- *Abrasion during transport*: It may cause destruction of mechanically unstable minerals. Experimental studies have shown that there are variations in the mechanical stability of heavy minerals subjected to abrasion. However, the effects of abrasion on heavy mineral assemblages appear to be negligible. For example, monazite, determined experimentally as the least mechanically stable mineral of all, is commonly found as a placer mineral in beach deposits, even though beach sediments probably suffer the greatest actual degree of mechanical abrasion of all environments, with the possible exception of eolian dune sands.
- *Weathering during periods of alluvial storage on the floodplain*: It may cause depletion of chemically unstable components. There is evidence to suggest this process plays an important role in modifying sand composition, both in terms of framework components (Johnsson *et al.*, 1988) and heavy mineral assemblages (Morton and Johnsson, 1993).
- *Hydrodynamics during transport and at the final depositional site*: Since heavy minerals are denser than quartz and feldspar, their hydrodynamic behavior is different. Furthermore, there is a range of hydrodynamic behavior within the heavy mineral group owing to the wide range of densities (Table H1). This is manifested by variations in both settling velocity and entrainment potential (Rubey, 1933; Slingerland, 1977). The variation in hydrodynamic behavior of heavy minerals is one of the major controls on the relative abundance of heavy minerals in sands and sandstones.
- *Diagenesis*: It causes depletion of minerals that are unstable in the subsurface. Case studies from widely separated

Table H1 Provenance of the most commonly recorded non-opaque detrital heavy mineral species. Note that high-stability minerals (such as zircon, rutile and tourmaline) are commonly recycled

Mineral	Density	Hardness	Stability in acidic weathering	Stability in burial diagenesis	Most common provenance
Anatase	3.82–3.97	5½–6	High	High	Various igneous and metamorphic rocks; commonly authigenic
Andalusite	3.13–3.16	6½–7½	High	Low	Metapelites
Amphibole	3.02–3.50	5–6	Low	Low	Various igneous and metamorphic rocks
Apatite	3.10–3.35	5	Low	High	Various igneous and metamorphic rocks
Cassiterite	6.98–7.07	6–7	High	Uncertain	Acid igneous rocks
Chloritoid	3.51–3.80	6½	Moderate	Moderate	Metapelites
Chrome spinel	4.43–5.09	7½–8	High	High	Ultramafic igneous rocks
Clinopyroxene	2.96–3.52	5–6½	Low	Low	Basic igneous and metamorphic rocks
Epidote group	3.12–3.52	6–6½	Low	Low	Low-grade metamorphic rocks
Garnet	3.59–4.32	6–7½	Moderate	Moderate-high	Metasediments
Kyanite	3.53–3.65	5½–7	High	Low-moderate	Metapelites
Monazite	5.00–5.30	5	High	High	Metamorphic rocks; granites
Orthopyroxene	3.21–3.96	5–6	Low	Low	Ultramafic rocks; high-grade metamorphic rocks
Rutile	4.23–5.50	6–6½	High	High	High-grade metamorphic rocks
Sillimanite	3.23–3.27	6½–7½	High	Low	Metapelites
Staurolite	3.74–3.83	7½	High	Moderate	Metapelites
Titanite	3.45–3.55	5	Moderate	Low-moderate	Various igneous and metamorphic rocks
Tourmaline	3.03–3.10	7	High	High	Metasediments; granites
Zircon	4.60–4.70	7½	High	High	Granites and other acidic igneous rocks

sedimentary basins around the world, including the North Sea (Morton, 1984) and the US Gulf Coast (Milliken, 1988) have shown that mineral suites become progressively less diverse as burial depth (and, in consequence, pore fluid temperature) increases. This is the result of dissolution of unstable minerals by circulating pore waters, a process known as *intrastratal solution*. The effects of burial diagenesis on heavy mineral suites can be considerable, since the process has the ability to alter an originally diverse, provenance-diagnostic suite to one solely comprising the stable group zircon-rutile-tourmaline-apatite. The relative stability of detrital heavy minerals during burial diagenesis is shown in Table H1.

Although the combined effect of the processes that operate during the sedimentation cycle obscures the original provenance signal, in many cases to a profound degree, all heavy mineral suites retain important provenance information. Morton and Hallsworth (1994) recommended a combined approach to isolate the provenance-sensitive component of heavy mineral assemblages. The approach concentrates on the stable components of the assemblages, and involves the determination of ratios of minerals with similar hydraulic behavior in conjunction with single-grain geochemical analysis of one or more mineral components (e.g., by electron microprobe). In order to minimize hydrodynamic sorting, ratio determinations should be made on minerals with similar grain sizes and densities (the two main controls on hydraulic behavior).

Provenance studies that concentrate on heavy mineral assemblages have become considerably more sophisticated

with the advent of single-grain geochemical analysis equipment. Most of the components of heavy mineral suites have variable compositions that can be readily determined using the electron microprobe. For instance, constraints on plate-tectonic settings of sedimentary basins have been inferred from microprobe analysis of detrital augite (Cawood, 1983), and exhumation of high-pressure metamorphic belts has been evaluated through analysis of amphibole populations (Mange-Rajetzky and Oberhänsli, 1982). Tourmaline compositions can be used to distinguish a variety of granitic and metasedimentary sources (Henry and Guidotti, 1985). Garnet compositions are particularly useful in provenance studies, in view of their response to differences in metamorphic grade and protolith composition. Some heavy minerals, notably zircon, can be dated radiometrically (Pell *et al.*, 1997), and this, combined with conventional heavy mineral analysis, is a very powerful tool for provenance studies.

Heavy minerals have important economic applications, both in the hydrocarbons and minerals sectors. Their use in paleogeographic reconstructions, especially in elucidating sediment transport pathways, is of particular value in hydrocarbon exploration. The recognition of changes in provenance within a sedimentary sequence provides a basis for correlation of strata that is independent of more traditional biostratigraphic methods. Heavy mineral assemblages have proven to be especially useful for correlating sandstones that lack age-diagnostic fossils, especially nonmarine sequences (e.g., Allen and Mange-Rajetzky, 1992). The use of heavy minerals in correlation has important applications in hydrocarbon reservoir evaluation and production. Recent advances have made it possible to utilise the technique on a 'real-time'

basis at the well site, where it is used to help steer high-angle wells within the most productive reservoir horizons (Morton *et al.*, in press).

Heavy minerals may become concentrated naturally by hydrodynamic sorting, usually in shallow marine or fluvial depositional settings. Naturally occurring concentrates of economically valuable minerals are known as *placers* (*q.v.*), and such deposits have considerable commercial significance. Cassiterite, gold, diamonds, chromite, monazite and rutile are among the minerals that are widely exploited from placer deposits.

HINDERED SETTLING

Gravitational segregation and settling of particles in an aqueous suspension are strongly affected by suspension concentration. Lone particles or particles in very low-concentration suspensions settle freely through a fluid unencumbered by hydrodynamic influences of other particles (see *Grain Settling*). However, at a sufficient volume concentration of solids, changes in fluid density and viscosity, particle interactions, and upwelling of fluid caused by downward particle motion (Hawksley, 1951; Davies, 1968) hinder particle settling. As a result, enhanced particle segregation occurs and overall particle-settling velocity is less than that of a single particle of the same size settling in an infinite fluid.

For nearly a century scientists have recognized that particle concentration affects the physical properties of fluids and particle settling behavior. Sedimentation of any given particle in a suspension is affected by both the mere presence of other particles as well as by motion of neighboring particles. The presence of rigid particles in a fluid distorts fluid motion as the fluid is at rest at particle surfaces. Such distortion leads to an increase in effective fluid viscosity, which is reasonably predictable for dilute (≤ 10 percent solids volume) suspensions (Einstein, 1906). Particle motion also distorts fluid motion by dragging fluid along as particles settle. However, owing to mass conservation, downward particle motion induces fluid upwelling which can enhance particle buoyancy and help hinder particle settling.

Over the past several decades, various models have been proposed to predict sedimentation velocities of different particle species in suspensions. Each of these models defines a so-called hindered settling function that describes the reduction of particle settling velocity as a function of particle concentration (e.g., Richardson and Zaki, 1954; Davis and Gecol, 1994). Efforts have evolved from modeling suspensions of monosized spheres at low Reynolds number ($Re < 0.5$) to multicomponent (i.e., multiple grain size and density) suspensions at finite (1–100) Reynolds numbers (Davis and Gecol, 1994; Manasseh *et al.*, 1999), and toward development of numerical models that simulate deposition from multicomponent suspensions containing large numbers of particles (e.g., Zeng and Lowe, 1992; Höfler *et al.*, 2000).

The following discussion outlines the effects of solids concentration on particle settling and the effects of particle settling behavior on the character of resulting sedimentary deposits. The discussion focuses on the behavior of non-flocculating suspensions in static fluids. Flocculent suspensions

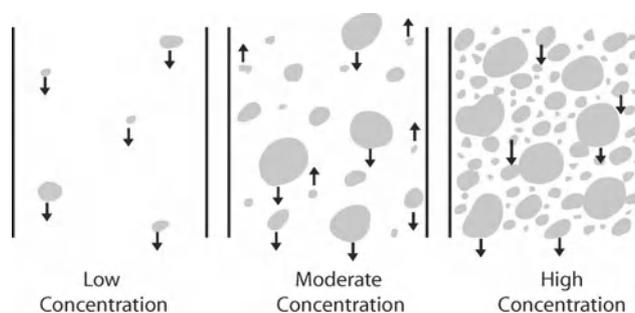

Figure H3 Particle settling in suspensions of various concentrations. At low concentration, particles settle according to Stokes' Law on the basis of size, density, and shape. At moderate concentrations hydrodynamic interactions among particles and concentration-induced changes in the physical properties of the suspending fluid affect particle settling and segregation. Settling of larger and denser particles displaces fluid and causes counterflow that carries smaller and lighter particles upward through the suspension, enhancing particle segregation and altering settling velocities. At high concentrations particle contacts suppress segregation, and all particles settle at the same velocity. Interstitial counterflow consists of nearly pure fluid. Arrows indicate direction of particle movement. (Reprinted from Journal of Volcanology and Geothermal Research, Volume 65, T.H. Druitt, Settling behavior of concentrated dispersions and some volcanological applications, pp. 27–39, Copyright 1995, with permission from Elsevier Science.)

(i.e., cohesive particles) form aggregates of various size and shape that can trap fluid, leading to greater effective particle volume than that of the primary particles (see *Flocculation*). The effective increase in solids volume increases suspension viscosity. In general, aggregate suspensions behave as multi-component suspensions that settle differentially at low and moderate concentration; however, predictions of settling behavior are complicated by floc formation. In turbulent and oscillatory flows, influences other than solids concentration and particle morphology strongly affect particle settling behavior. Such effects, however, are beyond the scope of this discussion.

Effect of concentration on particle settling

Low concentration

Significant interactions among nonflocculating particles generally are negligible at particle concentrations of a few percent or less. In dilute suspensions at low Reynolds number particles settle according to the principles of Stokes' Law, in which buoyant particle weight is balanced by drag forces owing to slow fluid motion around the particle. Settling velocity is affected by particle size, density, and shape as well as by fluid properties, but particles that are hydraulically equivalent settle at the same rate (Figure H3). In a homogeneous, uniform single-component suspension, all particles settle at the same rate, suspension concentration remains constant, and the suspension develops a sharp interface between the settling particles and supernatant fluid. In an initially homogeneous, uniform, multicomponent suspension the particles settle independently at different rates and are not hydrodynamically influenced by the presence of other particles (Cheng, 1980; Davis and Acrivos, 1985). As a result, the suspension becomes stratified into settling zones. The lowest zone contains all sediment components and maintains the initial suspension concentration. The overlying region contains all but the fastest settling component, and thus has a lower concentration. Successively higher regions contain one less component than underlying regions, and the uppermost region

contains only the slowest settling sediment. The regions are separated by discontinuities in sediment concentration. In a continuous sediment dispersion, the concentration gradient varies gradually with height.

Moderate concentration

At volume concentrations of greater than a few percent particles no longer settle freely and Stokes' Law breaks down. At volume concentrations up to about 50 percent, segregation occurs not only in response to differences in particle size and density, but also to concentration-induced changes in fluid density and viscosity and to fluid displacement by settling of larger and denser particles (Davies, 1968). At these moderate concentrations, sedimentation from multicomponent suspensions commonly is unstable and develops convective fingers (Weiland *et al.*, 1984). Fluid counterflow elutriates finer and lighter particles from lower depths in the suspension, carries them upward through the suspension, and concentrates them near the suspension surface. Settling behavior depends in detail upon solids concentration and on particle size, density, and distribution. In general, the effect of fluid counterflow is to enhance particle segregation. Greatest enhancement occurs in suspensions having large contrasts in particle size and/or density, and in suspensions having relatively high concentrations (Phillips and Smith, 1971).

High concentration

Particle contacts suppress segregation when solids concentration exceeds about 50 percent by volume. At these concentrations, sediment fractionation is negligible, all component particles settle at the same rate, interstitial counterflow consists of nearly pure fluid, and the initial concentration and species distribution are maintained (Figure H3). Strong reduction of vertical size segregation of the suspension results in *en masse* settling or zone sedimentation (Cheng, 1980). The concentration at which this mode of sedimentation dominates suspension behavior varies with particle sorting, size, and shape. In general, the more irregularly shaped or better sorted the

sediment components, the lower the concentrations at which this mode of sedimentation occurs (Davies, 1968).

Effects of suspension concentration and settling behavior on deposit character

Experiments by Druitt (1995) illustrate several aspects of settling behaviors of variably concentrated, multicomponent suspensions on deposit character. The experiments consisted of poorly sorted mixtures of variable size and density plastic and silicon carbide particles having total solids concentrations ranging from 10 percent to 60 percent by volume.

Low-concentration suspension

Despite violating the general conditions for free settling, a 10 percent concentration mixture generally settled as a typical low-concentration suspension. The densest particles segregated rapidly according to particle size and produced a normally graded deposit devoid of sedimentary structures. The lighter, but larger, plastic particles settled with their hydraulically equivalent silicon carbide counterparts, and were dispersed through the deposit according to their hydraulic equivalence. If settling was at all hindered by hydrodynamic particle interactions at this concentration, such hinderance was not readily apparent in the resulting deposit.

Moderate-concentration suspension

Hindered settling affected the sedimentologic characteristics of deposits from suspensions having concentrations ranging from 25 percent to 55 percent. Initially well dispersed suspensions segregated rapidly according to particle size and density, and formed suspensions having vertical concentration gradients. Settling of the dense silicon carbide particles generated vigorous upwelling that swept the finest and lightest particles upward through the suspensions. The light plastic particles segregated and rose upward to their levels of neutral buoyancy (near the surface in the more concentrated suspensions), and at the tops of the suspensions zones of fine particles developed that thickened with time.

Sedimentation by these suspensions produced normally graded deposits having *elutriation pipes* (finger-like zones of well sorted sediment resulting from upward fluid flow), "floating" rafts of light particles, and capping layers of fines elutriated by escaping pore fluid.

High-concentration suspension

A 60 percent concentration mixture settled as a typical high-concentration suspension. There was little contrast between the sedimentologic character of the suspension and its resulting deposit. Minor segregation of particles of different sizes or densities occurred, escaping fluid focused along discrete, high-permeability zones, and the suspension dewatered and consolidated upward from the deposit base (e.g., Major, 2000). The resulting deposit was poorly sorted and ungraded, and was capped by a very thin layer of elutriated fines.

Summary

The settling behavior of suspensions of nonflocculating solids is strongly affected by solids concentration in addition to

particle size, shape, and density. Particles segregate and settle according to size and density at low concentrations. At higher concentrations, particle segregation and settling are modified by changes in fluid properties wrought by increased particle volume, by hydrodynamic interactions among particles, and by fluid displacement and counterflow, which can greatly enhance size and density segregation. At sufficiently high concentrations, particle segregation is suppressed resulting in *en masse* settling of the entire suspension.

HUMIC SUBSTANCES IN SEDIMENTS

Introduction

Organic carbon compounds are a ubiquitous and essential constituent in sedimentary systems. They fuel virtually all biogeochemical cycles, and are important reservoirs for the major elements of living systems: carbon, hydrogen, nitrogen, oxygen, phosphorous, and sulfur. The physiology of living organisms combined with physicochemical transformations occurring during sediment burial and lithification imparts compositional, structural and isotopic characteristics to organic matter that serve as an important facet of the sedimentary record. Humic substances are high-molecular weight organic compounds defined operationally on the basis of solubility properties and high molecular weight (hundreds to 300,000 Da). They comprise a significant fraction (up to 70–80 percent) of organic matter in soils and recent sediments, and represent a complex organic mixture of primary biochemical compounds and their by-products formed by microbial degradation, oxidation, and incipient chemical polymerization/condensation. Continued thermal exposure and time result in more extensive chemical modification including the formation of kerogen and coal, as well as the release of organic acids, hydrocarbons, and carbon dioxide.

History and importance

Humic substances (HS) have had a long history of examination (compilations include Schnitzer and Khan, 1972; Gjessing, 1976; Christman and Gjessing, 1983; Aiken *et al.*, 1985; and Thurman, 1985). Since the late 1700s, workers have focused on the important role of humic substances in soils and agriculture. Stevenson (1985) provides a detailed history of the study of humic substances. Since 1970, advances in analytical techniques in organic chemistry and petroleum-related research resulted in great advances in understanding sedimentary organic matter as the precursor to kerogen (*q.v.*, and see Durand, 1980). In the 1980s and beyond, interest in HS expanded within ecology and environmental sciences. Many of these advances were related to efforts to better characterize HS (a major fraction of dissolved organic carbon) in a variety of aquatic environments, including groundwater systems (Aiken *et al.*, 1985). Now, at the turn of the millennium, the importance of humic substances in global earth systems and biogeochemical cycling continues to be a growing field. Biomedical technology has led to powerful new methods of analyzing important biomolecules such as DNA, which may be applied to HS. Yet even as analytical capabilities continue to better resolve the individual components of HS, the most fundamental questions are currently being revisited: what are humic substances? Are the traditional concepts of humic substances appropriate (Tate, 2001; Burdon, 2001)? And important new questions may be answerable: how does organic carbon sequestration in soils affect atmospheric CO₂? In what ways can/do humic substances attenuate the migration and bioavailability of anthropogenic organic chemicals and metals?

Composition

Humic substances are complex mixtures of organic compounds. They are operationally defined on the basis of solubility. Humic substances are separated by soil or sediment extraction into humic acid (soluble in aqueous media at pH > 2), fulvic acid (soluble in aqueous media across the range of pH) and humin (insoluble in aqueous media). In the traditional view, HS are mixtures of plant and microbial carbohydrates, proteins, and lipids, with degraded lignins and tannins combined in high molecular weight “polymers” through hydrophobic (e.g., van der Waals) and hydrogen bonds. Although each HS “molecule” is essentially unique, generalized formulas are based on average composition (C, H, N, S, and O content and proportions of various organic functional groups). Table H2 presents average elemental compositional ranges for humic and fulvic acids. Variations in initial organic matter composition, the availability of water and presence of oxygen all play a role in the transformation of labile biogenic compounds into HS.

Structure

Structural determinations of HS have historically been performed on HS after separation by a variety of isolation and fractionation procedures. Isolation generally involves extraction by use of sodium pyrophosphate or other solvents buffered over several pH ranges. Fractionation has been performed by use of resin columns (singly or in tandem), and more recently, through use of gel filtration techniques. Hayes and Malcolm (2001) summarize these procedures. Hatcher and others (2001) provide a thorough overview of structural determinations based on a variety of methods, including pyrolysis coupled with gas chromatography/mass spectrometry (GC–MS). The basic structure for a “typical” humic acid molecule consists of aromatic rings bridged by a variety of CH₂, N, S, and O groups, with peripherally attached protein and carbohydrate residues and simple carboxyl and phenolic moieties. Reconstructions of high-molecular weight substances consistent with observed products and considering the degradation associated with extraction and fractionation procedures has led to the conventional mega-structures thought to exist. Piccolo (2001) takes issue with these constructs and argues for an interpretation of simpler (and smaller) naturally occurring molecules. Advanced techniques in solid-state nuclear magnetic resonance (NMR; Hatcher *et al.*, 2001) which look directly at untreated organic structures, hold great promise for unraveling of these difficulties. Additional tools developed for biomolecular analysis with applications to HS include electrospray ionization and matrix-assisted laser desorption ionization (Hatcher *et al.*, 2001).

Table H2 Average Values of Elemental Compositions of Humic Substances

	Humic acid	Fulvic acid
Carbon	53.8–58.7%	40.7–50.6%
Hydrogen	3.2–6.2	3.8–7.0
Oxygen	32.8–38.3	39.7–49.8
Nitrogen	0.8–4.3	0.9–3.3
Sulfur	0.1–1.5	0.1–3.6

from Steelink (1985).

Despite advances in analytical methodology, often the characterized component of humic substances remains at only 20 percent.

Diagenesis

Humic substances are a transitional form of organic compounds between biomolecules and important fossil fuels (kerogen, coal, oil, and gas). Systematic changes in both structure and composition result as sediments undergo diagenesis and lithification during burial.

Terrestrial sediments

Terrestrial environments with significant components of humic substances include soils, peatlands, lakes, streams, and groundwater. Humic substances differ across these environments based on initial type of organic matter, subsequent exposure to organic matter recycling, and the extent of subsurface oxidation. Lakes sediments dominated by algal organic matter have higher than average H/C ratios do to the high proportion of sugars, carbohydrates and lipids as compared to greater oxygen content of cellulose and lignin-derived organic matter. Continued burial of terrestrial humic substances rich in oxygen (cellulose and lignin derivatives) leads to the formation of peat and eventually coal. The sapropel (algal-dominated) deposits of saline lakes eventually yield hydrocarbons due to the high H/C mentioned above.

Marine sediments

Humic substances in marine sediments derive from both degraded terrestrial organic matter and marine sources. Fulvic acid contents decrease with increasing burial depth in marine sediments. In the humic acid fraction, O/C and N/C ratios also decrease with burial. It is probable that fulvic acid is a product of oxidation of organic matter, and that its production decreases with depth due to a decrease in oxygen availability. Fulvic acid also decreases due to solubilization in the aqueous media and consumption by microbial populations. Humic acid becomes progressively less soluble with depth due to condensation reactions forming humin and eventually kerogen.

Summary

Humic substances in soils and sediment constitute a significant and dynamic reservoir of organic carbon, essential for considerations of carbon cycling. They are also critical in consideration of metal mobility and bioavailability due to metal binding capacities of immobile humic substances and the complexation stability of labile aqueous humic acids. Despite their study for more than two centuries, major advances in understanding HS with applications to agriculture, environmental change, and the energy industry await further investigation.

HUMMOCKY AND SWALEY CROSS-STRATIFICATION

Hummocky and swaley cross-stratification are two closely related forms of stratification that are generally attributed to the action of oscillating (wave-generated) currents or combined (oscillating and unidirectional) flows. While these structures were once thought to be ubiquitous to shallow marine storm deposits, similar forms of stratification have been recognized in both clastic and carbonate sediments of a variety of depositional environments.

Hummocky cross-stratification (HCS) was first described by that name by Harms *et al.* (1975) although the structure had been described in earlier literature by other names (e.g., “truncated wave ripple laminae”, Campbell, 1966; “crazy bedding”, Howard, 1971; “truncated megaripples”, Howard, 1972). This structure is characterized by internal laminae that locally dome upward (hummocks) passing laterally into laminae that are concave upward (swales) as shown in Figure H4. HCS is generally thought to be limited to coarse silt and fine sand (Dott and Bourgeois, 1982; Brenchley, 1985; Swift *et al.*, 1987) although it is rarely reported in coarse sand (e.g., Brenchley and Newall, 1982). The fundamental characteristics of HCS were listed by Harms *et al.* (1982, pp. 3–30) and remain important for the recognition of this structure: “(1) lower bounding surfaces of sets are erosional and commonly slope at angles less than 10°, though dips can reach 15°; (2) laminae above these erosional set boundaries are parallel to that surface, or nearly so; (3) laminae can systematically thicken laterally in a set, so that their traces on a vertical sequence are fan-like and dip diminishes

regularly; and (4) dip directions of erosional set boundaries and of the overlying laminae are scattered.” Harms *et al.* (1982) further stated that the scale of the stratification varies from medium to large scale (decimeters to meters from hummock crest to hummock crest). They attributed the form of the stratification to deposition on bedforms that consisted of, more or less, circular hummocks (positive topographic features) and swales (negative topographic features); thus, the form of the stratification mimics the morphology of the bedform.

Figure H4(A) shows the hypothetical morphology of the bedforms that result in HCS, approximately circular hummocks surrounded by circular swales, along with the internal laminae that make up the structure. Figure H4(B) shows the relationship between the internal laminae and the hummocky and swaley surfaces in terms of a hierarchy of surfaces (Campbell, 1966; Dott and Bourgeois, 1982). In Figure H4(B) the first-order surfaces bound one or more sets of HCS. Second-order surfaces are internal surfaces of scour that bound sets of hummocky laminae; these surfaces display the steepest angles of dip, ranging from 10° to 20°. Presumably second-order

surfaces are produced by erosion that makes up a hummocky/swaley surface on which internal laminae (bounded by third-order surfaces) are draped as sediment is deposited on the underlying hummocky surface. This mode of formation is supported by the common observation that internal laminae thicken from hummocks into the swales and become flatter upward within an HCS set (Figures H4 and H5).

Swaley cross-stratification (Figure H6) was first described by Leckie and Walker (1982). SCS is generally similar to HCS but lacks the positive relief associated with hummocks. In addition, Harms *et al.* (1982) stated that the maximum dip of second-order sets in SCS is somewhat shallower than HCS, not exceeding 10°.

While HCS-like stratification (HCS “mimics”, for example, Prave and Duke, 1990; Rust and Gibling, 1990) has been

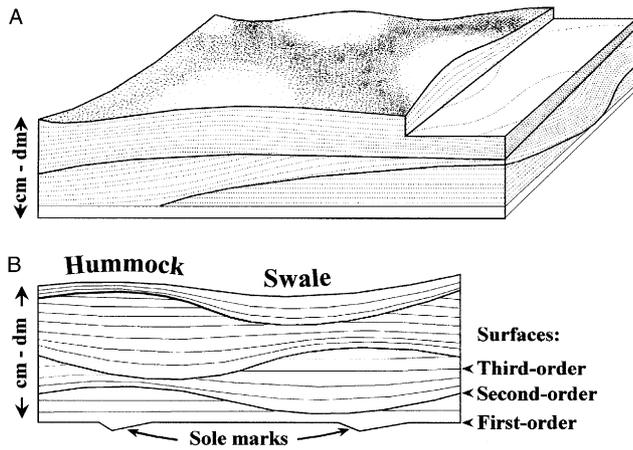

Figure H4 (A) Block diagram illustrating the characteristics of HCS (Harms *et al.*, 1975). (B) The form of stratification and ordered bounding surfaces commonly found in HCS sandstone beds (Cheel and Leckie, 1993).

described from the deposits of various depositional environments, HCS and SCS are most commonly reported in the deposits of shallow marine shelf settings that were influenced by periodic intense storms (see *Storms Deposits*). In a progradational (shallowing upward) sequence HCS first appears in basal, discrete sandstone beds, bounded by shales, which are commonly overlain by thick sandstones of amalgamated beds displaying HCS. In some such sequences SCS may be present stratigraphically above the amalgamated HCS beds.

