gamma}^2 h}{g} \quad (\text{Eq. 5})$$

The last two forms of equation 5 employ the relation, $\dot{\gamma} = v/h$, which is a suitable approximation for uniform shear flows (Figure G3). For cases with $\rho \gg \rho_a$, equation 5 reduces to the conventional definition of the Froude number for open-channel flow of dense liquid (e.g., water) beneath ambient air. Furthermore, Fr^2 defined in equation 5 bears a strong resemblance to N_{Sav} defined in equation 4a. Both definitions involve a ratio of inertial forces to gravity forces, but in N_{Sav} the forces are those of discrete solid grains, whereas in Fr^2 the forces are those of continuous fluid.

Micromechanical momentum transfer in dilute, gravity-driven mass flows depends not only on fluid inertia but also on

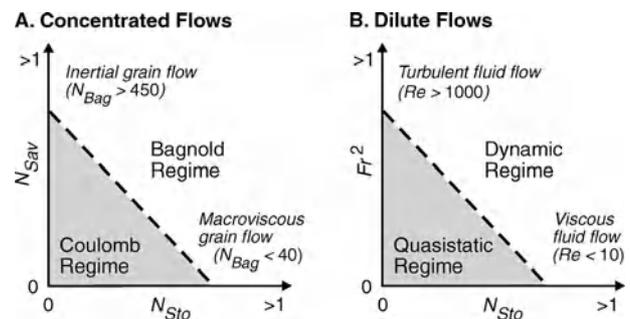

Figure G31 A scheme that uses values of dimensionless parameters to distinguish dominant modes of micromechanical momentum transfer in steady, uniform, gravity-driven shear flows of grain-fluid mixtures (See Figure G30).

the effective fluid viscosity, which is enhanced by the presence of suspended sediment. No generally applicable formula describes this enhancement, but for dilute ($v_s < 0.1$) aqueous mixtures of silt and clay-sized sediment, Einstein's (1906) equation provides satisfactory estimates. The Einstein equation, $\mu_{effective} = \mu(1 + 2.5v_s)$, indicates that effective viscosity is increased only moderately by suspended sediment.

Reynolds numbers are generally used to assess the relative importance of fluid inertia and viscosity, which together determine the propensity for fluid turbulence. An applicable Reynolds number (Re) for dilute mass flows is defined by the ratio of Fr^2 and N_{Sto} (just as a Bagnold number is defined by the ratio of N_{Sav} and N_{Sto} for concentrated flows). The form of this Reynolds number is simplest if it is assumed that $\rho_a = \rho_f$, so that $\rho' = v_s(\rho_s - \rho_f)/\rho$. In this case

$$Re = \frac{Fr^2}{N_{Sto}} = \frac{1}{v_s} \frac{\rho \dot{\gamma} h^2}{\mu} \quad (\text{Eq. 6})$$

If the factor $1/v_s$ is neglected, equation 6 is identical to the conventional Reynolds number describing steady, uniform shear flow of pure fluid with $\dot{\gamma} = v/h$.

Figure G31(B) illustrates a scheme that employs Fr^2 , Re, and N_{Sto} for distinguishing regimes of micromechanical momentum transfer in dilute, steady shear flows. Two basic regimes are identified: a quasistatic regime in which small values of Fr^2 and N_{Sto} indicate that gravity forces dominate, and a dynamic regime in which either viscous or inertial forces dominate, depending on the value of Re. Most dilute mass flows have relatively large values of Fr^2 and Re, indicating that inertial forces and turbulent flow are prevalent (Parker *et al.*, 1986; Bonnezaze *et al.*, 1993; Middleton, 1993).

The idealized steady flow regimes depicted in Figure G31 help identify parallels between dilute and concentrated shear flows. For example, Figure G31(A) and (B) illustrate an analogy between the Froude number of dilute flows and Savage number of concentrated flows. They also illustrate an analogy between the Reynolds number of dilute flows and Bagnold number of concentrated flows. Large values of Re and N_{Bag} indicate agitated flow regimes in which inertial forces dominate, and small numbers indicate more quiescent flows. However, owing to strong buoyancy effects that reduce the effect of gravity on most dilute flows, the Reynolds regime in dilute flows is more prevalent than is the Bagnold regime in concentrated flows.