HCS and its origin has been the focus of several studies but there remains no consensus as to the mechanism(s) of its formation. Harms *et al.* (1975, 1982) attributed HCS to deposition under powerful oscillatory currents generated by storm waves on the water surface. Others (e.g., Allen, 1985) have suggested that purely oscillating currents could not produce the bedforms that form HCS and that at least a unidirectional component (i.e., a combined flow) was necessary to produce the necessary bed topography. However, experiments by Arnott and Southard (1990) indicated that even a very weak unidirectional component of a combined flow led to the development of asymmetric bedforms that would generate cross-bedding which dipped preferentially in one direction (contrary to the definition of HCS). Similarly, a detailed analysis of grain orientation in within beds displaying HCS identified fabrics with a strong signature of an oscillating current and no recognizable component of the fabric due to unidirectional currents (Cheel, 1991). Cheel and Leckie (1993) suggested that under storm conditions on the open shelf, rogue waves may scour the bed into a hummocky/swaley topography that make up the second-order internal surfaces and, as the waves diminished, previously suspended sand would drape the bedform under the action of weaker waves which resulted in the internal laminae which drape second-order surfaces. SCS would develop under similar conditions but in shallower water where the hummocks have a low preservation potential due to their positive relief. Given the range of settings in which HCS-like stratification has been reported, it is likely that the same style of internal lamination and associated surfaces may be produced by a variety of mechanisms.

HYDROCARBONS IN SEDIMENTS

A hydrocarbon is strictly a compound composed of only the elements hydrogen and carbon. However, the term “hydrocarbons” is often extended within the Earth Sciences to include all the organic compounds that comprise petroleum and bitumen (the portion of organic matter that can be extracted from a rock using organic solvents) even though these include compounds containing other elements, especially nitrogen, sulfur and oxygen (NSO compounds). The elements carbon and hydrogen make up about 97.5 percent of an average oil (Hunt, 1996, p.24). Hence it is not surprising that hydrocarbons make up 80 percent to 90 percent of a normal crude oil with the remainder being NSO compounds and asphaltenes. The proportion of hydrocarbons in bitumen is more variable than in oils, depending on the thermal maturity and lithology of the rock, the type of organic matter and the solvent used for the extraction. Generally less than 50 percent of the bitumen, and commonly much less, are hydrocarbons. The difference between the composition of bitumen and crude oils is due to functionalized (NSO) compounds not being able to migrate as easy as hydrocarbons, and thus being selectively

origin of petroleum, and by implication, hydrocarbons in sedimentary rocks: inorganic, biogenic, and duplex origins.

In the nineteenth century, many people did not think that the formation of petroleum involved the biosphere. Reactions using inorganic substrates such as the Fischer–Tropsch reaction, which commercially is used to synthesize hydrocarbons from carbon monoxide and hydrogen on a metallic catalyst (Olah and Molnár, 1995, p. 66–75), were suggested as likely mechanisms. During the twentieth century, most people came to accept the biogenic theory outlined below although some workers still support an inorganic origin (e.g., Porfir'ev, 1974; Gold and Soter, 1982). A vast body of evidence indicates that this is very unlikely for most sedimentary hydrocarbons. Small amounts of abiogenic hydrocarbons, mostly methane, are found in Precambrian Shield and mantle-derived rocks but not enough to constitute economic deposits (Sherwood-Lollar *et al.*, 1993; Jenden *et al.*, 1993; Sugisaki and Mimura, 1994). The duplex theory holds that petroleum is a mixture of compounds having inorganic and biogenic origins. It was proposed (Robinson, 1963) at a time when it was more difficult to relate many of the constituents of petroleum to a biogenic origin. Many of today's proponents of an inorganic origin for petroleum tend toward a duplex origin in order to explain some of the more obvious biogenic compositional characteristics of oils, such as the occurrence of biomarkers.

Most geologists and geochemists believe that petroleum is the product of the thermal degradation of insoluble organic matter derived from dead organisms buried in sedimentary rocks. This is the only theory that satisfactorily explains the composition and geographical and geological distribution of petroleum. In the past, it was suggested that petroleum was simply an accumulation of the hydrocarbons derived from living flora and fauna that occur in recent sediments. Hence there was no need for any chemical conversion of organic matter into petroleum with time or depth of burial. This is no longer thought to be credible for a number of reasons, most notably because hydrocarbons are found in very low abundance in living organisms and recent sediments (these contain mostly non-hydrocarbon compounds), and petroleum contains abundant hydrocarbons not found in living organisms, especially in the lower molecular weight C₄–C₈ range.

There are three stages in the transformation of biogenic organic matter into petroleum (see also *Maturation, Organic*). *Diagenesis* is the low temperature (up to 50–60°), largely microbial mediated, irreversible alteration of organic debris in the water column, at the water/sediment interface and in near surface sediments. The biogenically derived organic matter that survives bacterial attack at this stage is preserved as mostly insoluble organic matter called kerogen. During diagenesis, hydrocarbons are in low abundance. Most of the compounds that can be extracted from sediments still contain functional groups and are directly inherited from living organisms. Biogenic methane due to methanogenic bacteria activity is the only hydrocarbon generated in significant amounts during diagenesis. *Catagenesis* is the second stage of organic maturation and takes place between about 50°C and 150°C. This is a thermally mediated process in which kerogen cracks to form oil and gas. The catagenesis stage thus includes the principle zone of oil formation and later, the initial stages of gas formation when C₂–C₄ hydrocarbon gases with an increasing amount of methane are generated in large amounts from the cracking of previously generated larger molecules and kerogen. Biogenically derived molecules are diluted by these

neo-formed hydrocarbons which have a less obvious structural relationship to their biogenic precursors. *Metagenesis* is the final thermal degradation of both residual kerogen and the bitumen formed during catagenesis to the most thermodynamically stable products, carbon (pyrobitumen or graphite) and methane. It occurs at temperatures between 175°C and 250°C.

HYDROXIDES AND OXYHYDROXIDE MINERALS

The group of oxides, hydroxides and oxyhydroxides comprises several cations such as Al, Fe, Mn or Ti, where the anionic part is either an oxygen (–O), a hydroxyl group (–OH) or an oxygen and a hydroxyl (–OOH). This article deals essentially with the iron minerals (collectively called iron oxides), because aluminum minerals such as gibbsite (α-Al(OH)₃), diaspore (α-AlOOH) and boehmite (γ-AlOOH) are handled in the article on bauxites (*q.v.*), whereas manganese oxides and phyllo-manganates are essential constituents of

iron–manganese nodules (*q.v.*). The TiO₂ polymorphs rutile, anatase and brookite are of minor importance in sediments and sedimentary rocks.

Minerals

In sediments and sedimentary rocks, oxides (hematite α -Fe₂O₃, magnetite Fe²⁺Fe³⁺O₄, maghemite γ -Fe₂O₃, wuestite FeO, ilmenite FeTiO₃) and oxyhydroxides (goethite α -FeOOH, lepidocrocite γ -FeOOH, ferrihydrite \sim FeOOH) do occur. Schwertmannite, Fe₈O₈(OH)₆SO₄, is transitional between oxyhydroxides and sulfates (for details see Cornell and Schwertmann, 1996).

Occurrences

The iron contents of sediments are highly variable. On average, carbonate rocks contain *ca.* 6 mg g⁻¹ Fe₂O₃, sandstones *ca.* 14 mg g⁻¹ and claystones *ca.* 71 mg g⁻¹. The iron oxides are either of detrital origin or neofomed in the sediments. Titanomagnetites and ilmenite belong to those detrital minerals that survive weathering due to high stability in surface environments, and, hence, may concentrate, for example, in placers (*q.v.*), up to mining quality. Hematite, which is the major pigmenting mineral in red beds (*q.v.*) or any other red-colored rock, may be either of detrital origin or it formed diagenetically. The *banded iron formations* (BIF) or *itabirites* are Precambrian, thin-bedded or laminated chemical sediments, where hematite and magnetite are interbedded with chert layers. In other kinds of sedimentary iron ores, hematite may be associated with goethite and/or magnetite (see *Iron-stones and Iron Formations*, and Füchtbauer, 1988). Yellowish to brown colors indicate the presence of goethite, which is present in small concentrations ubiquitously but in Paleozoic and older rocks to a lesser extent than is hematite. Laterites (*q.v.*), ferricretes and bauxites contain goethite, hematite and also maghemite. Quaternary bog ores, which are the younger analogs to ferricretes and bauxites, are dominated by goethite and ferrihydrite, whereas hematite is absent. Tertiary sediments may contain lepidocrocite in addition to goethite. Wuestite has been reported as rims around magnetite in sandstones.

Properties

The basic structural unit in most of the iron oxides are Fe³⁺ cations coordinated by six anions (O²⁻, and/or OH⁻). These units are connected either by sharing one oxygen across a corner, two oxygens across an edge or three along a face. With the addition of fourfold coordinated Fe²⁺ and/or Fe³⁺ cations in the spinel phases, distinct structures with densities between 4 g mL⁻¹ and 5.2 g mL⁻¹ can arise by mixing several kinds of bonds. In cases where one iron oxide is present, the color of sediments (*q.v.*) is an indicative property. Variations in crystal size, however, or mixtures of two minerals (e.g., goethite and hematite) not only change the hues, but also might mask other iron oxides. Identification and characterization is therefore better done by X-ray diffraction using Co radiation. Depending on “crystallinity”, detection limits may range from a few mg g⁻¹ for micron-sized hematites in sandstones to \sim 0.2 g g⁻¹ for ferrihydrite. Mössbauer spectroscopy offers even lower detection limits because of being sensitive to solely ⁵⁷Fe.

Crystal size and deviation from the ideal chemical composition reflect the physico–chemical environment in which authigenic iron oxides have grown. In laterites, ferricretes, and bauxites, crystal sizes of goethite and hematite range from tens to hundreds of nanometers, whereas in sandstones hematites may have grown to several microns in size. The first mentioned environments with their intensive chemical weathering yield also goethites and hematites, in which Al³⁺ substitutes for Fe³⁺. Maximum substitutions of 0.33 mol mol⁻¹ Al/(Al + Fe) have been found for goethites; in hematites the substitution seems to be limited to 0.16 mol mol⁻¹. Smaller crystal sizes and Al substitution distinguishes iron oxides derived from supergene weathering processes from those found in sandstones, carbonates and other rocks, where crystal sizes are usually much larger and substitution of foreign cations is almost absent.

Besides Al, other heavy metals such as V, Cr, Co, or Ni may substitute in iron oxides, although with much lower absolute contents. In ferricretes so much phosphate is associated with iron oxides that it spoils their use as iron ores. Phosphate sorbs strongly on iron oxide surfaces by forming a bidentate mononuclear complex, in which two oxygens of the PO₄³⁻ anion are shared with two surface oxygens (which were OH groups before adsorption) bound to two Fe³⁺ beneath the surface. Selenite and sulfate adsorb similarly, but less strongly. This kind of inner-sphere complexation has also been observed for arsenate and chromate bound to schwertmannite in sediments from acid mine drainages.

Unpaired electrons of structural Fe(III) and Fe(II) result in magnetic moments, which interact with each other and depending on thermal motion produce magnetic ordering in all iron oxides. The ordering temperatures of micron-sized crystals of magnetite, hematite and to some extent also goethite are high enough (850, 956, and 400 K, respectively) to preserve magnetizations even on a geological timescale. When such particles settle freely during sediment formation, they orient along the Earth’s magnetic field and build up a *detrital remanent magnetization*. Alternatively, a very stable *chemical remanent magnetization* is acquired, when these iron oxides grow authigenically in a sediment (see Dunlop and Özdemir, 1997).

Formation

Chemical weathering of primary, Fe(II)-containing silicates liberates Fe²⁺, which oxidizes and hydrolyses to form any of the above-mentioned phases. Which iron oxide forms is governed by pH, the rate of oxidation, the presence of inorganic and organic anions, temperature, activity of Fe²⁺ and other foreign compounds. Near-neutral pH values and higher temperatures favor formation of hematite over goethite. With decreasing oxidation rates of Fe²⁺, ferrihydrite, lepidocrocite or goethite are formed. In agreement with the occurrences of less crystalline and less stable iron oxides in younger sediments, kinetic factors seem to outweigh thermodynamic stabilities, because at conditions prevailing in surficial environments (i.e., low temperature, activity of water = 1, presence of oxygen), large crystals of goethite (α -FeOOH) are the only thermodynamically stable phase. The ubiquitous presence of hematite (α -Fe₂O₃) can be explained by lower activities of water due to stronger binding of water in small pores and/or due to higher temperatures, where hematite becomes stable despite of a_{H₂O} = 1 (*cf.* the formation of

hematitic red beds (*q.v.*) in a warmer climate). A further factor, which influences thermodynamic stability, is crystal size because of increasing contributions of surface energy.

Transformation

By heating in dry conditions, all OH-containing oxides transform finally to hematite via solid state reactions, but depending on the nature of the compound, its crystallinity, the extent of isomorphous substitution and other chemical impurities, temperatures between 140°C and 500°C are required. In the presence of water, dehydroxylation of goethite to hematite requires hydrothermal conditions, whereas the reverse reaction (hydroxylation of hematite) has not been observed *in situ* because of kinetic hinderance. ¹⁸O isotope measurements of such transformations have shown that a solution step with transport *via* water molecules is always involved (Bao and Koch, 1999).

The solubilities of Fe(III) oxides at naturally occurring pH values are so low that the concentration of Fe³⁺ in solution is orders of magnitudes lower than the solubility as Fe²⁺. Although complexing organic compounds increase the total solubility, the most efficient way to mobilize iron is by reductive processes mediated by bacteria or reducing compounds (e.g., HS⁻). The high mobility of Fe²⁺ then allow redistribution of iron from the nanometer scale to landscapes. An indicator for Fe²⁺ as the feeding source is substitution of V³⁺ in lateritic goethites and hematites. Under natural pH and Eh values, where Fe²⁺ is stable, tetravalent VO²⁺ coexists, but not the unstable V³⁺. A reduction VO²⁺ to V³⁺ followed by

incorporation is feasible, however, by a surface-mediated reduction after sorption of Fe²⁺ onto an oxide surface, which decreases the redox potential of Fe³⁺/Fe²⁺ in solution from 0.77 Volt to a value of ~0.35 Volt low enough to reduce sorbed V⁴⁺ to V³⁺ (Schwertmann and Pfab, 1996).

ILLITE GROUP CLAY MINERALS

The term '*illite*' usually is used in its petrographic sense as a name for the K-rich, argillaceous component of sedimentary rocks, identified by ca. 1 nm spacing for its 001 X-ray diffraction (XRD) peak. At 30 percent, illite is the second most abundant mineral component of sedimentary rocks (after quartz, 34 percent). Defined that way, it is not a mineral, but is the "illitic fraction" of a rock, which, in addition to the mineral illite, may contain admixtures of similar minerals, most often fine-grained micas, glauconite and mixed-layer illite-smectite. Used in the mineralogical sense, "illite" identifies a clay structure, which is of 2:1 type, dioctahedral, non-expanding, aluminous, and contains nonexchangeable K as the major interlayer cation. The potassium balances a negative layer charge, generated by Al for Si substitution in the tetrahedral sheet and (Mg, Fe²⁺) for Al in the octahedral sheet (Figure 11). This definition refers both to illite as a separate mineral (discrete illite), and as a non-expanding component of mixed-layer illite-smectite (I-S), known as the *illite fundamental particle* (Figure 11). Due to its complicated chemical composition and broad range of possible isomorphous substitutions, illite becomes an important sink for most major elements liberated at the Earth surface by interaction between rocks and the hydrosphere. Thin illite crystals contribute considerably to a rock's cation exchange capacity and they reduce its permeability. Illite group minerals are covered in detail in recent reviews by Środoń (1999a,b).

Origin and evolution of illite in the rock cycle

Common surface environments are not favorable for the formation of the mineral illite. Reports of illite formation in weathering or marine environments often are misleading because of eolian contamination (Šucha *et al.*, 2001). Illite may be partially stripped of its potassium by weathering and may fix it back in sedimentary environment without changing its silicate layers. Experiments indicate that smectites also may

fix potassium at surface temperatures without changing its silicate layers, thus forming mixed-layer I-S during the process of alternate wetting and drying, however, the geological significance of this process has not been assessed. Illite can be crystallized at surface temperatures at pH > 10 (Bauer *et al.*, 2000). In natural high pH environments (lacustrine, playa), ferruginous illite, having a composition intermediate between illite and glauconite, is a common product of low-temperature diagenesis.

Illitization becomes a major chemical reaction in sedimentary rocks above approximately 70°C. Three types of processes have been recognized: (1) alteration of smectite into illite *via* mixed-layer I-S; (2) direct alteration of kaolinite and feldspar into discrete illite; (3) crystallization of filamentous illite in the pore space. The first process, volumetrically dominant, is known in the most detail. Illitization of smectite is a continuous process, producing pure non-expandable illite at the bottom of the *anchizone* (ca. 275°C—this zone is the highest grade of burial diagenesis). If not uplifted and eroded, it gradually recrystallizes into coarse-grained mica up to 325°C (biotite isograd, McDowell and Elders, 1980).

In the weathering environment, eroded illite is very stable and commonly becomes recycled into new sediments either chemically intact or partially stripped of its potassium (soil vermiculite).

Mixed-layering, polytypes, and structural defects

Illite fundamental particles, which are only a few layers thick, are very flexible. They can join each other or smectite monolayers face-to-face to form multi-particle crystals (Figure 11), called *mixed-layer crystals* because the particle interfaces display not illite but smectite characteristics (e.g., exchangeable cations, swelling properties). In the course of diagenesis, smectite particles dissolve and illite particles grow in thickness (Środoń *et al.*, 2000), thus mixed-layering evolves along with increasing percent of illite layers from so-called R0 (smectite monolayers plus illite bilayers) into R1 (no smectite monolayers, bilayers dominant) and then R > 1 (3 nm or thicker particles dominant).

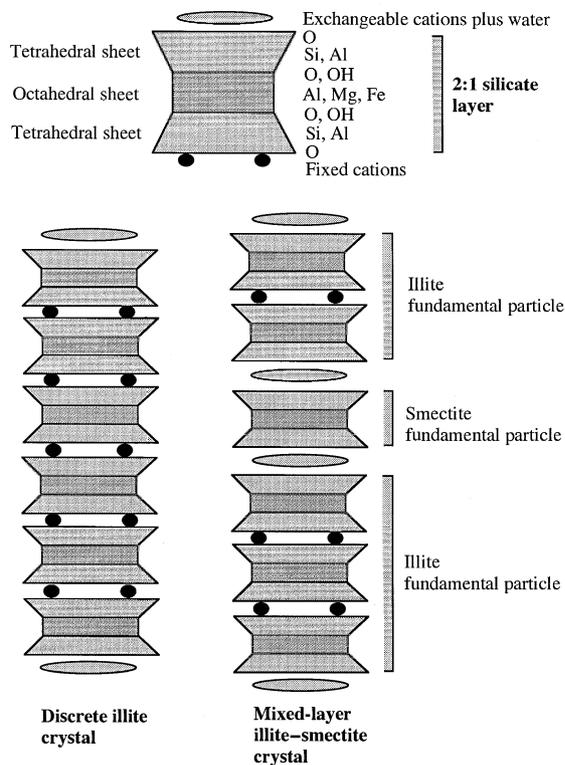

Figure 11 Schematic structure of the 2:1 silicate layer. The layer has two tetrahedral and one octahedral sheet and is dioctahedral, i.e., 2 out of 3 octahedral positions are occupied by cations. The lower part of the figure shows two types of occurrence of illite layers: as discrete crystals and as fundamental particles in mixed-layer illite-smectite crystals.

Mixed-layer crystals produce 001 XRD reflections at positions intermediate between the positions of end-members. The illite:smectite ratio is measured from these XRD positions (Moore and Reynolds, 1997) and used for tracing the increasing grade of diagenesis. Mixed-layering becomes undetectable at approximately 20 layers mean thickness.

Because of the pseudohexagonal symmetry of layer surfaces, subsequent layers in illite particles can be superimposed not only in the same direction, but also rotated by 60° or 120°. If such pattern repeats systematically a *polytype* is created. If the pattern is random, the structure contains stacking faults (structural defects). A second type of structural defect recognized in illites arises from the location of cation vacancies in the octahedral sheet. Only two of the three sites are occupied in dioctahedral minerals and the sites are not equivalent (two “*cis*” and one “*trans*” site). Illite layers can be either *trans* or *cis* vacant and both types are commonly found in one mineral (Moore and Reynolds, 1997).

Among common illite polytypes, 1M is characteristic of diagenesis and 2M₁ appears in the anchizone (intermediate between diagenesis and metamorphism). While 2M₁ is typically devoid of structural defects, 1M most often contains defects, which broaden and weaken its XRD diffraction peaks (so-called 1M_d illite). Polytypes and defects can be quantified by computer modeling of XRD patterns (Moore and

Reynolds, 1997) and used for tracing geological processes. For example, the 1M_d/2M₁ ratio is measured to quantify the ratio of diagenetic to detrital illite in the diagenetic zone, and the progress toward metamorphism in the anchizone. Generally, the density of defects decreases during diagenesis, with *trans*-vacant layers becoming dominant, but exceptions to this rule are known.

Crystal size, shape, and “crystallinity” (Kubler index)

Illite crystals and fundamental particles are plates terminated by 001 planes, either equidimensional (the shape common for shales) or highly elongated (the shape typical of “hairy illite” that clogs sandstone porosity). These shapes are controlled by crystal growth rates (Bauer *et al.*, 2000).

The thickness of illite fundamental particles, first measured by Nadeau *et al.* (1984), was studied in detail for bentonites (Srodoń *et al.*, 2000). Illite nucleates as particles 2 layer (2 nm) thick, which grow during the course of diagenesis, producing lognormal distributions of increasing mean thickness, broadening and skewness. The growth of fundamental particles is the major factor responsible for a decrease in the XRD 001 peak breadth (“Kubler index”) during anchizone metamorphism. Particle thickness distributions can be now measured directly by XRD (Eberl *et al.*, 1998).

Layer charge and fixed cations of illite

The typical structural formula for pure illite from bentonites:

corresponds to infinitely thick illite crystals. The thinner the crystals, the lower their bulk fixed charge, because the number of interlayers is always smaller by one than the silicate layers (Figure 11). In the extreme case of 2 nm illite crystals, the fixed charge equals 0.45 and there is a substantial number of exchangeable cations at crystal surfaces.

The charge of illite layers is satisfied mostly by fixed potassium. Minor Na substitution is well-known but there is no complete solid solution, and if sodium is abundant, Na-mica (paragonite) is formed in the anchizone (Frey, 1987). Solid solution between K and NH₄ is possible and NH₄-rich illites (tobelites) have been reported from deep diagenesis (Schroeder and McLain, 1998) and anchizone (Lindgreen *et al.*, 2000).

Illite as paleogeothermometer

Illite crystal growth has been traced in the diagenetic zone by measuring the illite:smectite ratio of mixed-layer I-S and in the anchizone by measuring the Kubler index. Students of the anchizone believed that the Kubler index indicates paleotemperatures; and anchizone limits were defined using its values (Frey, 1987).

In the diagenetic zone, the effect of bulk rock chemistry on the illite:smectite ratio has been demonstrated and explained by a deficiency of K in bentonites. Because of abundant K and relatively closed system, shales are considered the most suitable lithology for studying illite response to basin temperature. The approach, introduced by Hoffman and Hower (1979), assumes that the illitization reaction in shales is so fast that the time factor can be neglected and that maximum paleotemperatures can be evaluated from measured illite:smectite ratios. Other investigators take into account the

time factor and chemistry and use various kinetic equations to model the experimental illitization profiles.

K–Ar dating of illite

The interpretation of K–Ar dates depends on the type of host rock. In pure beach or eolian sandstones all illite can be authigenic (hairy illites) and the radiometric date indicates the time of hot fluid flow and perhaps oil emplacement (Hamilton *et al.*, 1992). Shales, even in the finest fractions, usually contain a mixture of authigenic and detrital illite. Techniques for obtaining both ages have been proposed. If extracted properly, the K–Ar date of diagenetic illite from shale represents the mean time that has passed between the onset of illitization and the time of maximum paleotemperature. This mean strongly depends on burial history (Środoń *et al.*, 2002). Many bentonites are free of detrital contamination, but the K–Ar date represents an even longer period of time than I–S from surrounding shales because of slow diffusion of potassium into the bentonite. This period of time can be evaluated by dating bentonites that are zoned, that is, less highly illitized in the center of the bed, and/or fractions of fundamental particles separated from a bentonite.

IMBRICATION AND FLOW-ORIENTED CLASTS

Imbrication is the overlapping arrangement of similar parts, as of roof tiles or fish scales. The earliest use of “imbricate” or related words by geologists quoted in the *Oxford English Dictionary* are by Dana (1852, 1862) and by A. Geike (1858) to describe biologic or paleontologic objects. An illustration of sedimentary imbrication is given as early as Jamieson (1860), reproduced here in Figure I2. A modified version of this figure appears in the 11th and 12th editions of Lyell’s (1872, 1875, p. 342) *Principles*, but neither Jamieson nor Lyell use any form of the word “imbricate” in their discussions of the figures.

Imbrication, which is a special case of flow-oriented clasts, is a common phenomenon, but observations and theory concerning it are published rarely. The flow-orientation of a single clast develops in many ways. To understand the flow orientation of clasts in different environments can improve interpretation of rocks, and lead to a better understanding of sediment transport.

Imbricated clasts must have unequal lengths for their *a*, *b*, *c* axes (*a* longest, *c* shortest). Usually, imbricated clasts are approximately tabular in shape, where the *a* and *b* axes significantly exceed the *c* axis. Roof tiles, or fish scales, or tabular rock fragments can be imbricated; basketballs, or grapes, or spherical sand grains cannot. As suggested by Figure I2, imbricated clasts must be approximately similar in absolute size: flat pebbles can form an imbricated group, but a flat pebble cannot imbricate with a flat boulder.

Jamieson (1860, p. 350) suggests that flow orientation, such as shown in Figure I2, “is best exemplified when the stones are pretty large, say, from six to twelve inches in length.” However, flow orientation and imbrication occurs in finer sediments, including sand (Gibbons, 1972), although compared to pebbles or boulders, sand grains have more random orientations because their size is smaller relative to the turbulent eddies, and their submerged weight is relatively less than the drag exerted by such eddies. On the larger scale, boulders have been imbricated in debris flows and floods (Blair, 1987, his figure 7C).

Sediment sorting determines the likelihood of imbrication. A well-sorted collection of flat pebbles commonly contains an imbricated array such as in Figure I2, but a poorly sorted sand

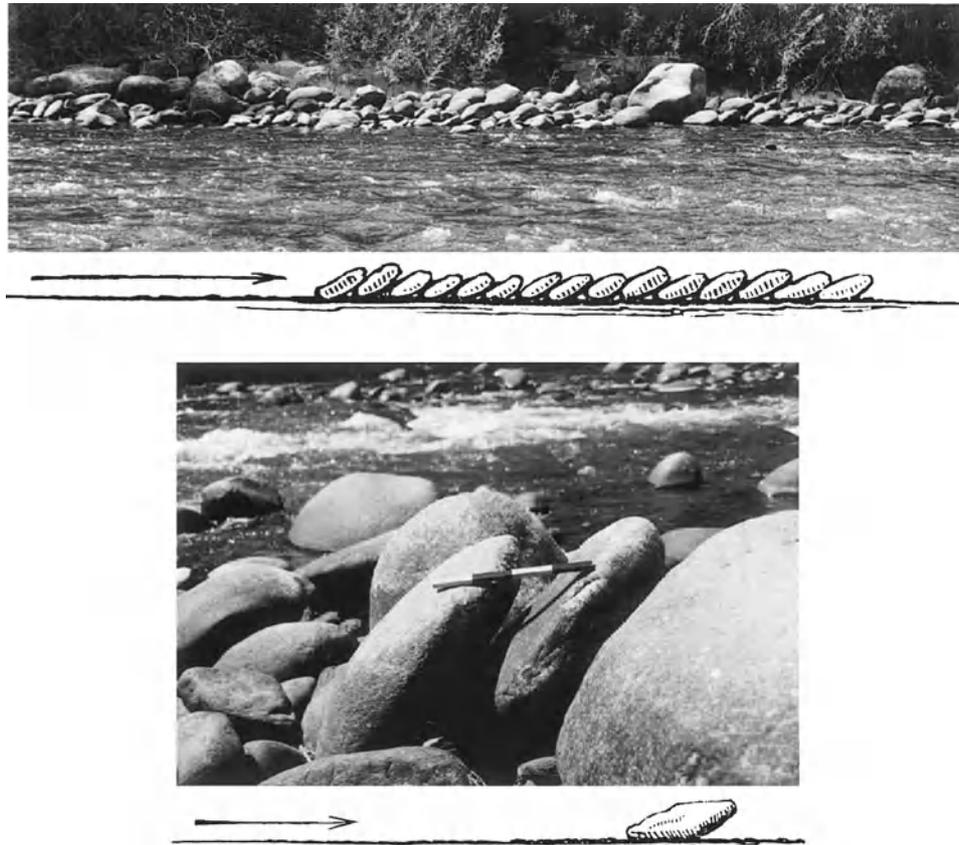

Figure 12 An early illustration of imbricated and flow-oriented clasts (Jamieson, 1860) and photos of the same phenomena from the Colorado Plateau. These illustrations and photos show regularly oriented clasts, where the a - b planes of the clasts dip down toward the upstream direction. Full scale is 30 cm.

with a gravel component will rarely contain imbricated pebble arrays.