Micromechanics: unsteady flow, changes of state, and sedimentation

Gravity-driven mass flows seldom resemble ideal, steady, uniform, rheometric flows. As mass-flow motion ceases, for example, $\dot{\gamma} \rightarrow 0$ and behavior necessarily shifts toward the origins of Figure G31(A) and/or (B). Thus, the apparent rheology of mass flows can change as flow speeds diminish and quasistatic gravitational forces surpass dynamic forces.

It is instructive to view departures from steady, uniform, rheometric flow in terms of changes in "state variables," which characterize partitioning of internal mechanical energy as a function of position and time (Iverson and Vallance, 2001). The central idea of the state-variable concept is that grain-fluid mixtures can exist in differing states, somewhat analogous to conventional solid and fluid states (Jaeger *et al.*, 1996). For

example, a rapidly flowing granular mixture can behave much like a fluid, whereas a static deposit of the same mixture can behave much like a rigid solid. Values of state variables depend on the composition of a mass flow but also evolve as flow proceeds from initiation to deposition. Therefore, state variables differ fundamentally from rheological constants.

Two readily identifiable state variables are the nonequilibrium intergranular fluid pressure, p , which is the observed fluid pressure minus the local hydrostatic equilibrium pressure, and the granular temperature, T , which is a measure of the intensity of grain velocity fluctuations around a mean value. Both p and T are zero in static equilibrium states. Both p and T can increase during a mass flow through conversion of bulk potential and kinetic energy to internal mechanical energy, and both can decrease through degradation of internal mechanical energy to thermodynamic heat. Increases in either p and T decrease the rigidity of a grain-fluid mixture and enhance its tendency to flow.

Large values of p exist when fluid pressures approximately balance the total stress due to the weight of the solid-fluid mixture. In dilute flows, large values of p exist continuously because the solid grains contribute little of the mixture weight. In concentrated flows, large values of p can result from subtle increases in v_s that occur if the sediment mixture settles gravitationally and transfers stresses to the adjacent fluid—a process known as *liquefaction*. Liquefaction transiently mimics the effects of enhanced buoyancy because it reduces Coulomb friction at grain contacts and inhibits further settlement. Therefore, a liquefied, concentrated mass flow can to some degree mimic the behavior of a dilute flow and exhibit great flow efficiency, but this behavior continues only as long as liquefaction persists (see *Liquefaction and Fluidization*).

Interdependence of changes in p , T , and v_s in unsteady mass flows has important consequences for sedimentation. A rudimentary understanding of this interdependence can be gained by considering the relative timescales of vertical grain settling and downslope mass-flow motion. Because downslope mass-flow motion is driven by the potential for gravity-driven freefall, the timescale for motion is $\sqrt{L/g'}$, where L is the flow length, typically similar to the slope length (Savage and Hutter, 1989). The timescale for gravity-driven settling of grains is the same as the timescale of dissipation of p in the absence of energy conversions that provide new inputs of p and T (Gidaspow, 1994, chapter 12). This settling timescale is h^2/D , where h is the flow thickness and D is the pre-pressure diffusivity or "consolidation coefficient." Values of D for mass-flow mixtures depend on sediment concentrations and grain-size distributions and can range over many orders of magnitude; typical values range from about 10^{-7} m^2 per second in concentrated, clay-rich slurries to about 0.1 m^2 per second in dilute suspensions of sand in water. The wide variation in D values produces wide variation in the ratio of the pressure-diffusion time scale to the mass-flow motion time scale, $(h^2/D)/\sqrt{Lg'}$.

If $(h^2/D)/\sqrt{Lg'} \gg 1$, settlement of grains from a moving mixture occurs much more slowly than does motion of the mixture itself. In such cases little tendency exists for grain-by-grain sedimentation, and deposition occurs by relatively abrupt deceleration and stoppage of the mass flow as a unit or series of rapidly accreted units. Such deposition generally produces massive bedding with few sedimentary structures (Major, 1997). On the other hand, if $(h^2/D)/\sqrt{Lg'} \ll 1$, grains can readily settle from a mass flow while it is still moving and

thereby produce bedding and structures reminiscent of fluvial deposits (Middleton, 1993). From a sedimentological perspective, differences between gradual, grain-by-grain deposition and abrupt deposition may constitute the central distinction between dilute and concentrated mass flows. Importantly, this distinction depends not only on flow composition but also on flow size (through dependence of $(h^2/D)/\sqrt{Lg}$ on h and L). Thus, large-size geological flows may produce deposits that differ from those produced by small-scale laboratory flows of the same composition.

Effects of sorting and mass change

The preceding sections emphasize idealized mass flows with more-or-less constant compositions, but in natural environments, mass flows can be highly heterogeneous and can alter their compositions through gain or loss of sediment and fluid in transit. This section considers some of these complications.

Grain-size sorting affects both the dynamics and deposits of mass flows. Generally, concentrated mass flows selectively sort large grains upward and toward flow margins, and thereby produce inversely graded deposits with coarse-grained perimeters. The sorting mechanism may be multifaceted (Vallance and Savage, 2000), but the dominant mechanism appears to be *kinetic sieving* (Middleton, 1970). Kinetic sieving occurs only when v_s is sufficiently large that spaces between grains are typically smaller than the grains themselves. Then agitation of the mixture allows unusually small grains but not unusually large grains to fall downward through intergranular voids, leaving a residue of large grains at the flow surface. Once this surface residue forms, a cumulation of coarse clasts tends to form at mass-flow margins because surficial sediment generally moves downslope more rapidly than does sediment nearer the bed. Coarse clasts that accumulate at flow margins produce blunt snouts as noted above, and can control the geometry of lobate deposits (Pouliquen *et al.*, 1997; Major and Iverson, 1999).

Sorting in dilute mass flows is influenced more by fluid forces than grain-to-grain interactions. In dilute flows sorting has much in common with that in typical fluvial systems, and it generally produces normally graded beds and a variety of sedimentary structures that may occur in characteristic sequences (Middleton, 1993). Dilute flows are unlikely to produce inversely graded beds or concentrations of coarse clasts at the perimeters of deposits.

Mass flows can not only sort sediment but can also gain or lose sediment (and fluid) in transit, with fundamental implications for flow dynamics and deposits (e.g., Imran *et al.*, 1998). Mass acquisition or loss is easily represented in the mass-conservation equation 1 by adding a term $\rho E(x, t)$ to the right-hand side, where E is the rate of erosion (or $-E$ is the rate of deposition). A corresponding term $-\rho v E(x, t)$ must then be added to the right-hand side of the momentum-conservation equation 2 to account for the force (expressed as a stress) required to accelerate the eroded sediment from zero velocity to velocity v . However, this added momentum-expenditure term provides no information about the forces that determine the magnitude of E . The term does not account of the additional force required to detach sediment eroded from a bed at rest, nor for the additional force exerted by the bed to decelerate sediment that is deposited.

The difficulty of accounting completely for the forces associated with nonzero E has hindered rigorous inclusion of

mass-change terms in models of concentrated mass flows. For dilute mass flows this difficulty has been circumvented by omitting terms such as $-\rho v E(x, t)$ (Imran *et al.*, 1998). The omission is justifiable only if sediment entrainment (or deposition) has negligible effect on momentum conservation in the mass flow as a whole.

Conclusion

Gravity-driven mass flows occur in a variety of subaerial and subaqueous environments. The principles of mass and momentum conservation provide a framework for understanding the behavior of all gravity-driven mass flows, but dilute and concentrated flows have some distinct differences.

Dilute flows generally occur where the ambient fluid and intergranular fluid are very similar and the sediment is sufficiently fine that it is readily dispersed by fluid turbulence. The ambient fluid affects the dynamics of dilute flows by exerting quasi-static buoyancy forces that reduce the effect of gravity and by exerting inertial reaction forces that retard motion of advancing flow fronts. Deposition by dilute flows can occur by settling of individual grains, and can produce sedimentary structures reminiscent of fluvial deposits.