Regularly-oriented clasts

Isolated tabular clasts are easily oriented by flowing water. Analysis of the fluid mechanics involved in overturning a tabular clast suggests that there is a critical overturning *Froude number* (\mathbb{F}_i) above which the clasts overturn,

$$\mathbb{F}_i = V/\sqrt{gc} \quad (\text{Eq. 1})$$

where V is the mean flow velocity affecting the clasts, g is the acceleration due to gravity, and c is the thickness (short axis) of the tabular clasts (Galvin, 1987). The critical overturning value of \mathbb{F}_i , above which the tabular clast is oriented by the flow, is about 3.0 to 3.5. This critical value decreases as the suspended mud content of the water increases. The analysis assumes that flow depth exceeds the a axis of the clast, a condition where the immersed weight of the clast resisting the overturning is significantly less than its weight in air.

Usually, the acceleration, g , in a Froude number can be treated as just another constant necessary to make the units balance, but Pathfinder photos of clasts on the surface of Mars suggest that these clasts may be imbricated or flow-oriented.

The lower Martian value of g to be used in equation 1 for explaining this imbrication or clast orientation implies that a given size clast overturns in flowing water on Mars when the velocity is only about 62 percent that needed to overturn it on Earth.

The expected orientation of an imbricated group of tabular clasts or an isolated tabular clast is one in which the planes containing the longer (a , b) axes dip down toward the source of the flow (Figure 12). For a clast in a stream, this means that the a - b plane usually dips toward the upstream direction. Clasts having this expected dip toward the upstream direction are *regularly oriented clasts*.

Reversely-oriented clasts

On active foreset beds, there may be exceptions to this upstream dip (Figure 13, top). On active foresets, isolated clasts may dip in the down-slope direction parallel to, or more steeply than, the slope itself, if turbulence shed by the clast scours a hole at the downstream edge of the clast, and (possibly) if grain flow exerts an overturning moment on the upslope edge of the clast. Clasts whose a - b planes dip in the downstream direction are *reversely oriented clasts*, so-called because the dip is opposite that expected from intuition developed by observations such as shown in Figure 12.

Figure 13 Reversely oriented clasts. Above: downstream dip of larger pebbles in a sandy member of the Cretaceous Potomac Formation, Lorton Station, Virginia. The horizontal is indicated by the central bubble of the level. Inferred flow is from right to left. Notice the collection of smaller pebbles in the wake of the large reversely oriented pebble. At a higher level in the same outcrop where the bedding is more nearly horizontal, flow-oriented pebbles have regularly inclined orientation. Below: in Brushy Basin Member of Morison Formation, reversely oriented blocky sandstone on “popcorn” montmorillonite shale, apparently the result of scour on the downslope edge of the clasts during sheet flow runoff.

In arid regions it is common to find clasts on eroding slopes whose a - b planes dip downslope more steeply than the slope on which they rest. This commonly occurs when volcanic rocks capping the uplands break up and slide down slopes of fine-grained volcanic ash. Such an orientation of clasts (flints) in surficial gravels were reported toward the end of his life by Charles Darwin from the south of England. Probably, the cause is runoff by overland sheet flow during rare, heavy thunderstorms. For sheet flow, the water depth is typically less than the c -axis, a condition where the effective weight of the clast on the bottom is nearly that of its weight in air. The sheet flow scours on the downslope side of the clasts, and the clast settles into the scoured depression with the result that the a - b plane of the clast dips more steeply than the slope (Figure I3, bottom). With respect to the presentation shown in Figure I2, the clasts in Figure I3 are reversely oriented because they dip toward the downstream direction of the flow. Such orientations of the a - b planes steeper than the underlying slope may superficially resemble the condition produced by waves on beaches.

Finally, a form of reversely oriented clasts develops when wedge-shaped or pear-shaped clasts are subject to sheet flow. The thick end of the clast exerts more weight on the underlying

Figure 14 Imbricated boulders at Monument Cove, Acadia National Park, Maine. Boulders are locally derived and abraded (Waag and Ogren, 1984). The long axes of boulders dip into the waves, usually more steeply than the foreshore slope.

Table 11 Classification of imbricated and flow-oriented clasts

Class	Flow	Condition
Regularly inclined	Stream flow (clear water) Debris flow	$F_1 > 3.0$ to 3.5 $F_1 < 3.0$
Reversely inclined	Delta flow (foreset beds) Sheet flow (erodible bed) Sheet flow (pavement)	Scour at downstream end of clasts with tilt due to fluid flow, gravity, and grain flow. Scour at downstream end of clast with tilt due to gravity. Pivot about thick end of clasts. Thick end fixed by friction
Wave-oriented	Waves Longshore currents	Onshore-offshore flow dominates. Clasts dip toward waves, more steeply than foreshore. Significant longshore flow accompanies waves. Clasts dip into longshore current.
Vertically oriented	Steady flows in streams or surf	High concentrations of plate-like clasts.

surface. If the weight produces sufficient friction along the underlying surface, the thin edge of the clast will be moved by the current, pivoting like a rudder about its post, to point downstream. Such orientations might be expected on large clasts after sudden extreme floods such as the floods that produced the channeled scablands on the Columbia Plateau or jökulhlaup deposits in Iceland.

Wave-oriented clasts

For clasts on beaches, the orientations of a - b planes have aspects of both regularly and reversely oriented clasts. For a clast subject to wave action on a beach foreshore, the a - b plane dips toward the incoming waves (Figure 14). The incoming wave is the dominant flow, so this seaward dip may be considered the expected regular orientation. Relative to the foreshore on which the clast rests, the clast dips more steeply so that the lower end of the clast is embedded in the foreshore. It appears that this embedding of the clast at its lower end is at least in part due to the currents draining seaward from the swash, in which perspective, the clast is reversely oriented. When the waves produce a significant longshore current, especially at the distal ends of spits, the a - b plane of the clast will reorient to dip toward (into) the longshore currents, producing a regular orientation from the perspective of the longshore current.

On low spits during times when waves actively overtop the spit, the overtopping due to the waves acts as a uniform stream which orients flat pebbles with their a - b planes dipping into that current. This results in clasts on the land-facing shore of spits having a seaward dip to the a - b plane.

Vertically-oriented clasts

Finally, there is the vertical orientation of a - b planes introduced when exceptionally thin clasts, such as relatively flat shells or slate, are subject to strong flows, such as surging waves (Sanderson and Donovan, 1974). This phenomenon is relatively rare on a worldwide basis but locally common, particularly where clams are shucked commercially. The origin of beds of shells with vertically oriented a - b plane appears to be similar to the origin of the more common phenomenon of leaf jams in streams flowing through deciduous woodlands. There, a heavy concentration of large leaves, such as oak leaves, in flowing water produces a stable orientation with the leaf planes vertical.

Summary

The relationship of the various factors to flow direction and slope are summarized in Table 11.

IMPREGNATION

Impregnation is a technique used to obtain high quality sections of soft or poorly consolidated sediments for preservation or petrographic analysis. The hardened sediment samples are also valuable for elemental and microfabric analyzes. It is also frequently beneficial to impregnate partially consolidated samples (e.g., diamicts) prior to facing and thin section preparation. The primary goal of any sediment impregnation method is to stabilize the material of interest in order to obtain undisturbed samples. Due to the range of sample characteristics and the varying needs of researchers, a large number of impregnation methods have been developed. Workers in the fields of sedimentology and soil science have made parallel developments in impregnation techniques and both fields, often in isolation, have adopted many common techniques. However, despite the wide use of impregnation techniques in sedimentology, geologists have not adopted one or more standard methods for sample preparation.

The main developments in sediment impregnation have resulted from the availability of new embedding materials. In particular, the advent of low viscosity epoxy resins has made impregnating clay-rich and compacted samples possible. Key criteria for selecting a particular method and embedding media depend on the sample cohesiveness, texture, and cementation. In most cases, the most appropriate method will produce an imbedded sample that is fully stabilized and has undergone minimal disturbance, particularly shrinkage. Thorough discussions of various materials and the comparative advantages of a large number of different techniques can be found in Bouma (1969) and Murphy (1986).

Main approaches

One of the earliest approaches used to obtain an impregnated sample from unconsolidated sediment samples was the production of a tape or glue peel (see *Peels*). This method is most appropriate for unconsolidated sediments typically found in sections and from split cores. The common approach is to saturate the sediment surface with diluted, water-soluble glue that is allowed to dry over several days. In coarse-grained samples, the glue typically penetrates to a depth of 0.5 cm to 2 cm. When dry, the glue surface can be separated from the remaining sediment, yielding a permanent sample for storage, mounting, and analysis. Although suitable for large exposures and field use, the chief disadvantage of water-soluble glues is that some degree of shrinkage occurs. The use of a

tacky acetate sheet applied to the sediment surface is an alternate approach that avoids the subsequent shrinkage problem. However, the acetate peel can only bond to surface grains and may not provide a complete, representative sample.

A more common approach to imbedding involves filling the entire sample with a cement to preserve the sedimentary structures. In practice, a large number of possible embedding materials exist, and availability varies in different areas. In general, embedding media can be characterized as either water-soluble or insoluble. Soluble materials are useful when the sample is wet, such as recent lacustrine or marine sediments. The two most common soluble materials include diluted ordinary glue and polyethylene glycol (PEG). The sample is immersed in the liquid embedding material and allowed to soak for several days or longer to allow the embedding fluid to fully infiltrate the sample. Generally, the PEG used for embedding is a high molecular weight (> 800) variety and is a waxy solid at room temperature. The PEG flakes must be melted by the application of heat during the soaking process. Although the water-soluble media are nontoxic and require no specialized equipment to use, they often result in some shrinkage, are generally too soft for thin sectioning, require non-aqueous grinding fluids, and they have poor optical properties.

Water insoluble media are generally either epoxy or acrylic resins that require the sample to be dehydrated prior to embedding to obtain full polymerization of the resin compounds. While air or oven drying may be suitable for sandy or gravelly samples, finer textured samples will crack and shrink during drying, and the dry permeability of the sample will often be too low to allow full infiltration of the embedding material, especially into the center of larger samples.

Two common methods for dehydrating samples to minimize shrinkage are to sublime the sample water under vacuum (freeze drying) or by using repeated liquid-liquid replacements. Freeze drying effectively dehydrates samples of all textures, although many commercial units are limited to small samples (less than a few centimeters). Where suitable equipment is available, freeze-drying produces minimal disturbance of the sample if the sample is first frozen with liquid nitrogen (Bouma, 1969). Pre-freezing is particularly important for clay-rich samples, as the rapid freezing in nitrogen prevents the formation of large ice crystals in the sample that result in voids in the embedded sample. However, some ice crystal formation tends to occur in very fine clay units, particularly if the sediment sample is more than 1 cm thick. Depending on the rate of sample drying and the sediment composition, some minor shrinkage may also occur and cracks may form at sedimentary contacts. Moreover, the freeze-dried samples are extremely fragile and coarse units may require support to prevent collapse during handling.

The second approach to dehydrating samples involves replacing the pore water with a water and resin miscible solution. Most epoxy resins are compatible with acetone and various alcohols. By replacing the pore water with such a fluid, there is no shrinkage or disturbance to the sedimentary structures. This method is suitable for a variety of sediments including those from clay-rich lacustrine, marine, and glaciogenic environments. The wet samples are submerged in the replacement fluid that is left to fully infiltrate into the sample, often for one or more days. The fluid is then drawn off and replaced with fresh solution until the specific gravity of the

supernatant indicates that the water content is below 1 percent (or less). Liquid-liquid replacement dehydration of samples results in the least disturbance of samples, as there is no shrinkage or danger of ice crystal casts in the final embedded sample. However, the process is time consuming and uses a large amount of the exchange fluid and resin. In some cases, application of a light vacuum during the resin infiltration can avoid extra resin waste.

Selection of the embedding resin varies considerably among users, ranging from slow curing acrylics (months) to rapid curing epoxies (hours). Some epoxy resins that cure rapidly are unsuitable because they are strongly exothermic and can disturb the sample. Depending on circumstances, a variety of resins can be used (Tippkötter and Ritz, 1996). Low viscosity resins used for embedding histological and material samples are readily available and suitable for fine-grained lacustrine and marine sediments. Less specialized, higher viscosity resins are suitable for coarser samples. Most require curing in an oven to fully polymerize. The advantages of impregnating samples with resin include standard handling procedures for thin section preparation, excellent optical characteristics, and permanent preservation of the sample. Compared to water-soluble media, impregnating samples with resin is often time consuming and relatively expensive. Moreover, more specialized equipment is required, including facilities to handle what are typically toxic chemicals.

Partial curing of an impregnated block, especially with epoxy resins, usually indicates the presence of water in the sample or poor resin infiltration. Increased infiltration times using resins with long working times can avoid this problem, and light vacuum may also accelerate infiltration. In some situations, samples with incomplete infiltration can still be cut and the exposed face treated with resin to complete the stabilization prior to mounting (Carr and Lee, 1998).

Impregnation of sedimentary samples has proven to be a valuable technique for geologists working in a wide range of environments where sample preservation and microscopic analysis has been limited by poorly consolidated materials. A number of methods are available for impregnation, depending on sample texture and moisture content. Samples that are dehydrated and embedded with epoxy resins are suitable for most applications, although simpler methods are available as well.

IRON-MANGANESE NODULES

Black to dark brown spheroidal to discoidal concretions of iron and manganese oxyhydroxides, generally a few cm in diameter, that cover extensive areas of the ocean floor in all water depths as well as the bottoms of some temperate latitude lakes (Figures I5 and I6). The ferromanganese oxyhydroxides are intimately mixed with mineral and rock fragments and fossil debris, and occur as concentric layers arranged around a central nucleus or core consisting of rock fragments (generally volcanic), fossils (e.g., fish teeth, whale ear bones, etc.) or broken nodules. Surfaces are either smooth or granular. Nodules are highly porous and have dry bulk densities ranging from 1.2 g cm^{-3} to 1.6 g cm^{-3} depending on the chemical composition.

Distribution and abundance

Nodules are most abundant on the sediment surface and occur sporadically within the seafloor sediment. Sampling and bottom photography has shown that average surface concentrations of 10 kg m^{-2} , reaching a maximum of about 35 kg m^{-2} , are typical of vast areas of the Indian and Pacific seafloors between 4 km and 5 km water depth. The highest concentrations are found where the sediment accumulates very slowly, so that the nodules are not covered and buried. Hence, dense pavements of nodules are characteristic of the central ocean basins most remote from continental sediment supply. Similar Mn and Fe deposits are found on northern European shelves, the Baltic Sea and some fjords. Ferromanganese oxyhydroxides also occur as crusts and coatings on rock and mineral surfaces, especially on seamounts and similar topographic elevations throughout the ocean basins.

Ferromanganese nodules are locally abundant on the floors of temperate zone lakes, such as those of Scandinavia and eastern North America (Cronan and Thomas, 1970). They occur as spherical and discoidal nodules and as coatings on rock surfaces.

Growth rate

The rate of accretion of ferromanganese nodules and crusts has been determined by dating rock nuclei by the K/Ar method (Barnes and Dymond, 1967), and by measuring the decay of natural uranium series (^{230}Th , ^{231}Pa) or cosmogenic (^{10}Be) nuclides in the oxyhydroxide layers (Ku, in Glasby, 1977). The median rate obtained with these different methods is around 5 mm/Ma , with a range of $<1 \text{ mm/Ma}$ to $>50 \text{ mm/Ma}$. In contrast, the rate of accumulation of associated sediment is of order 1 mm/Ka to 5 mm/Ka . This discordance, and the puzzling fact that most deep-sea nodules are found at the sediment surface, implies that they must be maintained at the sediment-water interface for very long time periods. Occasional disturbance of the seafloor, by currents, slumping or the activities of benthic fauna, is probably sufficient to remove sediment from the tops of the nodules and to turn them over from time to time (Piper and Fowler, 1980).

Chemical composition

The chemical composition of ferromanganese nodules and crusts reflects their constituent mixtures of mineral phases, comprising oxyhydroxides, aluminosilicates, carbonates and phosphates. They are significantly enriched in Mn, Fe and other transition metals compared with crustal rocks. Mn/Fe ratios are generally greater than unity and Cu and Ni concentrations are highest in the Pacific Ocean, whereas Mn/Fe ratios are less than unity and Zn and Pb concentrations are highest in the Atlantic Ocean (Table I2). On an ocean-wide

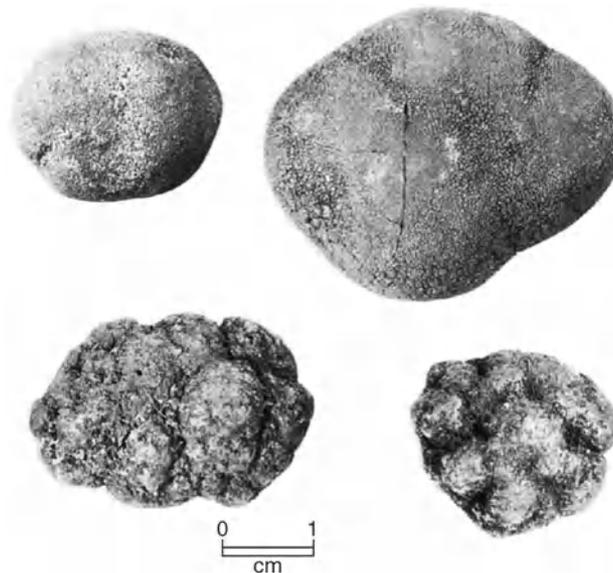

Figure I5 Photographs of Pacific seafloor ferromanganese nodules. The upper pair of nodules have smooth surfaces and were collected from the northern central region where sedimentation rates are very low. The lower pair of nodules have granular, botryoidal surfaces and were collected from the northern equatorial region where sedimentation rates are higher.

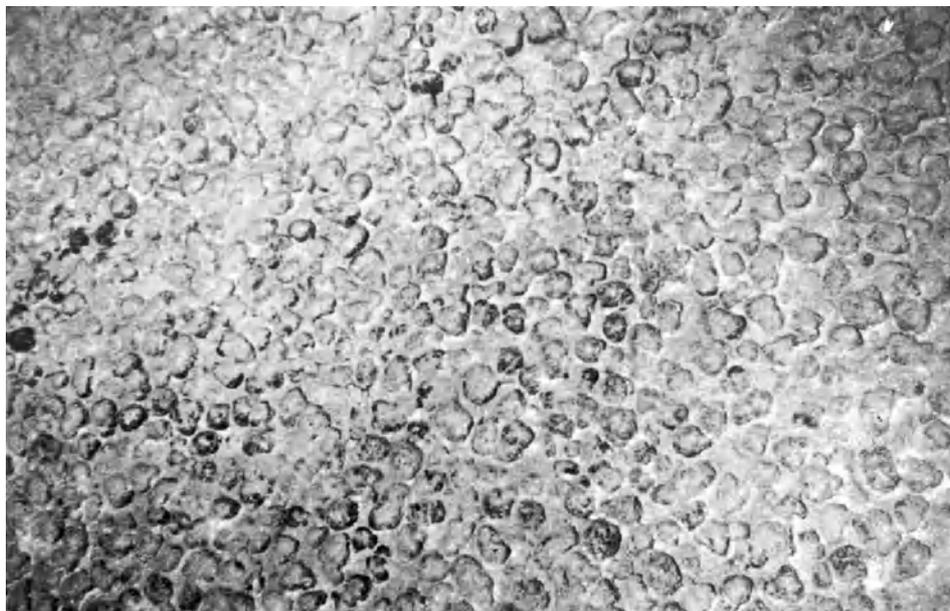

Figure 16 Seafloor photograph from the Southern Ocean (61° 41S; 170° 40'E; water depth 5160 m) showing dense pavement of nodules 2 cm to 8 cm in diameter with a light sediment coating. Surface concentration is approximately 25 kg m^{-2} . Photograph taken by S.E. Calvert using equipment owned by the US Navy.

Table 12 Average chemical composition of oceanic ferromanganese deposits (wt. per cent). From Cronan (1980)

Element	Pacific Ocean	Atlantic Ocean	Crustal abundance
Mn	19.8	15.8	0.1
Fe	12.0	20.8	5.6
Co	0.33	0.32	0.002
Ni	0.63	0.33	0.007
Cu	0.39	0.17	0.005
Zn	0.07	0.08	0.007
Pb	0.08	0.13	0.001

scale, minor element concentrations appear to be related to the Mn or the Fe contents; Ba, Cu, Mo, Ni, and Zn vary proportionally with the Mn content, whereas Co, Pb, Ti, and Ce concentrations correlate with the Fe content. These relationships reflect the substitution of the minor metals for Mn or Fe in the major oxyhydroxide mineral phases. *Buserite* is a fibrous manganate in which a number of divalent cations, including Mn^{2+} , Cu, Ni, Zn, etc., substitute for Mn^{4+} in a hexagonal array of edge-shared Mn(IV)O_6 octahedra thereby stabilizing the structure (Giovanoli and Arrhenius, in Halbach *et al.*, 1988); *vernadite* is a highly disordered manganate with the approximate formula MnO_2 which is intimately associated with ferrihydrite (FeOOH), the principal Fe phase (Burns and Burns, in Glasby, 1977). MnO_2 and FeOOH host minor metals that can exist in their higher oxidation states in the ocean (Co^{3+} , Pb^{4+} , Ti^{4+} , Ce^{4+}), but lack sites of the appropriate size for the substitution of divalent cations. Thus, buserite is only found in nodules with high Mn, Cu, and Ni concentrations, whereas vernadite occurs in nodules with high Fe and Co contents. Nodules from shallow water environments consist of

a mineral phase similar to buserite, which contains very low minor element contents and is unstable when dried in air (Calvert and Price, in Glasby, 1977).

Regional variations

The chemical composition of ferromanganese nodules varies markedly within a given ocean basin. This is best illustrated in the Pacific (Figure 17), where nodules that form in the marginal areas and in east-west zones north and south of the equator, have the highest Mn/Fe ratios. The abyssal Mn-rich nodules also have the highest Cu and Ni contents and they contain stable buserite as the principal Mn mineral phase (Cronan, 1976; Piper and Williamson, 1977; Calvert, 1978). The marginal Mn-rich nodules are impoverished in minor elements, and consequently they contain metastable buserite. Nodules and crusts that form in areas of the seafloor with very low sedimentation rates and on sediment-starved elevations above the abyssal seafloor (seamounts and banks) have the lowest Mn/Fe ratios, they lack buserite and have the highest

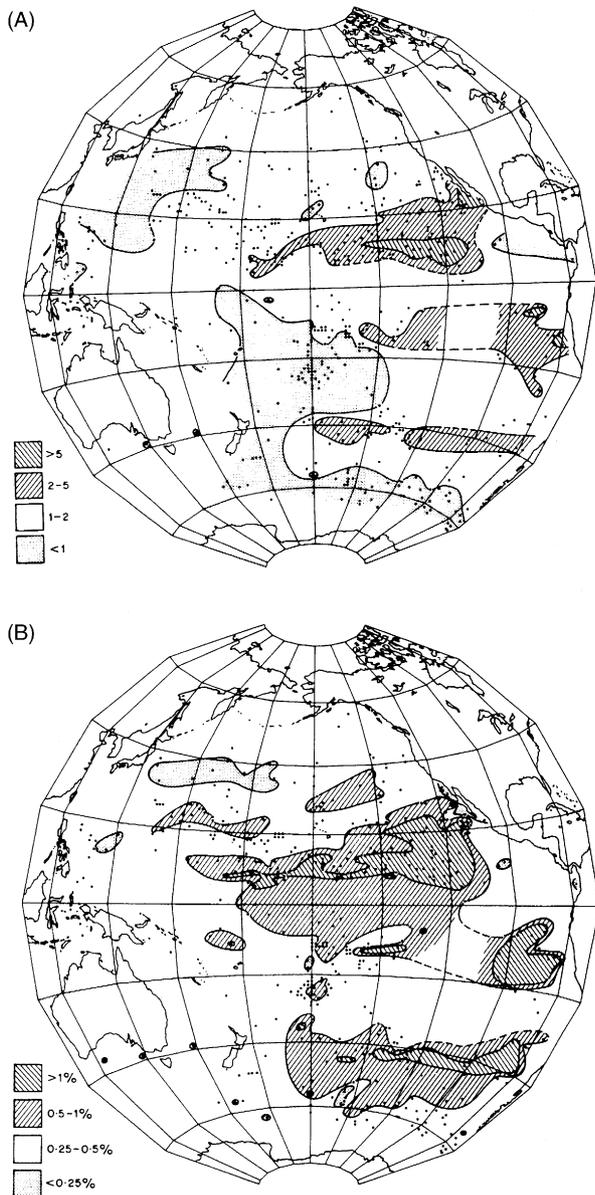

Figure 17 Ocean-wide variation in (A) the Mn/Fe ratio and (B) the Ni concentration in seafloor nodules from the Pacific Ocean. From (Cronan, 1980).

Co contents. This compositional variability reflects the two processes by which ferromanganese deposits are formed.

Origin

Hydrogenetic nodules and crusts form by the very slow precipitation of seawater Mn and Fe, supplied to ocean waters by rivers and seafloor hydrothermal sources, as very fine-grained or colloidal oxyhydroxides onto solid substrates (Halbach *et al.*, 1981). The nodules and crusts formed in this manner generally have smooth surfaces, and vernadite is the principal Mn phase. They have the lowest Mn/Fe ratios and

Cu and Ni contents, and the highest Co, Pb, Ti, and Ce contents. *Diagenetic* nodules form by the more rapid precipitation of Mn and divalent metals supplied to the seafloor in association with settling planktonic organic matter and recycled from the underlying sediment. Such nodules generally have granular surfaces and buserite is the principal Mn phase. They have much higher Mn/Fe ratios, and the highest Cu and Ni contents (Calvert and Price, 1977). These two types of precipitates can occur in the same nodule; in this case a distinctly discoidal nodule from the equatorial region of the Pacific Ocean has a smooth, vernadite-bearing upper surface with a low Mn/Fe ratio and high Co content, and a granular, buserite-bearing lower surface with a much higher Mn/Fe ratio and high Cu and Ni contents growing within the surficial sediment (Raab, 1972). Distinct compositional regions in the Pacific therefore identify environments where metals are either supplied mainly from bottom waters or additionally from the bottom sediment (Halbach *et al.*, 1988). Marginal nodules with high Mn/Fe ratios have low minor metal contents because diagenetic reactions in the subsurface anoxic sediment, fueled by high burial rates of organic matter, trap them as sulfides or cause them to be adsorbed on particle surfaces, thereby preventing their recycling to the sediment surface where they would otherwise be incorporated into surficial oxyhydroxides (Calvert and Price, in Glasby 1977). Lacustrine nodules form by very similar processes and have compositions that reflect the relative importance of metal precipitation from lake waters and the bottom sediments (Harriss and Troup, 1970).