Concentrated mass flows involve significant momentum exchange by solid grains, which is absent in dilute flows. The density of concentrated flows substantially exceeds that of the surrounding ambient fluid, particularly in subaerial environments. Therefore, effects of buoyancy are relatively small in concentrated flows, and effects of grain-size sorting are amplified by strong interactions between sediment clasts. Sorting commonly produces inversely graded vertical profiles and coarse-grained perimeters that enhance friction and growth of blunt snouts at flow fronts. The timescale of grain settling in concentrated flows commonly exceeds the timescale of downslope mass-flow motion. Thus, concentrated flows can produce massive beds with few features reminiscent of fluvial deposits.

GUTTERS AND GUTTER CASTS

The term “gutter cast” was coined by Whitaker (1973) for elongate downward-bulging, deep, narrow erosional structures on the base of sandstone beds. The overlying bed may be a small fraction of the thickness of the gutter cast to several times its thickness or, in cases, the gutter casts are isolated scour-fills surrounded by mudstone or shale. These represent the casts of small-scale erosional channels cut into consolidated mud. A wide variety of sizes and shapes have been described for these features using many different terms, including priels, furrows, rinnen, erosionrinnen, large groove casts, rills, etceteras (see Myrow, 1994). The term gutter cast is preferred and is in general use. The wide range of size, shape, lithology and internal structures of these erosional structures suggest that their origin is polygenetic. The sizes and geometries of gutter casts are likely a function of many variables including the intensity and nature of the eroding

flows, length of time that erosion takes place, and the grain size and diagenetic history (e.g., degree of compaction or lithification) of the underlying eroded substrate.

Gutter casts occur in association with pot casts, which are cup-shaped to cylindrical pillars of sandstone that formed from the infilling of potholes, or rounded nonlinear erosional depressions. They range in shape from discs to rounded loaflike forms to tall pillars, and in size from 1 cm to 20 cm in diameter or more. The bottoms of pot casts are commonly deepest around the outside, with a central erosional high. Pot casts have geometries and markings that indicates vertically oriented vortex flow (Myrow, 1992a) similar to that which forms potholes in bedrock in glaciated regions (Alexander, 1932).

Gutter casts are generally composed of sandstone but in some cases they contain conglomeratic lags. Internal structures include normal grading, parallel lamination, and wave-generated stratification including small-scale hummocky cross-stratification and 2d wave ripple lamination. The cross-sectional shapes of these gutter casts range from symmetrical to strongly asymmetrical, and include u-shaped, bilobate, v-shaped, semicircular, flat-based and wide, shallow forms (see Myrow, 1992a). The plan-view shapes of gutter casts are highly variable in width, and range from straight to sinuous to highly irregular. Some gutter casts bifurcate and pinch out along strike. Sinuous gutter casts may have geometries comparable to modern meandering rivers with steep to overhanging walls on the outside of meander bends. Sole markings are common features along the sides and bases of these gutter casts, and include groove marks, prods, and flute marks, and post-depositional trace fossils. The presence of delicate groove marks on the sides of gutter casts indicates that sand-sized sediment may have aided in their erosion as an abrasive agent.

Gutter casts are described from ancient deposits with paleoenvironments that range from tidal flat to submarine fan (Whitaker, 1973). Most gutter casts are described from shallow-marine rocks, and are considered to be storm-generated features (e.g., Aigner and Futterer, 1978; Kreisa, 1981; Aigner, 1985; Myrow, 1992a,b). Currents responsible for their erosion were likely highly variable. Unoriented (Allen, 1962) to bidirectional (Bloos, 1976; Aigner, 1985) prod marks on gutter casts indicating erosion by multidirectional and bidirectional currents/waves or combined flows (Aigner, 1985; Duke, 1990). The occurrence of spiraling or ropelike pattern of grooves on the soles of gutter casts has led to the suggestion that some formed by horizontal helical flows (Whitaker, 1973; Myrow, 1992a). In many cases, gutters were likely formed by powerful unidirectional flows that characterize the initial stages of deposition of tempestites (Myrow, 1992a). Aigner and Futterer (1978) suggested that gutters are produced by currents interacting with obstacles forming horseshoe hollows that were later developed into channels in a downstream direction. This is not readily apparent from most ancient deposits, although evidence for such and origin would likely be lost during continued erosion of the gutter. A series of laboratory experiments on fine-grained cohesive sediment are needed to constrain the nature of flows that could potentially be responsible for gutter erosion, and thus help constrain their conditions of formation within storm depositional models.