Summary

Ferromanganese nodules and crusts represent a common type of authigenic deposition in all oxygenated aquatic environments in all water depths. They grow very slowly by the accretion of very fine-grained and colloidal oxyhydroxides onto solid substrates, and often form dense pavements over large areas of the seafloor. They can be greatly enriched in transition metals, which are derived from normal ocean waters and from sediment pore waters. Their mineralogies and bulk compositions vary from ocean to ocean, within an ocean basin and on the scale of a single nodule. There are two end-member nodule and crust types, with all gradations between these forms. Hydrogenetic nodules and crusts are formed from bottom seawater, whereas diagenetic nodules also have a metal source from the associated sediment via diagenetic metal recycling. These processes are also responsible for the formation of similar deposits on shallow areas of the seafloor and in lakes.

Oceanic Sediments

IRONSTONES AND IRON FORMATIONS

Iron-rich sedimentary rocks contain ≥ 15 percent metallic iron by weight (James, 1966) and form a class of chemical sediments comparable to evaporites and phosphorites. Most workers recognize two main categories. *Iron Formations* are generally cherty, thinly laminated, and Precambrian in age. *Ironstones* are generally less siliceous, more aluminous, not laminated, smaller, and Phanerozoic in age. This distinction highlights time-related changes which constitute one of the most interesting aspects of iron-rich sedimentary rocks and has important implications for the evolution of Earth's atmosphere and hydrosphere. Both types have long been sources of iron for human use. Ironstones were mined in Roman times and were a key resource in the industrial revolution (Young, 1993). Mineralogical investigations of ironstone began in the mid-1800s. Studies of iron formations were begun in the late 1800s by geologists from the fledgling U.S. Geological Survey in the Lake Superior region. This work resulted in classic monographs focused on specific "iron ranges" as well as Van

Hise and Leith (1911). Fresh studies triggered by the demand for iron during World War II yielded a new round of U.S.G.S. publications and the seminal article by James (1954). Large iron formations and associated deposits of iron ore were still being discovered. The subsequent discovery and study of large iron formations in Western Australia have been particularly influential in shaping current perceptions of iron formations, even though they are exceptional in many ways (Trendall, 2002).

The vast majority of iron that is ever mined will be extracted from Precambrian iron formations or derivative deposits. Large iron formations are currently mined all over the world. In 2000, Australia produced over 160 million metric tons of iron ore worth in excess of US\$2.5 billion, and China and Brazil produced even more. The largest ore deposits occur where silica was leached and iron was oxidized in iron formations during the Precambrian (Morris, 1987). Ores produced by post-Precambrian weathering generally have lower iron contents and more impurities. Iron can also be extracted from unaltered iron formations by crushing them and separating the magnetite.

Iron formations have also yielded economic quantities of other materials. Iron formations in Archean greenstone belts host world-class gold deposits, and manganese is extracted in large quantities from iron formations in Brazil, India, and especially South Africa. Blue asbestos (crocidolite) was extracted from iron formations during the mid-1900s, but production dropped off precipitously as the highly carcinogenic nature of blue asbestos became clear.

Iron formations

The main iron minerals fall into four groups which James (1954) used to define four "facies" of iron formation: oxide, silicate, carbonate, and sulfide. In low-grade iron formations, the dominant minerals are magnetite and hematite in the oxide facies; greenalite and minnesotaite in the silicate facies; siderite and ankerite in the carbonate facies; and pyrite in the sulfide facies. Where detrital textures are not obscured by metamorphism, iron formations can be sub-divided into *banded* versus *granular* varieties. Banded iron formations or BIFs, by far the more abundant of the two, were originally chemical muds. Most BIFs exhibit a quasi- to highly rhythmic alternation of layers rich in iron and chert on a scale of millimeters to centimeters (Figure I8(A)). Granular iron formations or GIFs originated as well-sorted chemical sands (Figure I8(B)) in which the clasts were largely derived via intrabasinal erosion and redeposition of pre-existing BIF. GIFs lack the even, continuous banding of BIFs and generally belong to the oxide or silicate mineral facies, whereas BIFs show a much broader spectrum of iron minerals, including a greater abundance of reduced facies (James, 1954; Simonson, 1985). Layers of pure GIF thicker than a few meters are rare, whereas BIF can continue uninterrupted by GIF for tens to hundreds of meters stratigraphically. Iron formations with a mixture of BIF and GIF are actually more abundant than pure GIFs, and they show bedding that is more irregular than pure BIF, but less massive than pure GIF. In mixed iron formations, GIF takes the form of discontinuous lenses that probably represent bedforms generated by storm waves and currents (Simonson, 1985). Chert is not used to classify iron formations because it is a ubiquitous component, but its abundance helps distinguish them from ironstones. Another

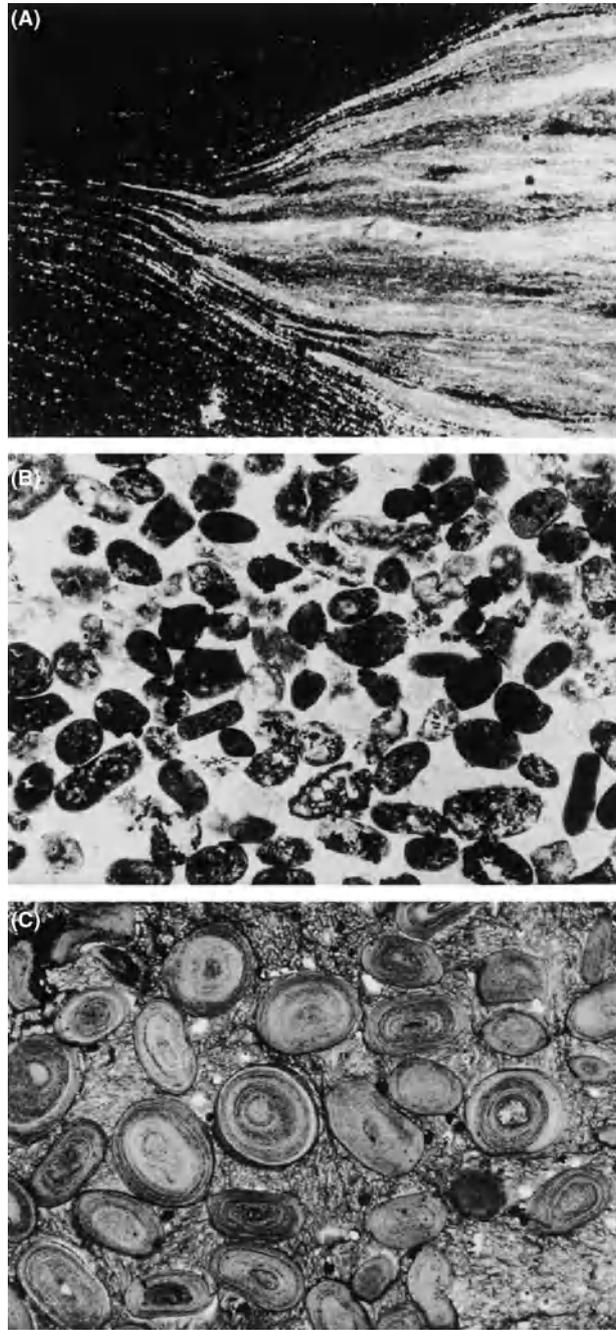

Figure 18 Photomicrographs of iron-rich sedimentary rocks in plane polarized light. (A) Banded iron formation from the early Paleoproterozoic Dales Gorge Member of the Brockman Iron Formation, Hamersley basin of Western Australia. Clear part is chert pod with opaque hematite impurities, dark part is dominantly magnetite; note the contrast in thickness and sharpness of laminae as they exit the chert pod into the surrounding BIF. Field of view is ~ 5 mm wide. (B) Granular iron formation from the Paleoproterozoic Sokoman Iron Formation, Labrador trough. Peloid-like granules consist of chert and hematite with lesser amounts of magnetite; the interstices are filled with slightly recrystallized chalcedonic cement. Field of view is ~ 2.5 mm wide. (C) Oolitic ironstone from the late Ordovician to early Silurian Don Braulio Formation, Sierra de Villicúm of the Argentine Pre-Cordillera. The ooids consist of silicate, show nice pseudouniaxial extinction crosses between crossed polarizers, and are locally truncated along dark stylolitic seams; the composition of the fine-grained matrix is undetermined, but it is probably a mixture of fine quartzose silt and chert. Field of view is ~ 5 mm wide.

scheme subdivides iron formations into Superior-type versus Algoma-type, as described below. Given their great age, most iron formations are tectonically deformed or metamorphosed to some degree, yet iron formations retain their distinctive chemical composition, even at high grades. The metamorphism of iron formations is a complex topic in its own right (Trendall and Morris, 1983, pp. 417–469).

Intrinsic characteristics

Despite their great antiquity, many iron formations have well-preserved sedimentary features. Like all arenites, GIFs consist of a combination of: (1) sand-size clasts (long referred to as “granules,” for example, Van Hise and Leith, 1911); (2) finer grained material (matrix), which is relatively rare; and (3) cements (interstitial, void-filling authigenic minerals) (Dimroth, 1976). In addition, diagenetic phases replace these primary constituents in part or whole in all iron formations. The granules, which are analogous to carbonate peloids and intraclasts, are mostly fine to coarse sand size (Mengel, 1973) and range from well-rounded to angular (Figure I8(B)). Ooids with concentrically laminated cortices are abundant locally (Dimroth, 1976; Simonson, 1987), but much rarer than granules. GIFs had depositional porosities of 40 percent to 50 percent, much of which was occluded by siliceous cement early in diagenesis (Figure I8(B); Mengel, 1973; Simonson, 1987). Other GIFs are heavily compacted and show tight frameworks and distorted clasts. Many GIFs have intergranular cavities, cracks, and vugs that are largely filled with chalcedonic and drusy quartz cements prior to compaction. Similar cracks and vugs are widely developed in the stromatolitic cherts found in some GIFs. These cracks and vugs probably originated via post-depositional shrinkage due to the dewatering of gelatinous precursors, and some contain internal sediment that is distributed geopetally (Simonson, 1987).

Depositional structures are often obscured by diagenetically redistributed minerals, but dune-scale cross-stratification is widespread in GIFs (Simonson, 1985). The few paleocurrents which have been measured show complex polymodal patterns with hints of herringbone typical of shallow marine sands (Ojakangas, 1983). Flat pebble conglomerates are a minor but widespread component of GIFs with the pebbles generally derived from more siliceous layers. Stromatolites that vary in width from a centimeter to over a meter and range in morphology from columnar to domal are another minor but distinctive sedimentary structure found in GIFs but not BIFs. Although they are usually interpreted as products of sediment trapping and/or precipitation by microbial mats, some stromatolites in GIFs have characteristics like those of siliceous sinters deposited in and around hot springs. Thanks to the early silica cementation, iron formations contain some of the best-preserved early Precambrian biotas in the world (Trendall and Morris, 1983, pp. 373–400).

In contrast to GIFs, BIFs generally lack any obvious detrital textures. Even though they are diagenetically reorganized, many BIFs are still remarkably fine-grained and uniform (Figure I8(A)). As noted above, BIFs show more diversity of iron minerals than GIFs, including substantial thicknesses of all four of James’ facies. Most of these minerals are thought to be derived from phases precipitated from the original basin waters, but some BIFs contain aluminous silicate phases, most notably stilpnomelane, due to the presence of volcanoclastic contaminants. Exquisite volcanic

shards replaced by stilpnomelane occur in some iron formations (LaBerge, 1966a,b).

As the name implies, most BIFs have well-developed thin lamination to thin bedding (Figure I8(A)). This is no surprise, given the lack of burrowers in the Precambrian, but the layers in BIFs (particularly those rich in iron oxides) can be quite striking, and in some cases they can be correlated for hundreds of kilometers (Trendall and Blockley, 1970; Ewers and Morris, 1981). The bedding in BIFs can also be highly cyclic via alternations of iron-rich and iron-poor precipitates or alternations of BIF and fine shaly or volcanoclastic strata (Trendall and Blockley, 1970; Ewers and Morris, 1981; Beukes, 1984). Trendall (1972) attempted to relate these cycles to orbital parameters, but they have yet to be tested for the periodicities typical of Milankovitch forcing. Sedimentary structures other than banding are rare in BIFs, except for chert pods (Figure I8(A)), which are best interpreted as localized pockets of early cementation. Chert-poor BIF surrounding the pods offers textbook examples of differential compaction following localized early cementation (Dimroth, 1976; Beukes, 1984; Simonson, 1987) which indicate chert-poor BIFs lost up to 90 percent or more of their original thickness during compaction; this is typical of muds in general. The minerals shielded within chert pods also indicate the original sediment had a range of compositions similar to the ones shown by present-day BIFs.

Stratigraphic context and secular variation

Although they are associated with a wide variety of lithologies, the nature of the rocks associated with iron formations changes progressively through time. Gross (1965, 1983) used this and other criteria to subdivide iron formations into Algoma-type and Superior-type. His original definitions have evolved through time, but the modifier Superior-type is still used for uniquely large iron formations of the late Archean and Paleoproterozoic that are associated with non-volcanic sedimentary rocks. The modifier Algoma-type is used for iron formations that are generally smaller and occur in Archean greenstone belts where they are associated with volcanic rocks (Fralick and Barrett, 1995). Virtually all of the Algoma-type iron formations are BIFs, and they run the full gamut from oxide to sulfide facies mineralogies. In contrast, the thicker, more laterally extensive Superior-type iron formations contain GIFs as well as BIFs; the BIFs again show a full range of iron mineralogies, but the GIFs are dominated by oxide and silicate facies rocks. Some of the Superior-type iron formations are associated with shallow-water deposits, but many of them as well as most of the Algoma-type iron formations are associated with deeper water deposits.

Iron formations range from early Archean to Paleoproterozoic in age and are found among the oldest sedimentary strata on earth in the Isua supracrustal belt in western Greenland. Iron accumulation climaxed during an interval of ≤ 800 million years in the Late Archean to Paleoproterozoic and ended rather abruptly on or before 1.8 Ga (Gole and Klein, 1981; Trendall and Morris, 1983, pp. 471–490). Algoma-type iron formations were forming in North America as the oldest Superior-type iron-formations formed in Western Australia and South Africa, indicating a gradual transition between the two.

A noteworthy episode of global sedimentary iron accumulation also took place in the Neoproterozoic, at which time iron-rich rocks often referred to as iron formations were deposited

on several continents. These late Precambrian iron formations tend to be richer in iron and have a simple iron mineralogy dominated by hematite (Beukes and Klein, 1992). Many of these iron formations are also closely associated with glaciogenic sediments (Young, 1988), so they may differ in origin.

Origins and implications for earth history

The slow rise and more rapid collapse of iron formation deposition early in Earth's history must be linked to co-evolution of the atmosphere, hydrosphere, biosphere, and lithosphere, but controversy continues over the details. Many hypotheses championed by early workers have been abandoned. For example, suggestions that iron formations originated via the replacement of carbonates, represent evaporites unique to the early Precambrian, or were deposited in lacustrine basins are no longer tenable. Sedimentological studies have made it clear that iron formations are primary precipitates deposited mostly in open marine settings (Ojakangas, 1983; Beukes, 1984; Simonson, 1985). The genetic model currently presented in most textbooks is likewise at odds with our current knowledge of iron formations. Cloud (1973) first suggested that dissolved ferrous iron was ubiquitous in the early ocean and iron formations formed wherever photosynthesizing microbes produced free oxygen, causing iron oxides to precipitate. It was an elegant hypothesis at the time, but we now know the iron minerals in iron formations are much more than just oxides and the iron concentrations in carbonate sediments contemporaneous with iron formations are not high enough to fit this scenario (Veizer *et al.*, 1990, 1992; Simonson and Hassler, 1996).

It is now widely believed that hydrothermal sources in the deep ocean supplied the iron to make iron formations. BIF deposition has been linked to hydrothermal activity with reasonably high confidence via stratigraphic context and facies relationships for some Algoma-type iron formations, and all types of iron formations show various geochemical signatures of hydrothermal sources (Klein and Beukes, 1992). It is also widely believed that iron formations precipitated along chemoclines in a stratified ocean (Beukes and Klein, 1992; Simonson and Hassler, 1996), which would explain why iron formations occur in many different tectonic settings and in association with many different rock types (Gross, 1983; Fralick and Barrett, 1995). Isley (1995) outlined a plausible scenario whereby iron-rich plumes released from deep-sea hydrothermal systems could travel to distant depocenters. The main point of contention is the mechanism(s) responsible for precipitating such great quantities of iron undiluted by other types of clastic or chemical sediment. Recent isotopic work indicates microbes played a role in the precipitation and/or diagenetic reorganization of the iron (Beard *et al.*, 1999).

Consensus has also been reached on the cause of the shift from Algoma- to Superior-type iron formations through time. The appearance of large iron-formations probably reflects the first development of extensive shelf environments in the Late Archean (Eriksson, 1995). This is consistent with the simultaneous appearance of laterally extensive examples of other stable-shelf deposits such the first large carbonate platforms (Grotzinger, 1994). Age differences among the largest iron formations on different continents could reflect the fact that the "cratonization" of shields was a highly diachronous process (Eriksson and Donaldson, 1986). The smaller size of Algoma-type iron formations is generally

believed to signal smaller depositional environments, but Gole and Klein (1981) point out that they are more highly deformed and some "may have been quite extensive prior to deformation and disruption." The growth in the size of iron formations through time could also involve changes in the bathymetry and/or chemistry of the world ocean that permitted the dispersal of iron over longer distances. However, this would require an increase in the mobility of dissolved iron, which runs counter to the prevailing view that the concentration of free oxygen in the atmosphere was increasing at that time (Eriksson, 1995). Even within the Superior-type category of iron formations, secular changes are evident. The oldest Superior-type iron formations are almost pure BIF, whereas GIFs reached their acme around 2.0 Ga. This suggests the locus of iron formation deposition shifted into progressively shallower environments, which may signal a progressive shallowing of a global chemocline through time.

The abrupt end to the deposition of iron formations in the Paleoproterozoic is presumably related more to atmospheric and hydrospheric than lithospheric evolution. Many lines of evidence signal a dramatic rise in atmospheric oxygen around 2.2 Ga to 1.9 Ga (Holland, 1994), which at some point ventilated the world ocean sufficiently well to prevent the storage and long distance transport of large quantities of dissolved iron. However, the disappearance of iron formations around 1.8 Ga may have actually been a result of the deep oceans becoming sulfidic rather than oxic (Anbar and Knoll, 2002). In either case a brief reappearance by iron formations late in the Precambrian may signal a return to these earlier conditions. The Neoproterozoic glaciations were so extreme that Hoffman *et al.* (1998) have argued they gave rise to a "snowball earth." Perhaps the ice capped the world ocean in such a way that it could become highly stratified for the first time in over an eon, thereby reactivating some of the mechanisms at work in the Paleoproterozoic. Like the older iron formations, the source of the iron for the Neoproterozoic iron formations appears to have been hydrothermal (Young, 1988).

Iron formations also differ from younger iron-rich sediments in their high silica content. Various lines of evidence including the cement-filled cracks and vugs in GIFs and the apparent syneresis of the original sediment indicate the silica in iron formation is a primary component. Given the absence of silica-secreting organisms, higher silica concentrations should have been present in Precambrian seawater to co-precipitate with the iron, but again the precise mechanism for this is unclear. On average, GIFs are probably more siliceous than BIFs, and oolitic and stromatolitic layers probably have the lowest iron contents of all. This is consistent with a deep-ocean source of iron, but it could also reflect a greater abundance of silica cement in GIFs.

Ironstones

The term ironstones encompasses a diverse group of rocks ranging in age from Proterozoic to Pliocene (Van Houton, 2000) which consist of materials ranging in size from sand to mud. Ironstones are one of several types of iron-rich sedimentary rocks formed during the Phanerozoic. The latter includes exhalative sediments formed directly by hydrothermal activity and "green sands," which are clastic sediments rich in glauconitic silicates. Such deposits have traditionally been differentiated from ironstones and that practice is followed

here, even though glauconitic sediments and ironstones have much in common (Van Houton and Purucker, 1984; Odin, 1988). Given their young geologic age, ironstones are much less likely to be deformed or metamorphosed than iron formations and commonly contain fossil debris. This has permitted detailed analyses of the depositional setting of ironstones (e.g., Hunter, 1970; Van Houton and Bhattacharyya, 1982), but consensus on the specific mechanisms and timing of iron precipitation has remained elusive.

Intrinsic characteristics

Ironstones contain representatives of all four of James' (1954) mineral facies, but differ from iron formations in some ways. Most ironstones consist of oxides and/or silicates, although siderite is also common in some (Odin, 1988). This is similar to the assemblages found in GIFs, but more oxidized than iron formations as a whole, given the widespread occurrence of reduced facies in BIFs. The oxides and silicates found in ironstones versus iron formations also differ systematically. Hematite is found in both, but goethite is only common in ironstones whereas magnetite is only common in iron formations. Likewise, chamosite and berthierine are the chief iron-rich silicates in ironstones but rare in iron formations. In addition to iron-rich phases, ironstones typically contain quartz sand, calcite, dolomite, and authigenic phosphorite and chert. All of these phases are rare in iron formations with the exception of chert. These mineralogical differences are reflected in lower iron and silica and higher alumina contents in ironstone versus iron formation, which is partly, but not entirely, a reflection of the age disparity between the two (see below).

Ooids are a distinctive feature of many ironstones (Figure 18(C)), but they are rarely its main constituent. Like those in iron formations, the ooids in ironstones consist of a nucleus plus a cortex with thin concentric laminations; no radial textures have been reported from ooids in either iron formations or ironstones. Ironstone ooids consist of iron silicates and/or iron oxides; these two minerals occur in alternating laminae in some ooids. The nuclei of the ooids are diverse in composition, ranging from calcareous fossil debris to detrital quartz sand grains to fragments of oolitic cortices. Replacement textures are commonly observed in the ooids, involving both iron-rich and iron-poor materials (including fossils) as both replacer and replacee. Despite the attention lavished on the ooids, other constituents probably form the bulk of ironstones. One common constituent is interstitial calcite or dolomite cement, but the most abundant are probably finely crystalline iron oxides, iron-rich silicates, and/or siderite. Much of this finer material is authigenic rather than detrital in origin (Odin, 1988). Many oolitic ironstones are cross-bedded, a sure sign they originated as well-sorted sands, but other ironstones are highly bioturbated, and show evidence of hardground-like induration in the form of local sediment reworked as intraclasts (Odin, 1988).

Stratigraphic context and secular variation

Most oolitic ironstones take the form of thin interbeds amidst successions of clastic and carbonate strata deposited in shallow marine environments. These are typically sediments deposited close to paleocoastlines in water on the order of a few tens of meters deep. In general, ironstones are formed closer to shore

and in shallower water than time-equivalent glauconitic deposits (e.g., Hunter, 1970), but the abundant remains of normal marine organisms and the evidence of repeated reworking indicate ironstones accumulated on the open seafloor rather than in restricted settings. Nevertheless, most workers believe ironstones did not accumulate in the highest energy environments, which is consistent with their common association with clastic mudrocks. Ironstones also tend to occur at stratigraphic breaks which coincide with transgressions (Van Houton and Bhattacharyya, 1982). Essentially, ironstones are now believed to constitute condensed sequences formed largely during times of maximum transgression and reduced clastic influx. This is also true on a grander scale; the two main pulses of ironstone accumulation coincide with Fischer's two "greenhouse" phases of sea-level highstand from the Ordovician to the Devonian and from the Jurassic to the Paleogene (Van Houton and Arthur, 1989).

Ironstones also vary in mineralogical composition as a function of age. Goethite and berthierine are both relatively common in the Mesozoic to Tertiary ironstones, whereas hematite and chamosite dominate the Paleozoic ironstones. This contrast probably reflects a higher degree of diagenetic equilibration by the older ironstones.

Origins and implications for earth history

The fundamental problem in the origin of ironstones is reconciling the evidence for deposition under open-marine, oxidizing conditions with the fact that dissolved iron is only mobile under reducing conditions (Odin, 1988). This leaves three options: (1) ironstones were originally deposited as something entirely different and replaced by iron-rich phases after burial; (2) conditions fluctuated between oxidizing and reducing during deposition; or (3) high concentrations of iron somehow managed to accumulate under oxidizing conditions. Some of the earliest investigators took the presence of ooids in ironstones to mean that they were diagenetically replaced carbonates. Even though carbonate fossils are locally replaced by iron-rich minerals, this interpretation has fallen out of favor due to the evidence of synsedimentary reworking of various types of ironstone and the apparent lack of any units of carbonate oolite that are half-converted to oolitic ironstone. Faced with a lack of sedimentological evidence for bottom water anoxia during deposition, most workers now envision ironstones as forming under a fully oxidized water column. This is clearly happening today in the case of glauconitic sediments (Van Houton and Purucker, 1984), and thin oolitic coatings of chamosite have been reported from pellets on the modern seafloor at one site (Rohrlich *et al.*, 1969). The latter are well below wave base, which suggests the coatings may be able to grow *in situ* without benefit of regular physical movement. Some researchers have even proposed the ooids originated entirely *in situ*, but the widespread breakage and regrowth of the ooids argue against this. Other workers have suggested they are pedogenic ooids that were transported then redeposited on the seafloor, but the highly concentrated nature of ironstones and their stratigraphic context makes this seem highly unlikely also. The current thinking is that ironstones originally accumulated mainly as ferric materials, then were modified considerably via early diagenetic authigenesis of the iron-rich phases very close to the sediment-water interface (Odin, 1988).

In summary, ironstones can probably originate in different ways, but most formed more or less where they were ultimately buried via a process of slow iron precipitation during times of highly reduced sedimentation rates. Proximity to a river mouth is also thought to be advantageous because the source of the iron is generally attributed to deep weathering on adjacent landmasses. However, this is somewhat at odds with the temporal correlation of ironstone and black shale deposition (Van Houton and Arthur, 1989). Whatever the source of the iron and the mechanism of deposition, both the iron-rich and iron-poor phases in ironstones were clearly affected by a host of early diagenetic transformations; many took place so close to the sediment/water interface that new phases were detritally reworked. In conclusion, the separation of iron formations and ironstones into two separate categories seems to be quite justifiable, but a closer comparison between these two might be very instructive in terms of revealing what processes were taking place on or near the early Precambrian seafloor.

ISOTOPIC METHODS IN SEDIMENTOLOGY

Introduction

Isotopes are atoms whose nuclei contain the same number of protons but a different number of neutrons. The nuclei of unstable (i.e., radioactive) isotopes decay spontaneously toward the stable condition through the emission of particles and energy. Radioactive decay of a particular unstable nuclide is generally accomplished by one or more of five decay schemes, broadly characterized by beta (β^-), positron (β^+) and alpha (α) particle emission, electron capture (e.c.) and fission. The decay schemes are accompanied by other nuclear emissions, including neutrinos, anti-neutrinos, gamma radiation, and X-radiation. The element undergoing radioactive decay (the parent) is transformed into another element (the daughter). The end-point of a radioactive decay scheme is the production of a stable nuclide. The daughter(s) of radioactive decay are referred to as radiogenic nuclides.

The nuclei of stable isotopes do not undergo radioactive decay to form other isotopes. Nevertheless, the relative abundances of an element's stable isotopes vary within and among phases bearing that element. These differences, commonly described as "fractionation" between two phases, are controlled by a variety of equilibrium and kinetic processes, including temperature and reaction rate.

Isotopic methods are utilized in sedimentology in two main ways. First, they provide a means to date sedimentary materials (commonly referred to as geochronology or radiometric dating). This is done almost exclusively using radioactive

isotopes. Geochronometers include the Rb–Sr, K–Ar, Sm–Nd, and U–Th–Pb systems (including U-series disequilibrium methods), and various cosmogenic and related radionuclides, including ^{14}C . The choice of geochronometer depends on the composition and nature of the material to be studied, and its estimated age. Radiometric methods can be used to provide many types of sedimentological information, including depositional ages, ages of detrital grains, crustal residence times for sediments, residence times of oceans, deposition rates, a temporal chronology for Pleistocene and Holocene paleoclimate proxies (minerals, organic matter, etc.), ages of erosion surfaces and landscapes, dates for diagenetic mineral formation, and temporal constraints on porewater evolution and its movement in sedimentary basins.

Second, isotopes can be used to trace the origin of inorganic and organic solids, liquids and gases within the sedimentary system, and their interactions within and among the hydrosphere, biosphere, atmosphere and deeper lithosphere. The stable isotopes of hydrogen, oxygen, carbon, nitrogen and sulfur are of special interest because they can be fractionated on a large scale by low-temperature processes. Commonly utilized radiogenic isotope tracers include strontium-87 (expressed as $^{87}\text{Sr}/^{86}\text{Sr}$ ratios) and neodymium-143 (expressed as $^{143}\text{Nd}/^{144}\text{Nd}$ ratios). These isotopic tracers can be used in identification of sediment provenance, characterization of physicochemical conditions during deposition and weathering/soil formation, determination of the temperature and fluids involved in diagenesis, characterization of organic-inorganic interactions within pore systems, description of fluid evolution and migration in sedimentary basins, and reconstruction of paleoclimate.

Dating methods and radiogenic isotopic ratios

The principles of radiometric dating are described by Faure (1986) and Bowen (1988). You are directed to these books for detailed discussion and references concerning much of what follows.

Basic equations

The decay rate of a radioactive parent nuclide (N) with time (t) is described by:

$$-dN/dt = \lambda N \quad (\text{Eq. 1})$$

where λ is the decay constant. Long-lived radionuclides (e.g., ^{147}Sm , ^{87}Rb , ^{232}Th , ^{238}U , ^{235}U , and ^{40}K) have very small values of λ (e.g., $6.54 \times 10^{-12} \text{ yr}^{-1}$ for ^{147}Sm) and hence long half-lives (the time it takes for 50 percent of the parent to decay). They can be used to date systems that are millions to billions of years old. Other radionuclides have much larger decay constants (e.g., ^{14}C , $\lambda = 1.21 \times 10^{-4} \text{ yr}^{-1}$) and hence much shorter half-lives. This restricts their application to much younger systems (e.g., $\sim 10^5$ years for ^{14}C).

Equation 1 can be integrated to produce the basic equation of radioactive decay:

$$N/N_0 = e^{-\lambda t} \quad (\text{Eq. 2})$$

where N_0 is the number of parent atoms at $t=0$. Equation 2 can be expressed in terms of the number of daughter atoms (D) as

$$D = D_0 + N(e^{\lambda t} - 1), \quad (\text{Eq. 3})$$

where D_0 is the number of daughter atoms initially present in the system ($t=0$). For radiometric dating to work, the system (rock, mineral, etc.) cannot have lost or gained parent or daughter atoms except through radioactive decay (a "closed" system), and the material analyzed must be representative of the system. If daughter atoms were present in the system prior to closure, their abundance must be determined accurately.

K-Ar methods

For some geochronometers (e.g., decay of ^{40}K to ^{40}Ar), there are few daughter atoms in the system at the time of closure ($D_0 \approx 0$), thus allowing the dating equation to take the form:

$$^{40}\text{Ar} = (\lambda_{\text{Ar}}/\lambda_{\text{total}})(^{40}\text{K})(e^{\lambda t} - 1) \quad (\text{Eq. 4})$$

In the K–Ar system, a factor expressing a ratio of decay constants ($\lambda_{\text{Ar}}/\lambda_{\text{total}}$) must be introduced, since the parent (^{40}K) undergoes decay not only to ^{40}Ar but also to ^{40}Ca . Additional complications arise because the daughter is a gas, and is easily lost from the system upon heating or over time. Correction for diffusive argon loss is possible in some minerals (e.g., K-feldspar) if stepwise heating and the $^{40}\text{Ar}/^{39}\text{Ar}$ method are employed (^{39}Ar is produced by neutron bombardment of ^{39}K in a reactor).

The $^{40}\text{K}/^{40}\text{Ar}$ and $^{40}\text{Ar}/^{39}\text{Ar}$ methods can be used to obtain depositional ages for some sediments. Sanidine and unaltered biotite are preferred for such measurements in bentonites, but clay minerals derived from the ash can also be used, provided that they formed very early in diagenesis and that their crystal growth is fully understood (Clauer and Chaudhuri, 1995; Clauer *et al.*, 1997). Syndepositional, K-rich glauconite (glaucony) formed close to the sediment-water interface in marine environments is also useful for obtaining depositional ages.

Dating of clay minerals presents a challenge. First, their large surface area and general reactivity encourages sorption of ^{40}Ar and K on one hand, and their potential loss during post-crystallization processes (both natural and during analysis) on the other hand. Minimum depositional ages are commonly obtained from poorly crystallized, low-K glauconite for these and other reasons (Clauer and Chaudhuri, 1995). Second, the same clay mineral in sediment can be of multiple origins; for example, detrital illite from several sources may be mixed with illite formed during several stages of diagenesis. During burial diagenesis of shales, K–Ar dates for illitic clays tend to decrease with increasing temperature and decreasing particle size, in tandem with the smectite to illite reaction. Diagenetic illite is concentrated in the finer clay fractions. However, even when the finest clay size-fractions (e.g., $<0.1\ \mu\text{m}$) are isolated, contamination by detrital illite can still occur. This can induce a substantial error in the calculated age. Likewise, diagenetic clays formed by transformation rather than direct precipitation may inherit radiogenic isotopes (including ^{40}Ar) from their precursor. Such problems of contamination and inheritance are much less severe for authigenic clays that have precipitated directly from solution in the pores of sandstones.

A novel $^{40}\text{Ar}/\text{K}_2\text{O}$ "pseudoisochron" method to identify sources of detrital clay assemblages has been described by Jeans *et al.* (2001). Pevear (1992) described a method of ^{40}K – ^{40}Ar analysis that allows both the detrital and diagenetic

end-member ages to be obtained over a range of illitic clay particle sizes. Such information contributes to our understanding of both the depositional and thermal histories of many potential petroleum source rocks. Authigenic illitic clays and K-feldspar, which are common in sandstone pores, can also be dated. Ziegler and Longstaffe (2000a,b), for example, used K–Ar dates for early K-feldspar and late illite to recognize multiple stages of fluid flow in sandstones of the Appalachian Basin, and related this behavior to regional and local tectonic activity. Girard and Onstott (1991) used laser-probe sampling and $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating methods to obtain separate dates for detrital K-feldspars and their secondary overgrowths at a precision and on a microscopic scale not possible using whole crystals. Likewise, $^{40}\text{Ar}/^{39}\text{Ar}$ dating of authigenic K-feldspar in carbonate rocks has been used to discern episodes of fluid flow and to relate their timing to regional tectonic events (Spötl *et al.*, 1998).

Rb–Sr and Sm–Nd isochron methods

Radiometric dating using many geochronometers, including the decay of ^{87}Rb to ^{87}Sr and decay of ^{147}Sm to ^{143}Nd , is complicated by an *initial* quantity of stable daughter in the system at $t=0$. Estimation of D_0 is normally accomplished using the isochron method. In this approach, isotopic analyzes are obtained for several cogenetic samples containing varying abundances of the parent and daughter elements (i.e., a range of Rb/Sr or Sm/Nd ratios). The isotopic abundances are expressed as a ratio using a common stable isotope of the daughter as the denominator. For the Rb–Sr and Sm–Nd geochronometers, these expressions are:

$$(^{87}\text{Sr}/^{86}\text{Sr})_{\text{total}} = (^{87}\text{Sr}/^{86}\text{Sr})_{\text{initial}} + (^{87}\text{Rb}/^{86}\text{Sr})(e^{\lambda t} - 1) \quad (\text{Eq. 5})$$

and

$$(^{143}\text{Nd}/^{144}\text{Nd})_{\text{total}} = (^{143}\text{Nd}/^{144}\text{Nd})_{\text{initial}} + (^{147}\text{Sm}/^{144}\text{Nd})(e^{\lambda t} - 1) \quad (\text{Eq. 6})$$

On an isochron diagram for the Rb–Sr system, for example, $^{87}\text{Sr}/^{86}\text{Sr}$ is plotted versus $^{87}\text{Rb}/^{86}\text{Sr}$ for each sample. The slope of the straight line ($e^{\lambda t} - 1$) formed by the data from a closed system provides the date, and the intercept of this line with the y-axis at $^{87}\text{Rb}/^{86}\text{Sr} = 0$ provides the *initial* ratio for strontium ($^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$). In sedimentary rocks, straight lines on isochron diagrams can also arise from mixing between source materials of different ages ("mixing" lines). If the system has been disturbed following closure (e.g., by weathering, interaction with formation waters, hydrothermal alteration), a straight-line fit to the isotopic data is not possible on the isochron diagram, and a date cannot be obtained.

Feldspars, micas and illitic clays are typical targets of the Rb–Sr isochron dating method in sediments. Ages of deposition that are consistent with K–Ar dates and other stratigraphic information are commonly preserved in well-crystallized glauconite ($\text{K}_2\text{O} > 6.5$ percent) (Clauer and Chaudhuri, 1995). Rb–Sr dates for secondary K-feldspar (adularia) in porous and permeable units can be used to define episodic brine migration in sedimentary basins (Harper *et al.*, 1995). Rb–Sr isochron dates have also been used to study the smectite to illite reaction during burial diagenesis of shales, and in particular to suggest that this reaction can occur

episodically rather than continuously (Morton, 1985; Ohr *et al.*, 1991).

Use of the Rb–Sr method to study clay mineral formation during weathering is more complex, because of the open nature of these systems, and the potential for gain and loss of parent and daughter isotopes. Progress is being made in this area by using the “internal” isochron method described by Clauer and Chaudhuri (1995). In this approach, each of acid-leached clay, untreated clay and leachate solutions are analyzed to determine whether the radiogenic ^{87}Sr in these fractions evolved together or was derived from different sources.

Sm and Nd are generally not fractionated during sedimentary processes. Hence, Sm–Nd isochron dating is rarely attempted in sediments because the spread in Sm/Nd ratios of cogenetic phases is normally insufficient. However, such dating of diagenesis in argillaceous sediments has been performed using authigenic apatite, Fe-oxides/hydroxides and fine clays ($<0.2\mu\text{m}$) (Awwiller and Mack, 1991; Ohr *et al.*, 1991). These Sm–Nd dates can survive isotopic rehomogenization during deeper burial, hydrothermal activity or metamorphism, unlike the Rb–Sr isotopic system, which is typically reset.

As for the K–Ar system, detailed mineralogical characterization (microscopy, crystal structure, chemical composition) that permits detrital and diagenetic minerals to be discerned and separated is required when applying Rb–Sr and Sm–Nd geochronometers to sedimentary rocks. “Best-practices” have been elaborated by Clauer and Chaudhuri (1995).

Model ages and epsilon (ϵ) values

In many sedimentary systems, it is not possible to obtain the *initial* ratio using the isochron method. In these cases, model ages can be calculated by assuming an *initial* ratio, although such results must be used with care. One approach is to derive the *initial* ratio from some generalized reservoir by assuming its linear evolution over Earth history. A common choice for this reservoir in the Nd-isotope system is CHUR (Chondritic Uniform Reservoir; DePaolo and Wasserberg, 1976). Differences between the $^{143}\text{Nd}/^{144}\text{Nd}$ ratio (or $^{87}\text{Sr}/^{86}\text{Sr}$) of a sample and the values of CHUR (or some other baseline) at a given time are commonly expressed as the epsilon (ϵ) parameter. The $^{143}\text{Nd}/^{144}\text{Nd}$ value of ϵ^0 (i.e., at present time) is described by:

$$\epsilon_{\text{CHUR}}^0 = \left[\left(\frac{^{143}\text{Nd}/^{144}\text{Nd}}{\text{measured}} \right) / \left(\frac{^{143}\text{Nd}/^{144}\text{Nd}}{\text{CHUR}^*} \right) - 1 \right] \times 10^4 \quad (\text{Eq. 7})$$

where CHUR* is the ratio at the present time. This approach allows small but significant differences between these ratios to be more easily expressed (Clauer and Chaudhuri, 1995).

The sediment load of modern rivers, as well as fine-grained clastic sedimentary rocks in general, acquire Sm/Nd ratios and Sm–Nd isotopic compositions similar to their igneous and metamorphic source rocks. These have $^{143}\text{Nd}/^{144}\text{Nd}$ ratios and hence ϵ_{Nd} values characteristic of their age (e.g., <-20 for Archean crust versus >2 for recent island arc volcanic rocks; Patchett *et al.*, 1999). The ϵ_{Nd} values of clastic sedimentary rocks can therefore provide useful information about their provenance, plus insight into the crustal residence time of the detritus (i.e., time elapsed since Nd was separated from the

mantle into the continental crust). Patchett *et al.* (1999) used ϵ_{Nd} values for sedimentary rocks from cratonic and syn-orogenic sequences to infer temporal patterns in the dominant sources of sediment in North America (600–450 Ma, continental shield; 450–150 Ma, Appalachian orogen; <150 Ma, Cordilleran orogen). Unterschutz *et al.* (2002) use a similar approach to demonstrate a mixed volcanic arc and cratonic provenance for metasedimentary rocks comprising the Triassic Quesnel terrane of the southern Canadian Cordillera. These data imply a pericontinental rather than exotic origin for the Quesnel terrane during the assembly of this portion of the Canadian Cordillera.

$^{87}\text{Sr}/^{86}\text{Sr}$ ratios in seawater and sediments

The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of stratigraphically well-identified marine carbonates (brachiopod shells, abiotic marine carbonates), phosphates (e.g., conodonts) and sulfates are used for regional and global chemostratigraphic correlation. They also provide a means to understand the interactions among global tectonic and climatic processes (mountain building, seafloor spreading, glaciation, erosion and weathering rates, sea level change, etc.) over geological time (Veizer, 1989; Edmond, 1992). Because Rb is not incorporated into most carbonates, phosphates and sulfates, they acquire and retain the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the water from which they precipitated, unless modified by interaction with later fluids. Such modification of strontium- (and oxygen-) isotope compositions is a significant concern, given the relative ease with which carbonate minerals recrystallize. Alteration is normally detected using stable isotopic, major and trace element, and cathodoluminescence methods, or avoided through the use of more resistant phases (e.g., euconodonts) (Derry *et al.*, 1992; Asmerom *et al.*, 1991; Ebneith *et al.*, 2001).

Water acquires its $^{87}\text{Sr}/^{86}\text{Sr}$ ratio through rock–water interaction (hydrothermal alteration, weathering, exchange). Interaction with mantle-related volcanic rocks produces water with abundant Sr but generally low $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (~ 0.7035), which characterizes deep-sea hydrothermal input to the oceans. The submarine hot-spring contribution to the oceans may have varied with changes in the rate of seafloor spreading, particularly during Paleozoic time, but likely represents a more or less constant flux of constant Sr-isotope composition during the Phanerozoic (Edmond, 1992).

Water associated with erosion and weathering of continental rocks and their soils normally acquires low Sr contents but relatively high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (~ 0.712), mostly as a consequence of interaction with feldspars and micas. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the leachate tends not to be as high as the rocks because of preferential dissolution of plagioclase relative to more radiogenic K-feldspar and biotite (Clauer and Chaudhuri, 1995). However, much higher contents of highly radiogenic Sr are released during erosion of Himalayan-style metamorphic core complexes (Edmond, 1992).

The flux of continental Sr is carried to the ocean by rivers and groundwater (Edmond, 1992; Basu *et al.*, 2001). The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio and Sr content of the meteoric water reflect the lithologies intersected, and can also vary with rainfall amounts in a region (Galy *et al.*, 1999). Continental hot springs associated with collisional orogens also contribute highly radiogenic Sr ($^{87}\text{Sr}/^{86}\text{Sr} \approx 0.77$) to the Sr-budget of some globally important fluvial systems, such as Himalayan rivers (Evans *et al.*, 2001). Variations in continental glaciation, atmospheric CO_2 levels, climate, vegetation, orogeny and

eustatic sea level all help to determine the rock types exposed at the Earth's surface, and the rates at which weathering and erosion occur.

Marine carbonates and evaporites are the sink for Sr from seawater, removing it from solution with no isotopic fractionation. These rocks typically release high Sr contents and intermediate $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (~ 0.7075 – 0.7080) to river water. These ratios correspond to the balance between crustal weathering and mantle-related processes at the time of chemical sedimentation. The carbonates and evaporites can be exposed by tectonic processes and eustatic changes in sea level. When this happens, they tend to dominate the fluvial flux of Sr to the ocean. This feedback attenuates the variations in Sr-isotope composition of seawater that otherwise would ensue if it was determined only by the balance between mantle-related activity and the weathering of sialic rocks (Edmond, 1992).

The oceans presently have a uniform $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.70906 ± 0.00003 , which reflects the long residence time of Sr in seawater. This value corresponds well with its proxy in modern marine carbonate (0.70910 ± 0.00004) (Burke *et al.*, 1982). Its composition has fluctuated widely over geological time. Values were high in the Late Cambrian (> 0.7092), but gradually declined through wide fluctuations to as low as 0.70676 in the Jurassic; such low values also occurred in the Permian. Since the Jurassic, the Sr-isotopic composition of seawater has increased irregularly, with a particularly rapid climb toward the present value beginning in the mid-Tertiary (Burke *et al.*, 1982; Edmond, 1992; Denison *et al.*, 1998; Ebner *et al.*, 2001).

The strongest variations in the strontium isotopic composition of seawater reflect changes in continental input. Edmond (1992) proposed that only Himalayan-style continental collisions can produce a sufficiently high flux of radiogenic Sr to account for the positive extremes in the seawater $^{87}\text{Sr}/^{86}\text{Sr}$ record. During such major orogenic events, the Rb–Sr systems of ancient continental rocks are disturbed, leading to the redistribution of highly radiogenic Sr ($^{87}\text{Sr}/^{86}\text{Sr} \sim 0.769$ in Himalayan core complexes) into minerals such as plagioclase, which weather easily following their exposure. During the late Proterozoic, $^{87}\text{Sr}/^{86}\text{Sr}$ ratios also rose from very low (~ 0.707) to high (~ 0.709) values. This may suggest a fundamental change from rifting and production of juvenile oceanic crust to continent–continent collisions, production of recycled continental crust, and its erosion (Asmerom *et al.*, 1991). Many research efforts continue to be directed toward finer-scale definition of the Sr-isotope seawater curve, and the specific variations arising from second-order processes, such as glaciation (Blum and Erel, 1995).

$^{143}\text{Nd}/^{144}\text{Nd}$ ratios in seawater and sediments

The $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of seawater (commonly recast in terms of ϵ_{Nd}) are controlled principally by erosion of the land masses adjacent to the oceans. Nd, unlike Sr, has a very short residence time in seawater relative to the mixing time of the Earth's oceans. The Atlantic Ocean, which is surrounded mainly by older sialic rocks, has a lower ϵ_{Nd} (-15 to -10) than the Pacific Ocean (-5 to 0), which is surrounded mostly by younger volcanic rocks related to subduction of oceanic crust (Piegras *et al.*, 1979). As a result, the spatial variation in Nd-isotope composition of modern seawater can be used to trace circulation within and among oceans.

Variations in seawater $^{143}\text{Nd}/^{144}\text{Nd}$ ratios can be tracked through geological time through analysis of phosphates (e.g., conodonts) and carbonates (e.g., brachiopods). They acquire Nd-isotope compositions characteristic of ambient seawater shortly after deposition at the sediment–water interface, and are largely unaffected by later alteration, including interaction with meteoric water (Banner *et al.*, 1988). This makes $^{143}\text{Nd}/^{144}\text{Nd}$ ratios more robust proxies of oceanic conditions than strontium- or oxygen-isotope ratios. The Nd-isotope compositions can be used to reconstruct the variation in the exposed crust of the Earth, and to deduce plate tectonic activity (i.e., the opening and closing of ocean basins) that determined the distribution of the Earth's oceans (Shaw and Wasserburg, 1985).

U–Th–Pb methods

The U–Th–Pb system provides a wide range of geochronometers useful in the study of sediments. It comprises three separate and complex decay series, ^{238}U to ^{206}Pb , ^{235}U to ^{207}Pb and ^{232}Th to ^{208}Pb . In each case, the decay scheme contains numerous intermediate daughters before the stable daughter is achieved. The intermediate daughters have much shorter half-lives than the parent, and under the condition described as secular equilibrium, the rate of the decay of these daughters is controlled by the rate of decay of the parent (Faure, 1986). For each of the U–Th–Pb decay schemes, model ages can be obtained by assuming reasonable *initial* Pb-isotope ratios (given relative to ^{204}Pb). Combination of any two of the U–Th–Pb geochronometers permits the concordia approach to dating to be used. The latter is particularly useful in studies of sediment provenance, which focus on detrital zircon and other U- or Th-rich phases.

The U–Th–Pb geochronometers that are perhaps most valuable in sedimentology are provided by certain intermediate radioactive nuclides (commonly with high values of λ and hence short half-lives). These intermediate daughters are used in a wide variety of ways, collectively described as U-series disequilibrium dating. Some allow dating of intervals between those accessible using the ^{14}C ($< 10^5$ years) and ^{40}K – ^{40}Ar ($> 10^6$ years) methods; others (e.g., ^{210}Pb) permit dating of modern materials (i.e., < 100 years old). U-series disequilibrium dating is possible because many intermediate daughters in the decay series have geochemical properties different from their parent. This allows parent and daughter to be separated during processes such as chemical weathering, (bio)chemical sedimentation, and adsorption onto clay minerals. For example, uranium (as the uranyl ion) tends to remain in solution in seawater, whereas Th is preferentially removed by precipitation of zeolites or by adsorption onto particulate surfaces (e.g., clays, organic matter, etc.). Radiometric dating is thus accomplished using an isolated intermediate daughter (e.g., ^{230}Th , ^{231}Pa , ^{210}Pb) that, free from replenishment by decay of the absent parent, disintegrates at a rate determined solely by its own (shorter) half-life. Alternatively, a daughter may be excluded from a geologic material at the time of its formation, leaving only the radioactive parent. The new daughter production from that parent can be used to obtain the time since the system was last open, at least until reestablishment of secular equilibrium (Faure, 1986).

U-series disequilibrium dating methods have proven most useful in the study of Pleistocene sediments, commonly through examination of $^{230}\text{Th}/^{232}\text{Th}$, $^{234}\text{U}/^{238}\text{U}$, $^{230}\text{Th}/^{238}\text{U}$,

$^{230}\text{Th}/^{234}\text{U}$, and $^{230}\text{Th}/^{231}\text{Pa}$ ratios. For example, oceanic sedimentation rates can be determined by obtaining these ratios with increasing distance from the sediment-water interface. Likewise, dates can commonly be obtained for young marine and nonmarine carbonates, given that their crystal structure incorporates uranium upon precipitation, but almost always excludes thorium. The activity of ^{230}Th in such carbonate derives from the decay of ^{234}U , which in turn is derived from ^{238}U . The ability to date growth bands in speleothem and other terrestrial carbonate cements allows temporal calibration of the paleoclimate information obtained from oxygen, hydrogen, carbon and strontium isotopic compositions of the same material (Schwarz, H.P., 1986; Dorale *et al.*, 1998; Kaufman *et al.*, 1998). Corals can be used in a similar fashion (Edwards *et al.*, 1993), and provide a chronology for sea-level fluctuations.

Because of its short half-life (22.26 years), the abundance of ^{210}Pb can be used to obtain sedimentation rates in lacustrine and marine sediments that are <100 years old. It is a radioactive daughter of gaseous ^{222}Rn within the ^{238}U decay series. Upon production, ^{222}Rn is released to the atmosphere, where it decays rapidly to ^{210}Pb . The ^{210}Pb is swept quickly from the atmosphere by precipitation, and accumulates in snow, ice, lakes, vegetation and sediments. The declining level of ^{210}Pb activity can then be used to calculate the time elapsed since separation from its parent (Faure, 1986).

Cosmogenic and anthropogenic radionuclides

Another useful dating tool in Pleistocene and Recent sedimentary environments is provided by cosmogenic nuclides. These isotopes are produced in the Earth's atmosphere by interactions between cosmic radiation and oxygen, nitrogen and argon. The most familiar of these reactions is the neutron-induced formation of ^{14}C from ^{14}N , and its subsequent return to ^{14}N via β^- decay with a half-life of 5730 years. Carbon-14 is incorporated into CO_2 , which mixes rapidly within the atmosphere and hydrosphere, and is fixed by photosynthesis into plants and the animals that eat them. Once an organism dies, replenishment of $^{14}\text{CO}_2$ ends, and the time elapsed since death can be determined from the remaining activity of ^{14}C . This model is complicated by many factors, including variations in the radiocarbon content of the atmosphere (e.g., Edwards *et al.*, 1993; Beck *et al.*, 2001). These have resulted from changes in the flux of cosmic radiation to the Earth, release of "dead" carbon by combustion of fossil fuels, addition of ^{14}C via nuclear devices, and mass-dependent fractionation among ^{12}C , ^{13}C , and ^{14}C .

In addition to organic matter from sediments and soils, considerable effort has been devoted to ^{14}C -dating of chemically or biologically precipitated calcium carbonate. For accurate dating of fresh-water shells, their carbon must have been derived wholly from the atmosphere, and the ^{14}C content must have not been modified by postmortem alteration. Complications also arise in marine environments in environments where older, deep ocean waters may have mixed with modern waters, both of which can supply carbon to the shells of organisms (Faure, 1986). Carbon-14 measurements have also been used to date groundwater and describe fluid mixing in the subsurface (Clark and Fritz, 1997).

Tandem accelerator mass spectrometry permits much smaller quantities of ^{14}C to be analyzed than possible using standard radiochemical methods. It has also made feasible

measurement of other cosmogenic (e.g., ^3H , ^3He , ^7Be , ^{10}Be , ^{14}C , ^{26}Al , ^{32}Si , ^{36}Cl , ^{39}Ar , ^{81}Kr) and anthropogenic radionuclides (e.g., ^3H , ^{90}Sr , ^{137}Cs) (Faure, 1986; Clark and Fritz, 1997). Cosmogenic radionuclides with long residence times in the atmosphere (e.g., ^{39}Ar , ^{81}Kr) provide the potential to date air bubbles trapped in ice cores (Faure, 1986). Others are removed quickly from the atmosphere by precipitation (e.g., ^{10}Be , ^{26}Al , ^3H , ^{36}Cl , ^{129}I). They can be used to determine sediment transport and deposition rates in marine and terrestrial environments, to measure accumulation rates of ice sheets, and to date groundwater and brines (Lao *et al.*, 1993; Wang *et al.*, 1996; Yechieli *et al.*, 1996).