The long axes of gutter casts are generally oriented perpendicular to shoreline (e.g., Daley, 1968; Myrow, 1992a,b) although some studies indicate shore-parallel orientations (Aigner, 1985; Aigner and Futterer, 1978). Gutter cast

orientation can vary within depositional sequences. McKie (1994) shows a shift from shore-parallel orientations in transgressive systems tracts that were dominated by geostrophic flow to shore-normal orientations in highstand deposits that reflect downwelling flows in friction-dominated conditions. Gutter casts have also been shown to develop at the base of highstand systems as a result of forced regression (Graham and Ethridge, 1995). They are also known from nearshore areas of sediment bypass under thick sediment-laden flows (Myrow, 1992b). In these cases, isolated gutter casts (or those connected by very thin overlying beds) are up to orders of magnitude thicker than intercalated tempestites and represent sediment that accumulated almost exclusively in the gutters during bypass to deeper shelf environments.

HEAVY MINERAL SHADOWS

First described by Cheel (1984) from the fluvial facies of the Silurian Whirlpool Sandstone of southern Ontario, heavy mineral shadows are accumulations of dark heavy mineral grains (e.g., magnetite, leucoxene) that form on bedding surfaces of predominantly quartz sand. Shadows have been observed on flat, planar surfaces associated with upper flow regime plane beds (Cheel, 1984) and on the stoss sides of some large dunes (Brady and Jobson, 1973). The accumulations display an asymmetric gradient in the concentration (Figures H1 and H2) with the highest concentration on the upstream side of the shadow, decreasing in the downstream direction. Observations in a flume indicated that shadows

migrate downstream by the periodic erosion at their upstream edges with subsequent deposition a short distance downstream; the amount of heavy minerals that are deposited decreases downstream, resulting in the downstream decrease in concentration of heavy minerals that characterize shadows. Active heavy mineral shadows were observed to be overlain by much faster moving quartz-rich sand. A series of flume experiments (Cheel, 1984) suggested that heavy mineral shadows were stable at the lower end (e.g., lower velocity) of the upper plane bed stability field and that they “washed out” as flow strength increased.

The main value of heavy mineral shadows is that they can be used as indicators of paleocurrent direction. On bedding plane exposures of upper plane bed deposits (internally displaying horizontal lamination), current (Allen, 1964) and

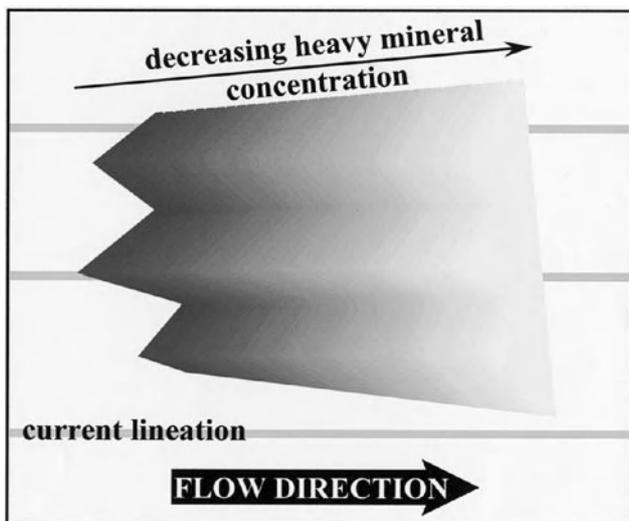

Figure H1 Schematic illustration of a heavy mineral shadow in relation to flow direction and current lineations on an upper flow regime plane bed.

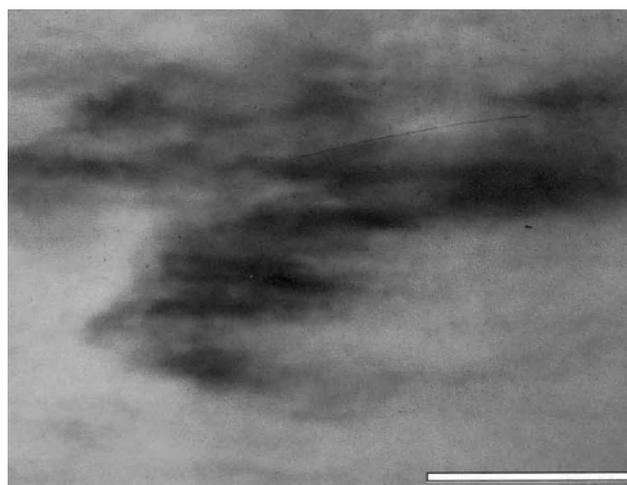

Figure H2 Plan view of a heavy mineral shadow on an active upper flow regime plane bed. The heavy mineral is chromite and the underlying bed is medium grained quartz sand. Flow is from left to right. White bar for scale is 5 cm long.

parting (McBride and Yeakle, 1963) lineations are commonly present (see *Parting Lineations and Current Crescents*), giving the sense of the flow direction but not the absolute direction. When heavy mineral shadows are present, the asymmetry of the heavy mineral concentration gradient indicates the absolute direction, along the lineations (Figure H1).

HEAVY MINERALS

Heavy minerals are high-density components of siliciclastic sediments. They comprise minerals that have specific gravities greater than the two main framework components of sands and sandstones, quartz (s.g. 2.65) and feldspar (s.g. 2.54–2.76). In practice, heavy minerals are usually considered to be those with specific gravities greater than 2.8 to 2.9, the limit being dependent on the density of the liquid used to separate them from the volumetrically more abundant light minerals. Density separation is required because heavy minerals rarely comprise more than 1 percent of sandstones, making it necessary to concentrate them before analysis can take place. Concentration is achieved by disaggregation of the sandstone, followed by mineral separation using dense liquids such as bromoform, tetrabromoethane or the more recently developed nontoxic polytungstate liquids. Heavy minerals are generally identified on the basis of their optical properties under the polarizing microscope. This is usually achieved using grain mounts but some workers prefer to use thin sections. Increasingly, identification is being made on the basis of grain composition, using microbeam techniques. See Carver (1971) and Mange and Maurer (1992) for more details on laboratory methods for the separation and preparation of heavy mineral residues.

Most heavy mineral studies are undertaken to determine sediment provenance, because heavy mineral suites provide important information on the mineralogical composition of source areas (Table H1). Over 50 different non-opaque heavy mineral species have been recognized in sandstones, many of which have specific parageneses that enable a direct match

between sediment and source lithology. See Mange and Maurer (1992) for comprehensive information on the optical properties and provenance of a large number of non-opaque heavy minerals.

Geographic and stratigraphic variations in heavy mineral suites within a sedimentary basin can be used to infer differences in sediment provenance. Such differences result either from the interplay between a number of sediment transport systems draining different source regions, or from erosional unroofing within a single source area. Heavy mineral data therefore play an important role in the understanding of depositional history and paleogeography. In some cases, sophisticated mathematical and statistical treatment of heavy mineral data may be required to elucidate the interplay between multiple sediment transport systems.

Although many heavy mineral species are provenance-diagnostic, it is rarely possible to directly match heavy mineral suites in sandstones with those of their source area. This is because a number of processes have the potential to alter the original provenance signal at various points in the sedimentation cycle. The identification of provenance on the basis of heavy mineral data therefore requires careful consideration of all the factors that may have influenced the composition of the assemblages. The factors identified as having significant potential to overprint the original provenance signal (Morton and Hallsworth, 1999) are:

- *Weathering in the source region*: This has the potential to affect the mineralogy prior to incorporation of sediment in the transport system, by increasing the relative abundance of stable to unstable minerals (see Table H1). The effects of weathering in the source region are unlikely to be extensive except under transport-limited denudation regimes (Johnsson *et al.*, 1991).