The abundance of cosmogenic nuclides has also been used to determine the age of erosion surfaces (Phillips *et al.*, 1996). The ^{10}Be and ^{26}Al contents of terrestrial surfaces, especially quartz, provide estimates of surface exposure time, and from this, erosion rates and the ages of exposed terrestrial surfaces can be deduced (Nishiizumi *et al.*, 1993; Bierman and Turner, 1995). Cosmogenic ^{36}Cl production in limestones has been used for similar purposes (Stone *et al.*, 1998). Anthropogenic radionuclides (e.g., ^3H , ^{137}Cs) have also been used to date and track mixing in modern groundwater, and to trace modern geomorphic processes in sediments and soils (Clark and Fritz, 1997; Vanden Bygaart and Protz, 2001).

Stable isotopes

The stable isotopes of hydrogen (^2H (or D), ^1H), carbon (^{13}C , ^{12}C), nitrogen (^{15}N , ^{14}N), oxygen (^{18}O , ^{17}O , ^{16}O) and sulfur (^{36}S , ^{34}S , ^{33}S , ^{32}S) are of most interest in the study of sediments. However, boron (^{11}B , ^{10}B ; Vengosh *et al.*, 1991; Williams *et al.*, 2001), silicon (^{30}Si , ^{29}Si , ^{28}Si ; Ding *et al.*, 1996; De La Rocha *et al.*, 1998), chlorine (^{37}Cl , ^{35}Cl ; Kaufmann *et al.*, 1993; Eggenkamp *et al.*, 1995) and iron (^{58}Fe , ^{57}Fe , ^{56}Fe , ^{54}Fe ; Zhu *et al.*, 2000; Bullen *et al.*, 2001) are attracting increasing interest. Reviews of stable isotope systematics pertinent to sedimentology include Fritz and Fontes (1980, 1986, 1989), Arthur *et al.* (1983), Faure (1986), Kyser (1987), Longstaffe (1987, 1989, 1994, 2000), Savin and Lee (1988), Bowen (1988, 1991), Swart *et al.* (1993), Clauer and Chaudhuri (1995), Clark and Fritz (1997), Hoefs (1997) and Kendall and McDonnell (1998).

Stable isotope results are reported using the delta (δ) notation in parts per thousand (‰ or permill). For phase A,

$$\delta_A = [(R_A - R_{\text{standard}})/R_{\text{standard}}] \times 1000, \quad (\text{Eq. 8})$$

where R is normally D/H, $^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, $^{18}\text{O}/^{16}\text{O}$ or $^{34}\text{S}/^{32}\text{S}$. The δ -value for the standard is defined as 0‰ exactly. For hydrogen, this standard is VSMOW (Vienna Standard Mean Ocean Water). Two standards are in use for oxygen, VSMOW and VPDB (Vienna Pee Dee Belemnite). While the VSMOW standard is preferred amongst isotopists, the VPDB standard is in common use among sedimentologists; VPDB has a $\delta^{18}\text{O}$ value of +30.91‰ relative to VSMOW. Stable carbon-isotope results are reported relative to VPDB, sulfur isotopes to CDT (Canyon Diablo Troilite), and nitrogen isotopes to atmospheric nitrogen (air). Most δ -values can be measured with a precision of at least $\pm 0.2\%$, except for hydrogen ($\pm 2\%$).

For oxygen and sulfur, which comprise three and four stable isotopes respectively, it is normally sufficient to measure only $^{18}\text{O}/^{16}\text{O}$ and $^{34}\text{S}/^{32}\text{S}$ ratios. However, non-mass dependent fractionation in the Earth's stratosphere makes $^{17}\text{O}/^{16}\text{O}$,

$^{36}\text{S}/^{32}\text{S}$ and $^{33}\text{S}/^{32}\text{S}$ ratios of interest in sedimentary systems where feedback from the atmosphere might be measurable (e.g., the Earth's early sulfur cycle, Farquhar *et al.*, 2000; studies of oceanic productivity, Luz and Barkan, 2000).

Recent advances in analytical methods

Most stable isotope measurements are made using the gas-source, triple-collecting, dual-inlet, stable isotope ratio mass-spectrometer. In the traditional approach, which dominated until the late 1990s, samples of solids or liquids were converted quantitatively into the appropriate gas (hydrogen, carbon dioxide, nitrogen, sulfur dioxide, etc.) using complex "off-line" preparation methods. These gases were then brought separately to the mass spectrometer for analysis. However, recent advances in stable isotope analysis of hydrogen, carbon, oxygen, nitrogen and sulfur now make collection of these data much more accessible to sedimentologists. In the new approach, known as continuous-flow, stable isotope ratio mass-spectrometry, "on-line" preparation devices (peripherals) are used to produce and concentrate the appropriate pure gas from a wide variety of solids, liquids and gases. This pure gas is swept by a stream of helium from the peripheral directly into the attached mass spectrometer for analysis.

This conceptually simple, but fundamental change in analytical approach has enormous implications for stable isotope research in sedimentology. Very small quantities of gas (routinely to ~ 200 nmols) can now be analyzed. Sample size largely ceases to be a limitation on the ability to measure stable isotope ratios. Lasers, for example, allow precision sampling and appropriate gas production from small (~ 30 – 100 μm) regions of many solids (e.g., carbonate, sulfides, some silicates). Other peripherals (gas chromatographs, elemental analyzers, thermochemical converters, thermogravimetric balances, etc.) allow similarly small quantities of water, organic matter and other materials to be analyzed in continuous-flow mode. Continuous-flow coupling of a gas chromatograph to a stable isotope ratio mass-spectrometer, for example, allows compound-specific stable isotopic fingerprints to be obtained for complex organic materials. Likewise, the coupling of a thermogravimetric balance and a stable isotope ratio mass-spectrometer makes possible separation and isotopic analysis of waters of hydration and hydroxyl groups from clays and other hydrous minerals. Such data can be used to determine temperatures and fluid evolution in many sedimentary environments.

The mass spectrometers and their on-line peripherals are automated, which allows large numbers of samples to be analyzed in short periods of time. This approach largely replaces labor-intensive, arcane and complex conventional procedures with a methodology that is accessible to most researchers. Accordingly, research problems requiring a large number of analyzes (typical of sedimentology) can be undertaken routinely.

Development of the ion-probe is also of interest to sedimentologists. Direct stable isotopic measurement of solids in thin section is now possible for some materials, with a precision that begins to approach that of conventional dual-inlet or continuous-flow methods. The ion-probe, for example, has been used to obtain the oxygen-isotope compositions of quartz overgrowths in sandstones, and from that, to infer temperature and fluid compositions during secondary quartz cementation (Hervig *et al.*, 1995). Like the laser methods

described earlier, the ion-probe has the potential to replace tedious and error-prone physical and chemical methods previously used to isolate such samples for stable isotopic analysis (Ayalon and Longstaffe, 1992).

Stable isotopic variations in water

Seawater and fresh (meteoric) water have characteristic hydrogen- and oxygen-isotope compositions, as do formation waters whose isotopic compositions evolved during rock-water interaction and mixing in sedimentary basins. Direct isotopic measurements of oceans, lakes, rivers, shallow porewaters, and formation waters from deep in sedimentary basins reveal much about the origin and evolution of these fluids. The stable carbon and hydrogen isotopic compositions of hydrocarbons in sedimentary systems provide analogous information about their sources, as well as hydrocarbon generation and degradation (Hoefs, 1997).

Seawater. Unmodified ocean water has $\delta^{18}\text{O}$ and δD values of about 0‰, which generally vary only slightly because of dilution by fresh water near major rivers. High latitude, shallow epicontinental seas that receive a large influx of surface runoff also can acquire isotopic compositions substantially less than 0‰, especially in surface layers (e.g., the Cretaceous Western Interior Seaway). Evaporation can also cause variation in the stable isotopic composition of seawater (and fresh water). Because ^{16}O and ^1H are preferentially partitioned into the vapor phase during evaporation, surface waters within a restricted basin are progressively enriched in ^{18}O and D, at least until extreme levels of solute concentration are reached. The isotopic composition of evaporated bodies of water is described by:

$$\delta\text{D} = m\delta^{18}\text{O}. \quad (\text{Eq. 9})$$

The value of m decreases as relative humidity declines. It is characteristic of a given region, and the resulting distribution of δD and $\delta^{18}\text{O}$ water values along this slope defines a "local evaporation line".

Continental glaciation can affect the oxygen and hydrogen isotopic composition of seawater. Continental ice caps are major reservoirs of ^{16}O - and ^1H -rich water; melting of the present Greenland and Antarctic ice caps would lower the $\delta^{18}\text{O}$ value of the ocean by ~ 0.7 ‰. Studies of Pleistocene ice-cover fluctuations suggest that the variation then was no larger than ~ 1 ‰ (Savin and Yeh, 1981).

Whether the oxygen isotopic composition of the ocean has changed with time on a larger scale remains unresolved. "Least altered" shell materials (mostly brachiopods) and marine carbonate cements suggest a trend toward ^{18}O depletion of seawater with increasing age (to -7 ‰ for the Cambrian) (Wadleigh and Veizer, 1992). Data from ophiolites and mud-rocks support the concept of a 0‰ ocean throughout much of geologic time (Muehlenbachs and Clayton, 1976; Land and Lynch, 1996). This behavior may reflect greater susceptibility of carbonates versus silicates to post-formational isotopic alteration. It may also arise from different water compositions in the deep, open ocean versus shallow, epicontinental seas.

Seawater sulfate. Ocean water is the Earth's major reservoir of dissolved sulfate. Modern seawater sulfate has an average $\delta^{34}\text{S}$ value of $+21.0$ ‰, and $\delta^{18}\text{O}$ value of $\sim +9.6$ ‰. The $\delta^{34}\text{S}$ values of sulfate minerals are very similar to the seawater from which they evaporated, whereas their $\delta^{18}\text{O}$ value are enriched

by $\sim 3.5\%$ (Hoefs, 1997). The stable isotope composition of seawater sulfate has varied throughout geological time, especially its $\delta^{34}\text{S}$ values, which have ranged from $\sim +10$ to $+30\%$ (Claypool *et al.*, 1980). The variations in $\delta^{18}\text{O}$ values are smaller and do not necessarily track those of sulfur, for reasons yet poorly understood (Hoefs, 1997).

Stable sulfur-isotope behavior in sedimentary environments is complex. The isotopic composition of seawater sulfate at any time is the baseline from which the δ -values of diagenetic marine sulfide and residual sulfate are derived. However, their δ -values also depend on whether open communication with seawater was maintained in the sediment during sulfide formation (i.e., an open versus closed system), and the nature, rate and temperature of the processes that drive reduction of sulfate to sulfide. The isotopic fractionations can be considerable; on average, diagenetic pyrite in sediments is depleted of ^{34}S relative to the dissolved sulfate by $\sim 50\%$ (Longstaffe, 1989; Hoefs, 1997).

The changes in sulfur and oxygen isotopic compositions of dissolved sulfate in seawater arise from variations in the input and output of sulfate to and from the oceans. The volumes and isotopic composition of these fluxes are controlled by microbial reduction of sulfate to sulfide and evaporite formation in seawater, contributions of sulfate and sulfide to the oceans from continental weathering, the cycling of seawater through mid-oceanic ridges, and the volume of seawater itself. Variations in seawater-sulfate isotopic composition through geological time can be linked to the same kinds of global tectonic and eustatic processes that drive variations in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of seawater. Variations in the S- and Sr-isotope seawater curves show many similarities through geological time. By comparison, the $\delta^{13}\text{C}$ values of marine carbonates, which capture the fluctuations in inorganic versus organic contributions to marine bicarbonate, tend to be antipathetic to marine sulfate $\delta^{34}\text{S}$ values (Hoefs, 1997).

Porewater in shallow marine sediments. The $\delta^{18}\text{O}$ and δD values of porewater in the first $\sim 800\text{ m}$ of Cenozoic oceanic sediments commonly decrease to values less than 0% with increasing depth from the sediment-water interface (Savin and Yeh, 1981). Numerous explanations have been offered for this behavior, including primary variations in porewater composition, and production of secondary clays, carbonates and zeolites. Low-temperature crystallization of ^{18}O -rich secondary minerals has the potential to deplete the porewater reservoir of ^{18}O in a quasi-closed system with a high rock/water ratio (Longstaffe, 2000). However, neof ormation of secondary minerals cannot easily account for the lowering of δD values in oceanic porewater, which can exceed 10% . Low-D water ($<200\%$) formed during oxidation of organic matter, methane and hydrogen may contribute to the composition of porewater in oceanic sediments, as may exchange with methane or hydrogen from deeper sources (Lawrence and Taviani, 1988).

Meteoric (fresh) water. Meteoric water has a large but systematic variation in isotopic composition ($\delta^{18}\text{O} \approx -55$ to 0% ; $\delta\text{D} \approx -400$ to $+10\%$) described by the Global Meteoric Water Line (GMWL) (Craig, 1961):

$$\delta\text{D} = 8\delta^{18}\text{O} + 10(\text{‰}). \quad (\text{Eq. 10})$$

This regularity is largely the product of Rayleigh distillation within the hydrological cycle. In the simplest situation, water evaporated from the ocean is progressively depleted of ^{18}O and

D through successive evaporation and condensation while travelling across the continents. This distillation produces a geographically controlled distribution of oxygen- and hydrogen-isotope compositions, with fresh water becoming progressively depleted of the heavier isotope at higher altitudes and latitudes. The depletion is further accentuated by lower average air-mass temperatures and larger values of $\alpha_{\text{liquid-vapor}}$ toward higher latitudes and altitudes, and by the re-evaporation of meteoric waters from the continental surface (Yurtsever and Gat, 1981).

Formation water. The $\delta^{18}\text{O}$ and δD values of formation water from sedimentary basins commonly (but not always) define a trend ("formation-water line") with a lower slope than the GMWL. Along this trend, hotter and more saline formation waters are generally more ^{18}O -rich than cooler, less saline samples. The formation-water line for a specific sedimentary basin commonly intersects the GMWL at an isotopic composition typical of local surface and shallow groundwater. This suggests that meteoric water comprises an important fraction of many formation waters (Clayton *et al.*, 1966). However, the deviation of the formation-water line from the GMWL (equation 10) indicates that other processes are also at play. These include evaporation (see equation 9), isotopic exchange between pore-lining minerals and porewater, release of water by the smectite to illite reaction, mixing between seawater and fresh water or their evolved equivalents, and perhaps membrane filtration (see Longstaffe, 2000 and references therein).

The extent of formation-water ^{18}O -enrichment *via* exchange depends on the isotopic composition of the exchanging solid phases, temperature, mineral/water ratio, and the exchangeability of the minerals in the pore system. Extensive exchange may be plausible in carbonate-rich rocks, but is unlikely in siliciclastic units, which exchange oxygen isotopes much less easily than carbonates. Isotopic exchange involving clays or organic matter may also contribute to the δD values of formation waters. Fluid movement from shales to sandstones in settings where the smectite to illite reaction controls shale porewater chemistry can explain the ^{18}O -rich nature of some formation waters, but this requires very high (originally smectite-rich) shale to sand ratios within the basin. Mixing between evaporitic brines derived from seawater and (later) meteoric water can also explain the stable isotopic composition of many formation waters.

It seems unlikely that there is a single explanation for the δD and $\delta^{18}\text{O}$ values of formation waters in sedimentary basins. Porewater evolution and movement follow different pathways, depending on the geological circumstances of each sedimentary basin. By understanding the range of stable isotopic compositions that can be expected for seawater, meteoric water and formation water, one can track the evolution of fluids in a sedimentary basin, using the proxies provided by secondary minerals formed in the pore system.

Stable isotopic variations in sediments and sedimentary rocks

Chemical sediments. Chemical sediments and sedimentary rocks generally have very high $\delta^{18}\text{O}$ values (up to $+45\%$), because they acquire their isotopic compositions at low temperatures in oxygen isotopic equilibrium with water, during which enrichment in ^{18}O of the solid phase is large. Modern marine limestones, for example, commonly have $\delta^{18}\text{O}$

values near 30‰ (VSMOW); fresh-water varieties have variably lower values that reflect the composition of the meteoric water involved. Dolomitization and other diagenetic modifications have a substantial impact on the $\delta^{18}\text{O}$ values of carbonates; for example, post-crystallization interaction with meteoric water invariably leads to a lowering of their $\delta^{18}\text{O}$ values (Arthur *et al.*, 1983). Care is needed in the study of ancient marine carbonates to obtain samples that have preserved their original oxygen isotopic compositions (Carpenter *et al.*, 1991).

Stable carbon-isotope variations. Marine carbonate rocks normally have $\delta^{13}\text{C}$ values of $\sim 0\%$, which reflect the balance between inorganic (^{13}C -rich) and organic (^{12}C -rich) carbon in the total dissolved marine carbonate reservoir at the time of formation (Land, 1980; Hoefs, 1997). Variations in the stable carbon-isotope composition of the oceanic reservoir through geologic time are normally related to changes in the amount of organic (^{13}C -poor) versus inorganic (^{13}C -rich) carbon added to or removed from the dissolved carbon reservoir.

The shifts in stable carbon-isotope composition of marine carbonates have normally been no more than $\pm 2\%$ throughout most of geological time, but relatively sudden shifts of larger magnitude and global distribution are known. Such decreases at the Precambrian/Cambrian, Permian/Triassic, and Cretaceous/Tertiary boundaries are commonly correlated to upwelling of ^{13}C -poor, anoxic, oceanic bottom-waters and substantially reduced organic productivity (extinction events?) in shallow marine environments (Veizer *et al.*, 1980; Hoefs, 1997; Kimura and Watanabe, 2001). Very high $\delta^{13}\text{C}$ values for marine carbonates ($> +10\%$) at $\sim 2.2\text{ Ga}$ to 2.0 Ga , and at the end of the Proterozoic, have been linked to periods of vastly increased burial of organic carbon. This behavior has been attributed by some to the complete freezing of the Earth's oceans (the "Snowball Earth" hypothesis) (Knoll *et al.*, 1986; Baker and Fallick, 1989; Derry *et al.*, 1992; Hoffman *et al.*, 1998).

Most carbonate-bearing sediments existed in zones of microbial activity during sedimentation and early diagenesis. In sediments with open access to the marine bicarbonate reservoir (presently $\delta^{13}\text{C} \approx 0\%$), the volume of carbon dioxide added to the system from microbial activity is too small to detect. However, when organic carbon comprises a significant fraction of the bicarbonate supply to the porewater, distinctive carbonate $\delta^{13}\text{C}$ values result (see Longstaffe, 1989 and references therein). For example, carbonate rocks invaded by meteoric water typically acquire lower $\delta^{13}\text{C}$ values because of the flux of low- ^{13}C , soil-derived CO_2 ($\delta^{13}\text{C} \approx -25\%$). Large variations in carbonate $\delta^{13}\text{C}$ values ($\delta^{13}\text{C} \approx -30$ to $+30\%$) are also characteristic of carbonate rocks intercalated with coals and other organic matter, such as organic-rich shales, oil-shales and oil-sands. Calcite with $\delta^{13}\text{C}$ values as low as -70% is associated with methane oxidation at seeps.

Growth of carbonate concretions in organic-rich mudstones and shales represents a special case where the CO_2 contribution from marine bicarbonate trapped with the porewater is small compared to that produced during diagenetic reactions. In the simplest case, each carbonate growth band acquires a $\delta^{13}\text{C}$ value characteristic of the processes dominant at that depth from the sediment-water interface (Irwin *et al.*, 1977). Consumption of organic matter in the shallowest zones is dominated by microbial oxidation. A zone of microbial sulfate reduction then follows in marine and brackish water environments. Both zones are characterized by CO_2 with $\delta^{13}\text{C}$ values of $\sim -25\%$. Still deeper zones are characterized by microbial

fermentation, which leads to production of ^{12}C -rich CH_4 ; in some extreme case, CO_2 reduction follows. Residual CO_2 available for fixation in carbonate minerals is therefore variably enriched in ^{13}C (avg. $\delta^{13}\text{C} \approx +15\%$). At still greater depths, residual organic matter is gradually destroyed by a variety of abiotic, thermally driven reactions, which release CO_2 with $\delta^{13}\text{C}$ values of $\sim -25\%$ to -10% (see Longstaffe, 1989 and references therein).

Clastic sedimentary rocks. The bulk oxygen-isotope composition of clastic sedimentary rocks is highly variable ($\delta^{18}\text{O} = +8\%$ to $+25\%$) because it reflects varying contributions of (i) detrital minerals and rock fragments that normally retain oxygen-isotope compositions characteristic of their original high-temperature source, (ii) ^{18}O -rich weathering products ($\sim +10\%$ to $+30\%$); clays, altered feldspars and rock fragments, etc., and (iii) ^{18}O -rich cements. To summarize, clastic sedimentary rocks are typically richer in ^{18}O than igneous rocks ($+5\%$ to $+10\%$) because they contain some minerals that acquired their isotopic compositions at low temperatures in oxygen isotopic equilibrium with water (Savin and Epstein, 1970a,b; Longstaffe and Schwarcz, 1977). Shales and mudstones generally are enriched in ^{18}O relative to sandstones because of the former's much higher content of clay minerals and secondary silica.

Diagenetic minerals such as carbonate, silica and clays are of particular interest because they are the product of a complex mineralogical, fluid and thermal history. They form by precipitation from solution, and by transformation or alteration of pre-existing phases. Their isotopic composition is controlled by several parameters, including composition of the fluid, the degree of isotopic equilibrium during crystallization (including microbial effects), the mass balance for the element of interest between the mineral and the pore fluid, and the extent of isotopic exchange following crystallization.

Clay minerals are the most important mineral reservoirs of hydrogen in sedimentary rocks, with δD values that normally range from -100% to -20% , typical of phases formed during weathering (Lawrence and Taylor, 1971, 1972; Savin and Hsieh, 1998; Longstaffe, 2000). However, lower values ($\sim -150\%$) are known for clay minerals formed or exchanged at high latitudes or altitudes or during diagenesis in the presence of low-D porewater (Longstaffe, 1989; Longstaffe and Ayalon, 1990). Soil clays typically display a systematic variation in δD and $\delta^{18}\text{O}$ values that describe a trend parallel to, but offset from the GMWL. The position of these "clay weathering lines" relative to the GMWL is determined by the hydrogen- and oxygen-isotope mineral-water fractionations for the temperature of clay formation (Sheppard *et al.*, 1969; Lawrence and Taylor, 1971, 1972; Mizota and Longstaffe, 1996).

Equilibrium stable isotope fractionation and geothermometry

The difference between two phases in the ratios (R) of an element's "heavy" to "light" isotopes (e.g., oxygen in $\text{CaCO}_{3(\text{solid})}$ and $\text{H}_2\text{O}_{(\text{liquid})}$) is known as fractionation. The stable isotope fractionation factor between two phases A and B is defined as:

$$\alpha_{A-B} = R_A/R_B. \quad (\text{Eq. 11})$$

Values of α are normally very close to unity. For example, $\text{CO}_{2(\text{gas})}$ in equilibrium with $\text{H}_2\text{O}_{(\text{liquid})}$ is enriched in ^{18}O

relative to the water, hence the value of α is positive. At 25°C, $\alpha^{18}\text{O}_{\text{CO}_2\text{-H}_2\text{O}} = 1.0412$ (Friedman and O'Neil, 1977). As for all temperature-dependent fractionations, this value increases at lower temperatures and decreases at higher temperatures. Equilibrium fractionations derive from small differences in the thermodynamic properties between compounds containing an isotope with a higher (e.g., ^{18}O) versus a lower mass number (e.g., ^{16}O). This relative mass difference exerts important control on the size of equilibrium fractionations. As a result, the largest fractionations in nature are typically observed for stable hydrogen isotopes.

The ability to calculate values of α from δ_A and δ_B

$$\alpha_{A-B} = (\delta_A + 1000)/(\delta_B + 1000), \quad (\text{Eq. 12})$$

is of special significance in equilibrium systems, because α is temperature (T) dependent. Experimentally determined α -values for mineral-mineral or mineral-water pairs (α_{A-B}) normally fall on smooth curves when $10^3 \ln \alpha_{A-B}$ (known as permil fractionation) is plotted versus $10^6/T^2$ or some variation of that function (T in Kelvin). The smectite and water system provided a typical example of an equilibrium oxygen-isotope geothermometer (Savin and Lee, 1988):

$$10^3 \ln \alpha_{\text{smectite-water}} = 2.58(10^6)T^{-2} - 4.19. \quad (\text{Eq. 13})$$

Such relationships are commonly used to deduce the crystallization temperature of an authigenic mineral, provided that the composition of the mineralizing fluid is known. Stable isotope geothermometers of use in sedimentary systems have been summarized by Kyser (1987), Savin and Lee (1988), Longstaffe (1989) and Sheppard and Gilg (1996). New or revised equations appear regularly (e.g., Bird *et al.*, 1994; Vitali *et al.*, 2001). Stable isotope geothermometers are useful in low temperature systems provided that (i) equilibrium was attained between phases A and B, and (ii) subsequent isotopic exchange was negligible. Knowledge of the rock/water ratio for the element of interest is also important when considering the stable isotopic behavior of mineral-water systems (Longstaffe, 1989, 1994).

Isotopic Exchange. Temperature, grain-size, surface area, crystal chemistry, mineral/water ratio and, in some cases, microbial activity are important factors controlling isotopic exchange between minerals and water (see Longstaffe, 2000 and references therein). Isotopic exchange between minerals and water requires dissolution and recrystallization of the solid phase. Consequently, post-crystallization isotopic exchange between many minerals and water is insignificant at surface temperatures. For example, post-crystallization oxygen-isotope exchange between quartz and water is not detected at <200°C, even for the finest particles. By comparison, such exchange can affect calcite and, to a lesser extent, dolomite, because these minerals are much more easily recrystallized at low temperatures in the presence of porewater. The $\delta^{13}\text{C}$ value of carbonates is generally less affected by such processes, as the mineral/water ratio for carbon is very high in most cases.

Stable isotopic exchange in clay-water systems is complex, and manifested differently in clay-dominated shales and mudstones (where porewater is most affected) versus fluid-dominated systems such as porous and permeable sandstones (where clay is most affected). Exchange of oxygen isotopes between water and structural sites in clay minerals is extremely slow in low-temperature environments, including modern ocean sediments (Savin and Epstein, 1970a,b; Yeh and Eslinger, 1986). Without neof ormation, oxygen-isotope

exchange is insignificant in marine environments, even for very fine (<0.1 μm), smectite-rich clay assemblages. The rate of oxygen-isotope exchange between clay minerals and water increases as temperatures rise, with significant exchange occurring by 300°C. Mineralogical reactions, such as the smectite to illite conversion, facilitate this behavior (Yeh and Savin, 1977).

Hydrogen-isotope exchange between clay minerals and water also occurs slowly at low temperatures, but the rate is faster than for oxygen. Measurable hydrogen-isotope exchange can take place at <100°C; by 200°C, extensive hydrogen-isotope exchange can occur unaccompanied by oxygen isotopic effects. Some studies suggest that hydrogen-isotope exchange between seawater and detrital clay minerals from 2 million to 3 million year old ocean sediments was restricted to the <0.1 μm size-fraction (Yeh and Epstein, 1978); others suggest that exchange with expandable clay minerals occurs readily at surface temperatures. Significant post-formational hydrogen-isotope exchange between non-expandable clays and porewater can also occur over millions of years at 30°C to 40°C without a corresponding effect on the oxygen-isotope composition of the clay (Longstaffe and Ayalon, 1990).

Applications of equilibrium stable isotope fractionation

Stable isotope geothermometry underlies the vast body of research in which oxygen-isotope compositions of ice cores, foraminifera, brachiopods, diatoms and biogenic phosphate in the oceans, and speleothem carbonates on land are used to reconstruct the Earth's past climate (Shackleton, 1968; Emiliani and Shackleton, 1974; Schwarcz, 1986; Bowen, 1991; Petit *et al.*, 1999; McDermott *et al.*, 2001; Norris *et al.*, 2002; Stanton *et al.*, 2002). These stable isotope proxies for temperature are coupled with radiometric, biostratigraphic and paleomagnetic information, which provide an absolute chronology for the scale and rate of climate change.

Stable isotope geothermometers for oxygen and hydrogen are also used to identify the type(s) of water (seawater, fresh water, brine) involved in formation of chemical sediments, provided that independent temperature data are available (e.g., see equation 13). Likewise, this approach has been combined with stable carbon-isotope, $^{87}\text{Sr}/^{86}\text{Sr}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ ratios to explain dolomitization, and to identify multiple fluid regimes responsible for diagenesis of carbonate rocks (e.g., Land, 1980, 1991; Banner *et al.*, 1988; Coniglio *et al.*, 1988; Chafetz and Rush, 1995; Benito *et al.*, 2001).

The stable isotopic compositions of carbonate and silicate cements from siliciclastic rocks have been used in a similar fashion. A common application is to deduce the mixing and movement of seawater, meteoric water and their evolved brines on basinwide scales over time, and to relate this behavior to the generation, migration and degradation of hydrocarbons (e.g., Longstaffe and Ayalon, 1987, 1991; Ayalon and Longstaffe, 1988; Tilley and Longstaffe, 1989; Longstaffe, 1993, 1994, 2000; Ziegler and Longstaffe, 2000a,b). Neof ormed minerals (pedogenic clays, hydroxides, carbonates) from paleosols and regoliths can also be used to deduce the $\delta^{18}\text{O}$ and δD values of ancient meteoric water. These results provide critical insight into continental paleoclimate because the oxygen- and hydrogen-isotope compositions of meteoric water are strongly determined by temperature and the precipitation–evaporation regime at the time of soil formation (Lawrence and Taylor, 1971, 1972; Bird *et al.*, 1992, 1994; Mizota and Longstaffe,

1996; Stern *et al.*, 1997; Savin and Hsieh, 1998; Yapp, 1998; Girard *et al.*, 2000).

Kinetic stable isotope fractionation and its applications

Kinetic isotope effects, which occur during incomplete and unidirectional processes, are a second important source of stable isotopic fractionation in sedimentary systems. These occur during rapid evaporation of water, and are also especially important in biologically mediated systems. For example, $^{12}\text{CO}_2$ is selected preferentially over $^{13}\text{CO}_2$ during photosynthesis (Hoefs, 1997). The magnitude of the fractionation depends mostly on reaction rates and pathways. For example, significantly larger stable carbon-isotope fractionations characterize the C_3 versus the C_4 photosynthetic pathways. Hence, stable carbon-isotope analysis of ancient organic matter and pedogenic carbonates in sediments and soils can provide significant paleoecological and paleoclimatic information (Cerling, 1984; Cerling *et al.*, 1989, 1997).

Kinetic isotope fractionation associated with microbial activity in sedimentary systems is of special importance. The stable carbon- and hydrogen-isotope compositions of methane and carbon dioxide emanating from wetlands, for example, can be used to identify the reaction pathways that produce these greenhouse gases (Hornibrook *et al.*, 1997). As discussed earlier, many early diagenetic processes are also driven by microbially mediated reactions. These produce characteristic stable carbon- and sulfur-isotope compositions in secondary carbonates and pyrite (Irwin *et al.*, 1977; Curtis *et al.*, 1986; Longstaffe, 1989; Habicht and Canfield, 1997, 2001; Canfield, 2001). A full understanding of these reactions allows stable carbon and sulfur isotopic data for these phases, particularly from concretions, to be used to reconstruct ancient depositional environments. Likewise, one can deduce the geochemical conditions at and beneath the sediment-water interface during early diagenesis. Depositional and early diagenetic interplay between fresh and marine waters as sea level fluctuated in shallow epeiric seas can also be elucidated, using the stable carbon-, sulfur-, and oxygen-isotope results for secondary minerals (Irwin *et al.*, 1977; Curtis *et al.*, 1986; Longstaffe, 1987, 1989, 1994; Mozley and Burns, 1993; McKay *et al.*, 1995; McKay and Longstaffe, 2002).

Equilibrium oxygen-isotope mineral-water geothermometers are generally used to identify the water involved during formation of early diagenetic minerals in sedimentary systems. However, microbial activity is known to mediate the precipitation of some oxygen-bearing phases, such as siderite. The oxygen-isotope fractionation associated with microbially produced siderite at low temperatures is different than the equilibrium (inorganic) fractionation for this system. Use of the latter will result in calculated $\delta^{18}\text{O}$ values for porewater that are lower than produced by the former; this can lead to incorrect identification of paleoenvironments (Mortimer and Coleman, 1997). The potential consequences of such microbial interventions on mineral-water oxygen isotopic fractionation in sedimentary and early diagenetic environments remain to be explored fully.

Conclusion

The use of radioactive, radiogenic and stable isotopes is now common in sedimentology. These methods are used to study

rates of deposition and erosion, characterize depositional environments, identify the provenance and dispersal of sediment, make regional and global chemostratigraphic correlations, understand diagenetic processes and geochemical conditions at and near the sediment-water interface, define the timing and nature of regional fluid flow in sedimentary basins, deduce global paleoclimate both in terrestrial and marine environments, infer variations in global biogeochemical cycles and their significance, and make global paleogeographic and tectonic reconstructions. The most important advances over the last decade are the ease with which isotopic measurements can now be made, and the fact that a comprehensive approach to the use of isotopic methods is now the norm. Multiple isotopic chronometers and tracers are employed together to test and constrain hypotheses much more rigorously than possible from use of a single isotopic tracer or geochronometer. The hallmark of effective utilization of isotopic methods is their integration with sedimentological, stratigraphic and other geological data.

KAOLIN GROUP MINERALS

Kaolin is a name given to a group of phyllosilicate minerals whose layers have a 1:1 structure with a composition of $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$. The 1:1 designation indicates the individual layers are composed of sheets of corner sharing tetrahedra in a distorted hexagonal arrangement and a sheet of edge sharing octahedra. The tetrahedra are occupied by silicon atoms and the octahedra are occupied by aluminum atoms in a dioctahedral manner. The join between the two sheets is effected by sharing of what would be the apical oxygen atoms of the tetrahedra with atoms of the octahedra. This creates an asymmetrical layer since one of the surfaces of the layer consists of basal oxygen atoms of the tetrahedral sheet while the opposite surface is populated by hydroxyl groups. The stacking of the layers and the nature of the material, if any, between the layers generate the individual minerals in the group.

The bonding between the layers is due to hydrogen bonding involving hydrogen atoms of one layer and the basal oxygen atoms of the adjacent layer (Hendricks, 1939). To this should be added the interfacial interactions of the layer surfaces. The geometric requirement necessary to create a number of different stable stackings is to enable the hydroxyls (the hydrogen bond donors) of one surface to be close to the basal oxygen atoms (the hydrogen bond acceptors) of the adjacent layer. Newnham (1961) analyzed this and incorporated other factors such as the superposition of cations of the two layers that would be a destabilizing contribution. He determined that there were theoretically 36 possible stackings of the layers taken two at a time. When considering 1-layer structures, two of the stackings were judged to be most stable. These correspond to a right and left-handed kaolinite structure. For two layer structures only 2 of the 36 were likely because the other stackings were destabilized by other factors such as tetrahedral rotation and tilting and the distortions of the individual layers. These two correspond to dickite and nacrite.

Thus, of the large number of possible stackings of the 1:1 kaolin layers, only three are observed. These are kaolinite, dickite and nacrite. There is normally a fourth mineral added to the kaolin group; halloysite, a hydrated (interlayer water) version. Of these four minerals, kaolinite is by far the most common and, along with halloysite, the only mineral that is commercially exploited.

Structures

Kaolin minerals, in common with many clay minerals, occur only as small particles so that traditional single crystal diffraction studies are not possible. There are occasions when one finds what appear to be macroscopic crystals, but these are always either not single crystals or they are highly disordered and not suitable.

Kaolinite derives its name from a locality in China where it was first mined (Grim, 1968). Early attempts to understand the structure of these minerals were based on X-ray powder diffraction experiments. This is difficult because of the low symmetry. Hendricks (1936) observed the characteristic 7.1Å basal spacing. Knowing the thickness of the layer structure allowed Pauling (1930) to outline the architecture of the kaolinite structure. There were a number of attempts to refine the structure suggested by Pauling. Initially, the structure was thought to be monoclinic (Gruner, 1932; Hendricks, 1936), but later Brindley and Robinson (1945) demonstrated that the unit cell is really triclinic and this allowed them to determine the positions of the non-hydrogen atoms. The structure is based on a simple shift of $\sim -a/3$ where a is the unit cell axis. The vacant octahedral site is the same in each of the layers.

The hydrogen atoms clearly are extremely important in the interlayer bonding of these minerals so there has been great interest in locating their positions so as to understand the interlayer hydrogen bonding. Various attempts were made to infer the hydroxyl orientations using infrared absorption spectroscopy (Farmer, 1964). There were great problems in these efforts. Later, potential energy calculations were used to locate the OH orientations that corresponded to the minimum energy (Giese and Datta, 1973; Giese, 1982).

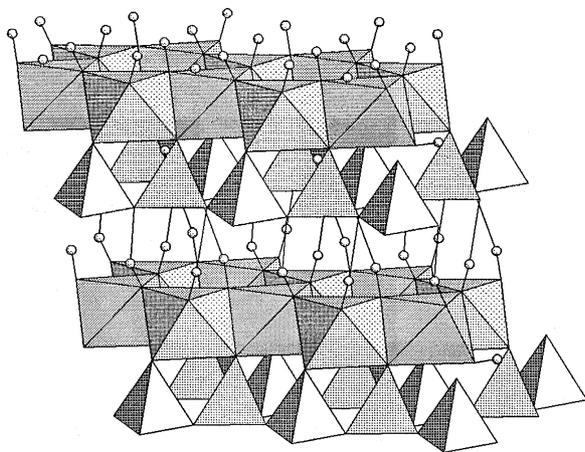

Figure K1 Clinographic view of the kaolinite structure showing two 1:1 layers. The hydrogen atoms are shown as small circles and the hydrogen bonding is indicated by the longer solid lines to oxygen atoms in the adjacent layer (drawing produced with the program ATOMS, by Shape Software, www.shapesoftware.com).

The kaolinite structure has been refined several times since then with increasing accuracy aided by improvements in the refinement of structures based largely on powder diffraction data (see Giese, 1988, for a discussion). Oddly enough, refinements still seem to be in progress even though there seems little justification for such work.

Dickite is named after the mineralogist (Dick, 1888; see Newnham and Brindley, 1956). The major features of the dickite structure were determined by Newnham and Brindley (1956) and there are a number of modern refinements. The stacking is $\sim -a/3$ as for kaolinite. The dickite structure differs from that of kaolinite in that the vacant octahedral site alternates its position in adjacent layers giving a two-layer structure. It is possible to find small but useful single crystals of dickite and these have eased the search for the hydrogen atoms.

Nacrite was named for its nacreous appearance. The structure is different from those of kaolinite and dickite (Blount *et al.*, 1969). The stacking between layers follows the 8.9 Å *a* axis and there is a rotation of the 1:1 layer by 180° between successive layers. The unit cells and space groups can be found in recent refinements of the structures; viz. Bish and von Dreele (1989) for kaolinite, Joswig and Drits (1986) for dickite and Zheng and Bailey (1994) for nacrite.

Defect structure

It was noticed early on that there were wide variations in the X-ray diffraction patterns of kaolinite samples from different localities. These varied from patterns with narrow Bragg reflections to those in which many of the typical kaolinite diffraction bands were diffuse and there was typically a high background between peaks. This was correctly interpreted as some sort of stacking disorder. The peaks most affected had indices with $k \neq 3$. This suggested that the disorder was due to random shifts of $\pm b/3$ (Brindley and Robinson, 1945). It was also pointed out that rotations of $\pm 2\pi/3$ would result in a shift in the vacant octahedral site from layer to layer while

maintaining the interlayer hydrogen bonding (Murray, 1954). The variations in the diffraction patterns were of some use in determining the physical properties of kaolinites, so there were several attempts to formulate an empirical estimate of the degree of disorder. The most widely used index was that of Hinckley (1963). It should be noted that Hinckley used the term “crystallinity” in the title of the paper placed in quotes, presumably to indicate that he was not using the term in strict sense of the word. Unfortunately, subsequent usage has emphasized the normal meaning of crystallinity. Typical values of the Hinckley index range from roughly 0.2 to 1.7 with the larger values corresponding to a low level of structural defects. Recent work has shown that for values of the index greater than 0.43, the samples are mixtures of two kinds of kaolinite, one having few defects and the other having a high concentration of defects (Plancon and Giese, 1988, Bookin *et al.*, 1989, Plancon *et al.*, 1989).

Chemistry

The kaolin minerals in general are reasonably pure with small amounts of iron and titanium. The chemistry is somewhat clouded because kaolinite is now known to occur with interstratified smectite. The admixed smectite introduces alkali and alkaline earth elements, increases the surface area and accounts for the small amount of water often found in samples. Pure kaolinites have small surface areas (approximately $<20 \text{ m}^2/\text{g}$ and very modest cation and anion exchange capacities. Typical chemical analyzes are shown below (Murray and Keller, 1993).

Component	Georgia kaolinite	England kaolinite	Theoretical
SiO ₂	45.30	46.77	46.55
Al ₂ O ₃	38.38	37.79	39.50
Fe ₂ O ₃	0.30	0.36	—
TiO ₂	1.44	0.02	—
MgO	0.25	0.24	—
CaO	0.05	0.13	—
Na ₂ O	0.27	0.05	—
K ₂ O	0.04	1.49	—
LOI (water)	13.97	12.97	13.96

Common mineral impurities in kaolinite deposits are anatase, smectite, and ilmenite.

Recent measurements of the enthalpy of formation of the kaolin minerals has allowed more accurate determinations of the standard free energy of formation (de Ligny and Navrotsky, 1999). The values show that kaolinite is the stable mineral while the other forms are metastable. Further, the variation in the standard free energy of formation does not vary measurably as a function of the defect structure.

Origin and occurrence

There are two types of kaolin deposit; primary and secondary. The primary kaolins are derived from feldspar and muscovite in granite or rhyolite under conditions of high rainfall, moderate to high temperatures above the water table. The large amounts of water are necessary to remove the potassium

and prevent the formation of illite rather than kaolin. A higher temperature regime can result in hydrothermal kaolins. If the kaolin remains in place, the deposit is termed residual. On the other hand if the kaolin is transported by running water and deposited elsewhere, one has a secondary deposit. The formation of kaolinite is favored by low pH and low concentrations of alkali ions as shown in Faure (1998).

Hydrothermal deposits are known in China, Japan, and Mexico. These deposits are exploited primarily for ceramic clay. Residual deposits are found in Australia, Czechoslovakia, Germany and Indonesia. These are used in paper filling and ceramic manufacturing. Deposits which were formed from a combination of hydrothermal and chemical weathering are found in Cornwall, England and New Zealand. The Cornwall kaolinite is particularly well-ordered and pure, and is extensively used in paper coating. There are large deposits of sedimentary kaolin in Australia, Brazil, Germany, Spain, and the United States, principally in Georgia and South Carolina (Murray and Keller, 1993). There are many occurrences of kaolinite "books" in sandstones where they have formed under diagenetic conditions.

KEROGEN

Kerogen is the solid, high molecular-weight fraction of sedimentary organic matter (OM) that is insoluble in organic solvents (e.g., chloroform) as opposed to the soluble fraction called bitumen. Kerogen is a macromolecule of condensed cyclic nuclei linked by heteroatomic bonds or aliphatic chains. The importance of differentiating the soluble and insoluble fractions of OM in standard organic solvents is based on the origin and formation of petroleum in sediments. The soluble fraction contains "free" hydrocarbons (HC) formed during geological processes, whereas the insoluble fraction has large proportions that are liable to form HCs (Durand, 1980). The insoluble nature is linked to condensation of OM and thus represents polycondensed or polymerized states of OM in contrast to the biogenic polymers of the living matter.

Introduction

Kerogen has been defined in several studies, which are summarized in Durand (1980). Durand (1980) proposed to call kerogen *sensu stricto* the fraction of sedimentary OM that is insoluble in standard organic solvents. The distribution of kerogen in the earth's crust is estimated to be 10^{16} t, with most of the kerogen occurring in the fine silt or clay fraction deposited on continent shelf and slope (Figure K2). Kerogen makes up the largest part of the total organic matter and can represent more than 95 percent of the weight of recent OM. Kerogen content is generally estimated on the basis of organic carbon content of the sediment, which yields often an underestimated value that has to be corrected by a factor of 1.5 or 1.6 for slightly evolved sediments. The proportion of kerogen progressively changes during burial and the formation of soluble and/or volatile products, such as HCs, which makes it often difficult to estimate the average proportion of kerogen of the total sedimentary OM (Durand, 1980).

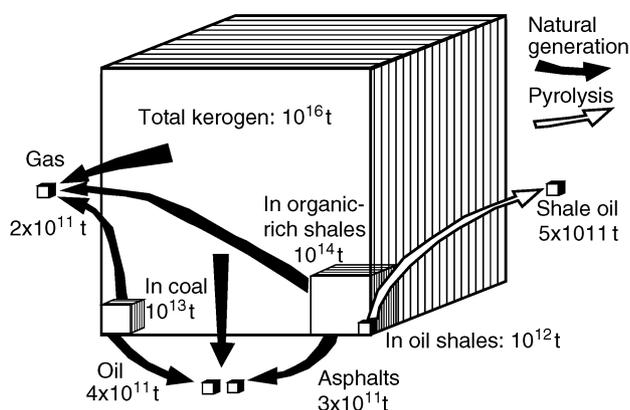

Figure K2 Comparison of kerogen abundance in the earth's crust and the ultimate resources of fossil fuels. Modified after Durand (1980).

Historical development

Scientists studying the oil-shales of the Lothians of Scotland end of the 19th century named the oil-yielding, waxy part of OM “kerogen” (from Greek keros = wax) or “pyrobitumen” (Bailey, 1927, p.158). Kerogen and kerogen maturation received much attention throughout the 20th century, because of its importance for fossil fuels. Numerous methods identifying kerogen type and kerogen maturity have been developed and are summarized in Barnes *et al.* (1990), Bustin *et al.* (1983), Bustin *et al.* (1990), Durand (1980), Hunt (1979), Peters (1986), Taylor *et al.* (1998), and Tissot and Welte (1984).

Characterization of kerogen

Accumulated organic matter in sedimentary deposits provides the potential source for kerogen and hence HC formation during diagenesis. The kerogen concentration, composition, and state of maturation are important parameters for the formation of oil and gas. The OM in sedimentary deposits derives from either living or dead particulate OM or dissolved OM. Amount and type of kerogen will determine the amount of oil or gas that has been or will be generated from OM in sedimentary deposits.

Kerogen type is commonly determined either by optical (petrography) or chemical methods. Petrographic analyzes allow morphological classification of OM of various depositional environments, such as marine or lacustrine deposits, and the level of maturation, while geochemical analysis allow the classification based on chemical properties. In coal geology, three main groups of *macerals* (kerogen constituents of organic matter) are distinguished: liptinite, huminite/vitrinite, and inertinite (Figure K3). During progressive diagenesis, these maceral groups become enriched in carbon but each component follows a predetermined and distinct coalification path (Figure K3). Vitrinite reflectance (R_o percent) is widely used as a parameter of the digenetic level of kerogen (see *Maturation, Organic*).

In petroleum geochemistry, four kerogen types (I to IV) are commonly differentiated (Figure K3). All kerogen types are determined solely on H-, O-, and C-content. Type I, consisting

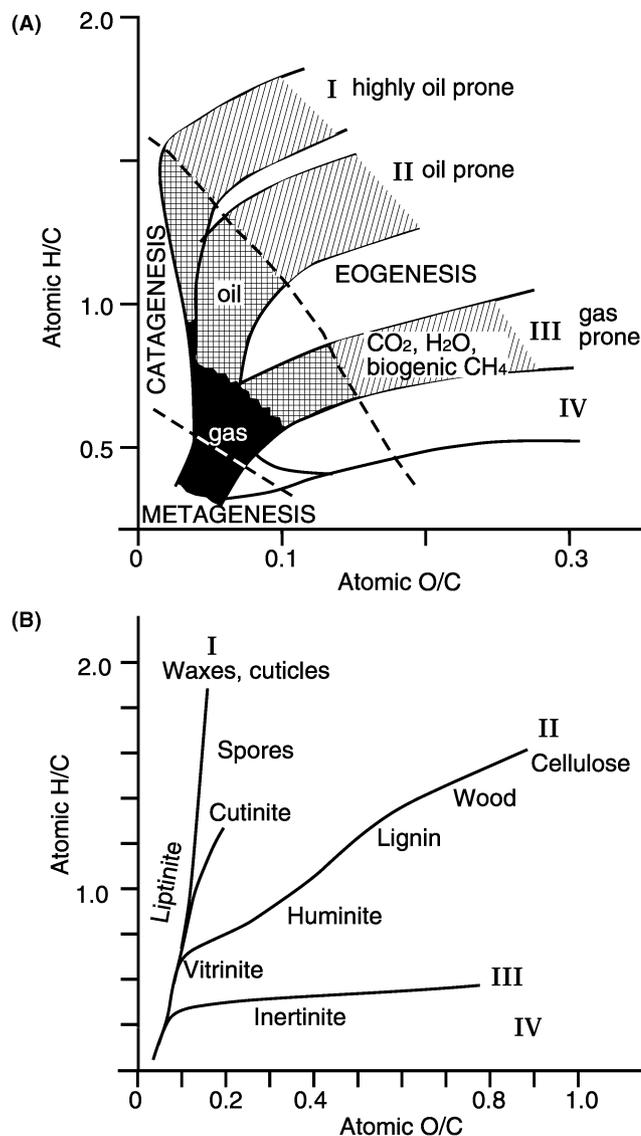

Figure K3 (A) Kerogen evolution illustrated on a van Krevelen diagram. Several evolution stages occur during progressive diagenesis, which have different principal HC production depending on original type of kerogen. During progressive diagenesis, kerogens become enriched in carbon. Note that type IV organic matter does not have an evolution path. Modified after Tissot and Welte (1978). (B) van Krevelen diagram of the diagenetic pathway of coal macerals (kerogen types determined on morphology). During progressive diagenesis, the three maceral groups (liptinite, inertinite, huminite) become enriched in carbon. The diagram shows the changes in terms of H/C and O/C ratios. Modified after Bustin *et al.* (1983).

of mainly algal and amorphous kerogen that is highly likely to generate light oil; Type II, mixed terrestrial and marine material (algae, spores, cuticles) that can generate waxy oil and some gas; Type III, woody terrestrial source material that typically generates gas; and Type IV, also called residual or refractory kerogen, composed of resedimented, oxidized OM,

that has no potential for oil and gas generation (Tissot and Welte, 1984).

Diagenesis of kerogen

Upon deposition and burial of sedimentary deposits, OM (e.g., biogenic polymers, such as proteins, carbohydrates) is transformed (biochemical degradation) and polycondensed structures (geopolymers) are formed which are the precursors of kerogen. The initial stage of diagenesis, called *eogenesis* (Barnes *et al.*, 1990), includes processes of bacterial oxidation, sulfate reduction and fermentation. The most important HC formed during this stage is CH₄ (Figures K3, K4). Oxygen elimination of kerogen takes place and results in the formation of CO₂, H₂O, and some heteroatomic (N, S, O)-petroleum compounds of high-molecular weight (e.g., asphaltenes and resins) are liberated. Most carboxyl groups are removed (Barnes *et al.*, 1990; Bustin *et al.*, 1990). Type III kerogen may produce some gas (Figure K3).

Increasing burial and progressive diagenesis (increase in temperature and pressure) of the sediments results in the production of liquid petroleum from kerogen. During this stage of thermal maturation, called *catagenesis*, both liquid oil and condensate, including methane, are formed (wet gas phase) (Figure K4). HC molecules, such as aliphatic chains, are produced from kerogen and cracking results in the production of light HCs. Because of the chemical structures present, immature kerogens that are hydrogen-rich will generate crude oil and hydrogen-poor kerogens will yield only gas. As burial depth and temperature increase, the residual kerogen becomes depleted in H (labile compounds) and has an atomic H/C ratio of about 0.5 by the end of the catagenesis (Tissot and Welte, 1984).

Further increase in pressure and temperature leads to the stage of *metagenesis*. During this stage, kerogen is structurally reorganized and a higher degree of ordering is obtained. Only

minor amounts of methane are formed from the residual kerogen during the last stage of diagenesis.

Determining level of kerogen maturity

With increasing levels of organic diagenesis, the color of kerogen in transmitted light changes progressively and several methods have utilized such characteristics for kerogen classification, for example the *thermal alteration index*, a numeric scale used to classify the color changes of palynomorphs. Because of the widespread abundance of palynomorphs in sedimentary deposits, optical determination of the level of kerogen maturity is seldom a problem. Another optical method is fluorescence microscopy, which determines the irradiation level of liptinite components (algae, spores, resin, cutin). In coals, similar changes are recorded by analyzing the *vitrinite reflectance* (R_o). The vitrinite reflectance is commonly used to classify coal rank and OM maturity level (see *Maturation, Organic*).

Classification of kerogen by chemical means is limited to the pre and early oil generation maturities because generation and expulsion of hydrogen-rich oil and gas alters the hydrogen content of the original kerogen (Figure K3). Numerous methods are used for determining the geochemistry of kerogen. The most important methods are: pyrolysis, ultimate analysis, infrared spectroscopy, electron paramagnetic resonance, carbon isotope studies, proximate analysis, calorific value, etc., (Bustin *et al.*, 1990; Garcette-Lepecq *et al.*, 2000). *Pyrolysis* or progressive heating of the sample up to 550°C, utilizing Rock-Eval[®] instruments (see Peters, 1986), measures three types of gases: (1) the HCs residual in the sample (S₁); (2) HCs generated during thermal cracking between 300°C and 550°C (S₂, T_{max}), and (3) CO₂ (S₃). This allows determination of the level of organic diagenesis and type of HCs the kerogen will yield. This method is widely used despite the fact that some surface samples tend to be prone to alterations and thus erroneous T_{max} (see Copard *et al.*, 2002).

Ultimate analysis determines elemental concentrations of C, H, and O and H/C and O/C ratios are plotted against each other in a *van Krevelen* diagram. van Krevelen diagrams allow characterization of kerogen type and maturity level (Figure K3).

Infrared spectroscopy quantifies the main functional groups. During progressive diagenesis of OM, carboxyl, carbonyl, and saturated HCs decrease and aromatic C-H groups are formed and removed (Bustin *et al.*, 1990). Kerogen type, the precursor of the functional groups as well as diagenetic stage can be determined.

Summary

Kerogen is the fraction of OM in sedimentary deposits that is insoluble in standard organic solvents. It is a macromolecule of condensed cyclic nuclei linked by heteroatomic bonds or aliphatic chains. Different types of kerogen (I to IV) occur depending on the composition of the organic matter, most of which generate oil and gas upon diagenesis. Burial of the sediments, including increasing temperature and pressure, results in the rearrangement of kerogen. During eogenesis, elimination of heteroatomic bonds and functional groups occurs and CO₂, H₂O and some heavy N, S, O compounds are released, while CH₄ is produced. During catagenesis, HC chains and cycles are eliminated and crude oil and gas are

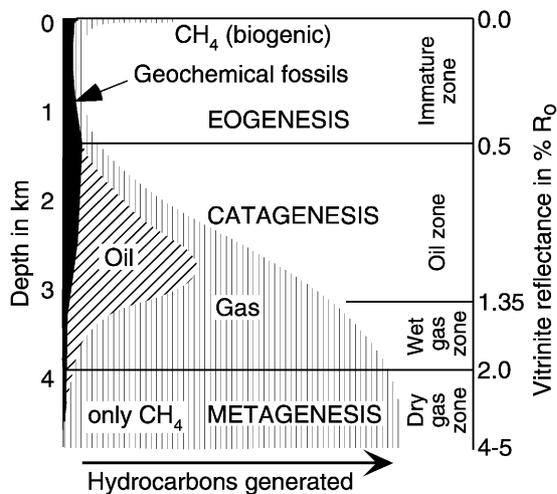

Figure K4 Hydrocarbon generation changes in sediments during their evolution of progressive diagenesis. Vitrinite reflectance (R_o %) corresponds to the degree of organic matter maturation and is dependent on type of kerogen, burial history and geothermal gradient. Modified after Bustin *et al.* (1990).

formed. During metagenesis, aromatic sheets of kerogen are rearranged and form clusters while some gas is generated. Progressive changes of HCs occur with progressive diagenesis. Whilst biomolecules are dominant during eogenesis, medium to low molecular weight HCs become predominant during catagenesis and CH₄ is practically the remainder during metagenesis.

L

LACUSTRINE SEDIMENTATION

The lake is a system, that is, a bounded entity possessing a set of unique, interconnected elements, especially of process and response, that can be recognized as such regardless of how they are dealt with by scientific enquiry (Strahler, 1980). Further, the lake is an open system; processes beyond the boundaries relate to those within the system to produce mass and energy exchange across the boundaries. For a lake in equilibrium with its environment, the components of these exchanges lead, over the long term, to a zero-sum result; what goes in must come out. While that is generally true of energy and of water, sediment flux is normally not balanced because input and storage much exceed loss from the system.

Sedimentary processes and deposits in lakes are determined by the physical, chemical and biological environment of the lake and of its watershed and airshed. The processes and products of this environment are controlled in complex interactions among climate, hydrology, biology, geomorphology, geology, and, increasingly, human actions. Figure L1 sets out a conceptual framework that associates these factors and indicates qualitatively the way in which the sedimentology of the lake is controlled.

Limnologic processes affecting sedimentation

The processes in a lake are driven by the energy of the lacustrine system. The most important input of energy is through solar heating as part of the radiation balance which reaches an average of about 200 W/m^2 in summer in mid latitudes. The major ways in which heat energy is lost from the lake are by sensible heat transfer and evaporation. Solar heating is particularly effective because the mean albedo (reflectivity) of the water surface is less than 10 percent, one of the lowest of any natural surface. Solar radiation penetrates water up to several tens of meters before being absorbed and heating the upper part of the lake, thus reducing the density of the water and leading to a tripartite structure of the water

column: an upper epilimnion separated from a colder, higher density hypolimnion by a zone of thermal change, the metalimnion. In mid-latitude lakes the isolation of these zones breaks down twice each year in spring and autumn as water in the epilimnion warms or cools, respectively, through the temperature of the hypolimnion. This semi-annual overturn and mixing of the lake water, referred to as *dimixis*, is important in mass (including sediment) and energy transfer throughout the lake. In high latitudes and tropical to subtropical regions heating or cooling to the near-bottom temperature occurs only in summer or winter, respectively, giving rise to one period of overturn, or *monomixis*. In lakes less than about 2 m to 10 m deep depending on fetch (Gorham and Boyce, 1989) wind-generated forces frequently overcome thermal stabilization of the water column, leading to repeated or near continuous overturn of the lake water referred to as *polymixis*.

Mass exchange of water (the water balance) is important to sedimentary processes because normally a significant amount of sediment is delivered to lakes by rivers. The annual pattern of precipitation is especially important, leading to flushes of water and its sediment load in seasonal events, for example related to snowmelt in the mid to high latitudes or monsoons in the sub-tropics, and to irregular, catastrophic, major storm events. Where evaporation from the lake exceeds precipitation and runoff into the lake, outflow does not occur and dissolved salts accumulate in the lake water. This commonly leads to a persistent structure based on lower density (fresher) water near the surface, and high-density, in some lakes hypersaline, water at depth which does not permit overturn and is referred to as *meromixis*. In extremely arid environments the entire lake may be hypersaline. Salts may also be present in lakes lifted from the sea by tectonic processes. A review of the water and energy balances of lakes is provided by Lerman *et al.* (1995).

The components of the water balance determine the *residence time* of water in the lake which is an important factor influencing sedimentary processes. This is the time that water spends in the lake on average between when it enters the lake as runoff or precipitation and when it leaves the lake as outflow or through evaporation. It is a function of the relative volume of the lake with respect to the volume of input, and can

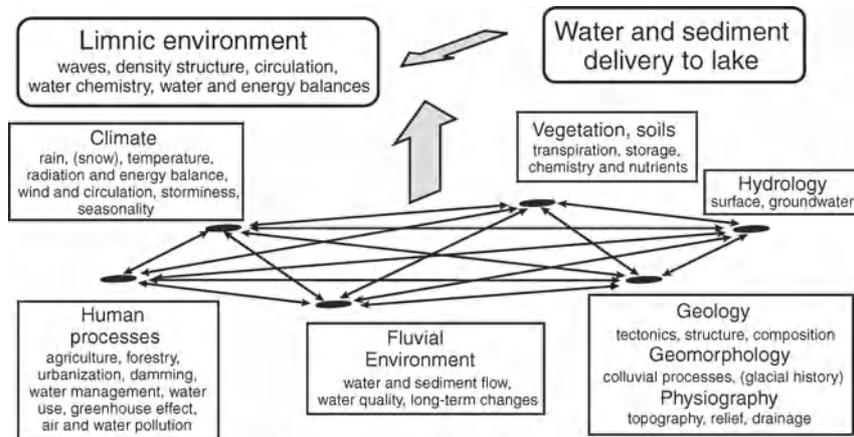

Figure L1 Conceptual model of the relation between the characteristics of the drainage basin and the nature of lacustrine sedimentation.

vary from a few days to many centuries, the latter for large lakes with small drainage basins. The longer the residence time, the more likely that a given sediment particle will have time to settle to the lake floor rather than being swept from the lake. Thus, depending on the formation of precipitates, most of the sediment in solution passes from the lake, while greater amounts of progressively coarser-grained clastic and biogenic sediment are trapped. As a general rule, lakes having residence time of 0.1 years trap 80 percent to 95 percent of the sediment input, while those with residence times of 1 year or more trap 95 percent or more (Brune, 1953).

Of the many other processes that occur in lakes, the action of waves generated by wind is the most important to the sedimentology of the lake, even though as a source of energy to the lake as a whole, waves represent a relatively minor component. The size and energy of waves is governed by the velocity and duration of the wind, and the effective fetch (the distance the wind blows across open water, accounting for the irregularities of the shores: Håkanson and Jansson, 1983). There are a number of graphical and numerical methods by which calculations of wave size may be made (e.g., Sinclair and Smith, 1972). Because of the role of waves in shaping coastal environments, wave energy plays a very important role in the sedimentology of the entire water body. Fundamental is the concept of *wave base*, the water depth to which waves erode sediments on the lake floor. This depth is about one quarter of the length (crest to crest distance) of the wave in deep water (Sly, 1978), and so is a function of wind velocity and fetch (Figure L2). In large lakes having an effective fetch of 100 km or more, wave base may reach 40 m in the largest storms. Fine-grained sediments are winnowed from deposits on the lake floor above wave base, and are transported to deeper water for redeposition. In addition, waves generate circulation of the lake water, moving mass and energy through the lake and affecting sedimentary processes.

Types of lacustrine sediment

Classifications of lacustrine sediments include those based on their place of origin, the processes of their transportation and deposition, their location in the lake, and their composition (Håkanson and Jansson, 1983). Sediments which are transported from the watershed or the airshed to the lake, and

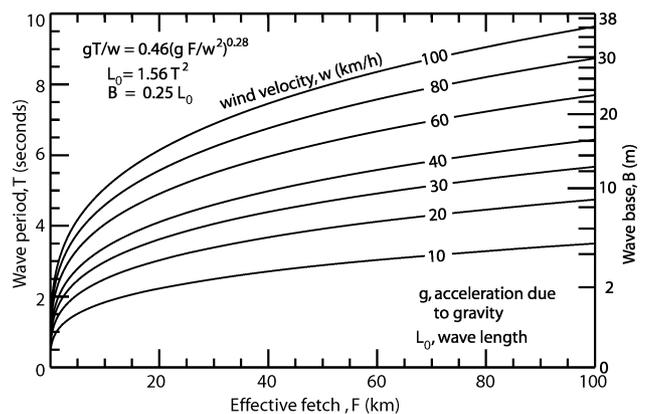

Figure L2 Relation of effective fetch to wave period according to Sinclair and Smith (1972), and wave base. Results correspond with observations of sediment erosion on the lake floor (Håkanson and Jansson, 1983).

are deposited in the lake with little physical or chemical alteration are referred to as *allochthonous*. Those that originate within the lake itself are referred to as *autochthonous*. Most commonly these are created as a result of precipitation of salts dissolved in the lake water or from the remains of aquatic plants and animals. At least some of the components of autochthonous sediments come from outside the lake (as the dissolved or nutrient loads of incoming streams, for example), but the form in which they are deposited is very much altered from the form in which the constituents arrived at the lake.

Primary deposits are those which have undergone only minor changes since they were deposited, while *secondary* or *reworked* deposits have been significantly altered since deposition. Gravitational processes, erosion by waves and currents, and bioturbation are the principal ways in which sediments are reworked and redistributed in the lake. The distinction between primary and secondary deposits becomes important, for example, where ancient sediments are eroded from the lake floor and redeposited elsewhere along with sediments newly arrived in the lake, mixing an ancient paleoenvironmental

signal (that might be interpreted from the physical, chemical or biological nature of the sediment) with the signal from the modern environment.

Classification based on the composition of the sediment, divides deposits into *lithogenic*, *biogenic*, and *hydrogenic* sediments. Lithogenic sediments are the clastic detrital products of the physical and chemical weathering of rock or unconsolidated sediment. These sediments may be further classified on the basis of mineral composition, grain size (from boulders to clay size), sedimentary structures and stratigraphy, color, magnetic characteristics, and so on. Biogenic sediment is the remains of aquatic organisms with normally lesser amounts of allochthonous organic material. It includes detritus dominated by carbon-based molecules, including those in association with calcium (as calcite and aragonite), phosphorous (as phosphate), and silica. This black organic ooze referred to as *gyttja* dominates many mid-latitude lakes. Hydrogenic sediment results from precipitation from solution of salts in the lake water or the interstitial water of previously deposited sediments. Included in this class are the *evaporites* (*q.v.*) of saline lakes and the *marl* deposits of hard-water lakes.

A geochemical classification considers the presence of oxygen in the sedimentary environment. *Oxic* sediments are those in which there is oxygen in sufficient quantity (more than about 10^{-6} moles per litre) to determine processes dominated by oxidization. *Anoxic* sediments where oxygen is insufficient to allow oxidation are divided into *sulfidic* and *non-sulfidic*, depending on the presence of dissolved sulfide. Non-sulfidic environments are divided again into *post-oxic*, where oxygen removal has occurred without sulfate reduction and *methanic* where sulfate reduction and methane gas formation have occurred. These environments commonly change as the redox boundary migrates upward as sediment accumulates, and so remains just below the sediment surface. Oxic deposition is followed by post-oxic, sulfidic and methanic. Deposition of iron and manganese in the sediments or as nodules at the surface is closely associated with this chemistry.

Lacustrine sedimentary processes

Figure L3 shows a generalized, conceptual model of sedimentation in a lake. Not included are components that are unimportant in many lakes (such as the action of seasonal ice cover). Three sources of sediment to lakes are indicated in Figure L3. Fluvial sediment, including coarse-grained bed-load and fine-grained suspended load (wash load), is the most important source of sediment for most lakes. Fine-grained airborne sediment (dust), including mineral and organic material of natural and human origin is important in many lakes, especially where pollutants such as the sulfur and nitrogen compounds that create acid precipitation, and phosphorous in various forms, for example, are delivered in significant quantity. Autochthonous sediments are commonly created from the dissolved load (especially calcium carbonate and similar minerals) in inflowing streams and groundwater, as well as from biological activity, especially photosynthesis.

A delta commonly forms at the mouths of rivers bearing large clastic loads. Flow decelerates in hydraulic backwater, allowing bed-load deposition in a wedge of foreset beds created near the subaqueous angle of repose by quasi-continuous avalanching, overlain by topset beds deposited in response to changing fluvial gradient as the delta advances. Variations occur in lakes having fluctuating water levels and

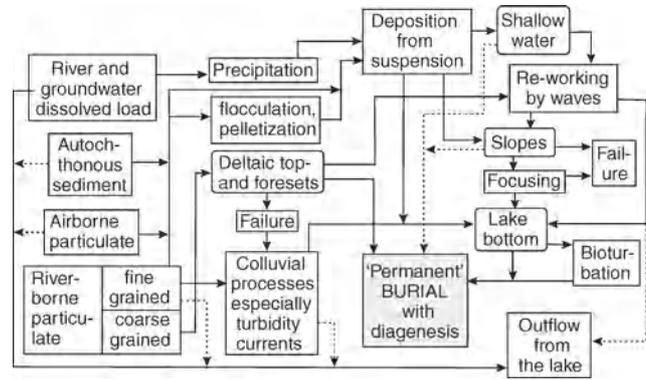

Figure L3 Generalized components of the lacustrine sedimentary environment. This model does not consider coastal processes and sediments.

where alluvial fans extend from land to water. Finer-grained material in suspension is transported into the lake in a decelerating jet to be deposited distally from suspension as bottomset beds. Deltas are absent or poorly developed at many river mouths where clastic sediment input is low or where vigorous waves and currents redistribute sediment as quickly as it is delivered.

Fine-grained sediment in suspension settles to the lake floor through calm water according to Stokes Law:

$$v = (\rho_s - \rho_w)g d^2 / 18\eta$$

where ρ is the density of the sediment (_s) and water (_w), g is the acceleration due to gravity, d is the particle diameter, and η is the dynamic viscosity of the water. Accordingly, a 10 μm diameter particle requires about one to two weeks to settle 100 m, while a 1 μm particle requires several years. An analysis that includes sand size particles where viscous resistance is small in comparison to the weight of the particle (i.e., beyond the range of Stokes Law) and the effect of particle shape is presented by Dietrich (1982). Actual rates of transfer to the lake floor are greater than settling predicted by these models for two principal reasons. First, floculation even in fresh water increases the effective particle diameter especially of clay minerals such as kaolinite and illite and settling time is reduced by an order of magnitude or more (Droppo *et al.*, 1997). Complimenting this is the incorporation of fine-grained sediments into fecal pellets produced by zooplankton. Second, general circulation carries parcels of water and suspended sediment to depth, although the presence of thermal or chemical stratification prevents mass transport throughout depth, except during overturn.

Colluvial (gravitationally driven) processes commonly redistribute sediment from shallow to deeper basins in a lake. Slides move large quantities of sediment along a well-defined glide plane with little internal deformation, so the deposit remains as a coherent mass retaining clearly recognizable sedimentary characteristics of the original deposit. In slumps the sediment is deformed but the final deposit is recognizable as a single event (Figure L4). In *gravity flows*, which are significant where deposition of clastic sediment predominates, the sediment is completely reworked during transport (see

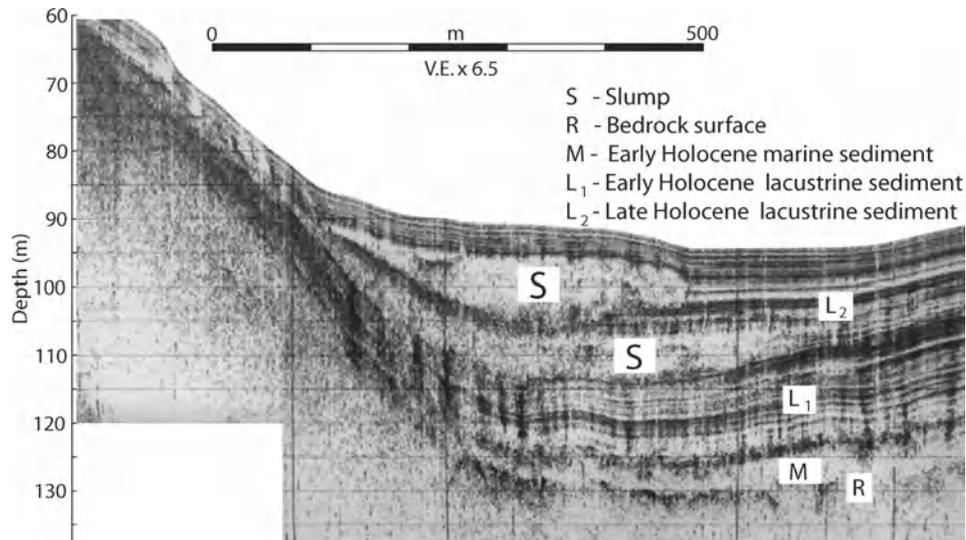

Figure L4 3.5 kHz subbottom acoustic profile from Stave Lake, British Columbia, Canada showing marine sediments deposited over bedrock immediately following deglaciation, then lacustrine sediments deposited and focused to the lake basin, including by slumping, through the Holocene.

Gravity Driven Mass Flows). Middleton and Hampton (1976) distinguish *fluidized flow* in which the sediment is supported by escaping pore water, *grain flow* where particles are supported by grain-to-grain interaction, *debris flow* as a slurry where coarse particles are supported by the matrix of fine particles, and *turbidity currents* where sediment is supported by turbulent flow. Turbidity currents are generated directly from inflowing streams or as a result of colluvial processes on the lake floor; in either case, the current is driven down slope by its greater density due to suspended particulate matter. Behaving as a river under the water of the lake (considering the buoyant effect of the ambient water and the interfacial shear stress with the flow—Middleton, 1966), turbidity currents intermittently distribute relatively coarse-grained sediment widely over the floors of some lakes, even creating leveed channels in a few cases.

An important consequence of the reworking of sediments by waves from the coast to the depth of wave base, and by rapid, episodic, and slow, continuous colluvial processes throughout the lake is that sediment is focused to the deepest basins of the lake (Figure L4). The result is that rates of accumulation vary significantly throughout lakes (Blais and Kalff, 1995). This must be assessed when deciding the location of point samples (cores) used to reconstruct depositional rates and sedimentary history of a lake.

Sediments deposited in deep water are normally subject only to reworking by bioturbation and to diagenesis as they are sequentially buried. Diagenesis refers to the changes that the sediment undergoes after it has been deposited on the lake floor, normally as it is buried in the sediment column (Berner, 1980). The common forms of diagenesis occurring in lacustrine sediment include: (1) compaction and dewatering caused by loading with associated increase of shear strength of the sediment; (2) diffusion or mass transport in pore water of dissolved salts, including metals through the sediment; (3) dissolution or precipitation of, for example of marl

(calcium carbonate); and (4) decomposition of organic material by aerobic or anaerobic bacteria. Thus, after the sediment is buried in the lake floor, it may change significantly, and assessment of environmental change from the characteristics of the sediment must take into account these possible changes. For example, a pollutant that migrates upward from older to more recently deposited sediment as compaction and dewatering occur may appear to indicate more recent contamination of the aquatic system than has actually occurred.

Lacustrine sediment as paleoenvironmental proxy

Figure L1 indicates a strong, if complex relation between terrestrial systems and the nature of sedimentation in lakes. If these pathways are understood, the sedimentary record has potential to provide a wealth of knowledge about the lake and its contributing region, both in the present and throughout the history of the lake. Facilitating this are the characteristics of limnic processes and lacustrine sediments:

1. Lacustrine sediments are normally deposited quasi-continuously without subsequent erosion and only minor diagenesis, so according to the Law of Superposition, a long, uninterrupted, decipherable record from present to the beginning of the lake can be assessed.
2. Most of the sediment entering the lake is trapped there so that whatever has occurred in the lake or its basin is registered in the sedimentary record.
3. Commonly, the finest grained sediments are deposited in the lake, while gravel and even sand are left in the rivers and deltas, and on the land. It is this fine organic and inorganic material that is most diagnostic of the environment of the watershed and airshed contributing to the lake.
4. Sediments deposited in a lake represent the entire drainage basin and so integrate and smooth catastrophic events. Thus, while a major storm or localized soil erosion event

may be represented in the lacustrine record, they do not overwhelm a sedimentary sequence as may occur in the terrestrial record.

5. Commonly, annual cycles (varves, *q.v.*) are preserved in lacustrine sediments. These are powerful as dating tools and in high-resolution paleoenvironmental assessment.

There is an extensive and rapidly growing literature interpreting changes in climate, hydrology, geomorphology, and human actions on scales from intra-annual to hundreds of thousands of years. Proxies include the physical characteristics of clastic sediments (Lamoureaux, 1999), the chemistry of precipitates (Last and Slezak, 1988) and biologic material including diatoms (Stoermer and Smol, 1999) and pollen.

Investigating the lacustrine sedimentary record

The nature of sediment in a lake is commonly investigated at two scales. First, at a synoptic scale, acoustic techniques provide remotely sensed imagery of the entire lacustrine sedimentary package (Figure L4). Even conventional high frequency (50 kHz and above) echo sounding penetrates soft, organic sediments such as gyttja but lower frequency (commonly centered on 3.5 kHz) provides penetration of tens of meters into most types of lacustrine sediment. In a few cases, low frequency seismic surveys have provided very deep penetration through extremely thick lacustrine sequences. From these records the distribution and thickness of sediment in the lake is mapped, sedimentary processes and rates of accumulation are inferred, and changes in sedimentary processes and deposits through time are documented.

Second, samples of the sediment are recovered for detailed analyzes. Many samplers have been devised, each designed to particular needs. Dredges, including trawls and samplers with closing jaws, recover surficial material. Samplers having a chamber to retain sediment include box corers, gravity and piston corers, and side-opening samplers. Adhering samplers cause sediment to accumulate on their outer surfaces, normally by freezing due to a mixture of dry ice and alcohol inside the sampler. All are designed to recover material from the surface or near-surface of the sediment to depth of up to tens of meters with as little disturbance as practicable. Unlike oceanographic surveys where a large ship with heavy equipment is normally available, a major concern in sampler design and deployment in many lake studies is light weight, portability and ease of deployment from small vessels, or where conditions permit, from an ice cover. Details of lacustrine sedimentary analyzes are documented in a number of sources including Håkanson and Jansson (1983).

LATERITES

Laterites, products of tropical weathering, cover about one third of the world land surfaces. Inventories and interpretations concerning the worldwide distribution of laterites have considerably progressed during the last 50 years: new concepts have been emerging in geomorphology, soil science, petrography and geochemistry, while the nomenclature has been progressively revised (Millot, 1964; King, 1967; Michel, 1973; Nahon, 1976, 1991; Bardossy and Aleva, 1990; Thomas, 1994; Segalen, 1994, 1995; Tardy, 1969, 1993, 1994, 1997; Tardy and Roquin, 1998).

Definition

The terms laterite and lateritic materials no longer refer to hardening. Even if several types are effectively indurated (when concretionary and nodular), they may be also soft (if massive)

or loose (if pisolitic and granular). They do not refer to color even if most of them are dominantly red. They may be yellow, white, pink or even black in color. The major constituent minerals are dominantly kaolinite, goethite or hematite (secondary minerals) and very often quartz (primary mineral). Frequently the aluminum hydroxide gibbsite, and rarely other oxides or oxihydroxides such as boehmite, pyrolusite, cryptomelane, etc., are sometimes formed in large proportions, depending on the nature of the parent rock and climate. Laterites are products of humid tropical or subtropical weathering. Profiles developed under arid or semiarid climates, in which carbonates, salts, smectites or amorphous silica could be formed are excluded; so are profiles which retain easily hydrolysable primary minerals such as feldspars or amphiboles. While each type reflects a quite precise climatic zonality, lateritic profiles are generally very old and polyphasic, that is, resulting of an imbroglio of different successive paleoclimates.

Nomenclature

Lateritic materials can be classified into several categories, distinct by nature of their mineralogical compositions, petrographical structures and degree of maturity. Three major groups are distinguished, characterized mostly by the qualities of their upper horizons, the most sensitive to climatic changes. They are *Ferricretes*, *Bauxites*, *Latosols*, and, as an extension which could be considered as abusive, *Gibbsitic Podzols*.

Lithomarges are fine saprolites, roots in common to all lateritic profiles, and continuously formed below the water table. The structure is massive and the features of the parent rock are conserved. Kaolinite is the dominant secondary mineral; goethite and hematite are also present; preserved quartz is abundant on granitic rocks and sandstones. Concretions are not observed and lithomarges are so widely distributed that they have no climatic or paleoclimatic significance—except thickness—which can sometimes exceed 100 m.

Mottle horizons are intermediate between lithomarges and ferricretes, and formed in the domain of water table fluctuations. Pedological features observed are essentially mottles, resulting of iron mobilization, exhibiting two contrasted domains: (1) yellow or red colored, in which goethite and hematite accumulate intimately associated with kaolinite, within originally clay-rich and quartz-poor litho-relict features (inherited from the parent rock weathering) or pedo-relict features (originated by secondary illuviation of kaolinite); and (2) pale or white uncolored, resulting of iron leaching out from clay-poor or quartz-rich litho-relict features. With mottles, the beginning of hardening takes place (carapace).

Ferricretes are nodular horizons, in which *concretions*, made of original kaolinite, intimately associated with abundant small sized hematite, organize by progressive iron accumulation, leading a dark red color and a significant hardening, similar to bricks (*cuirasse*). At the bottom of the profiles, the transition between mottle horizon and ferricrete is progressive and accompanies the iron enrichment. From the bottom to the top, quartz dissolves and may even disappear, while hematite contents increase significantly and kaolinite amounts remain constant or smoothly augment. Ferricretes develop *in situ*, sometimes over considerable thickness (when old) by leaching of soluble elements and accumulation of poorly soluble materials, which reorganize into concretions.

Granular horizons. Toward the top of the profiles, ferricretes dismantle, yielding loose horizons, made of *granules*, round in shape, and constituted essentially of relicts of concretions of hematite+kaolinite, surrounded by rings of secondary goethite (often called pisolites). In peculiar cases, together with goethite enrichment, gibbsite appears in pores of large size. The round granules are not transported but also formed *in situ*, accompanying hydration and leaching of the upper horizons of ferricretes.

Ferricretes and their associated horizons are formed specifically under tropical (warm) but seasonally contrasted climate, alternatively dry and humid. Their maximum extension is observed during the Eocene, even far away from the equatorial zone. They are the parental source of many latosols and orthobauxites, formed at their expense, under subsequent wetter or cooler tropical or subtropical climates.

Latosols are thick and soft horizons, red or yellow in color, with massive or *microgranular* structure, developed above *lithomarges*, from whose they are generally separated by a *stone line*. The microgranules are ancient nodules of hematite+kaolinite earlier formed in *ferricretes*, and later dismantled under wetter climate, in which goethite and gibbsite secondarily develop in significant proportions. Stone lines are made not only of quartz gravels derived from quartz veins, but also of blocs and granules of ancient ferricretes, buried under the latosolic horizons by termite activity. *Red latosols* are located mostly on relict plateaux of the oldest surfaces, high in altitude; they generally bear high quantities of gibbsite and rather low amounts of quartz, so that could be considered as *protobauxites*. On quartz-poor parent rocks, they could lead with time to real *orthobauxites*, also red in color. *Yellow latosols* are located downslopes on younger surfaces; they generally bear higher quantities of quartz and siliceous phytoliths, in the upper part accompanying large amounts of kaolinite associated with goethite. They generally exhibit very low if any concentrations of gibbsite at the top but may develop a bauxitic layer at the bottom, leading with time under very wet tropical climates to the formation of exploitable *cryptobauxites*, also yellow in color. Both red and yellow latosols are developed *in situ* by chemical weathering and insect bioturbation. Most, not to say all of them, derive from ancient ferricretes, later submitted to warm but very wet tropical climate or cool and humid subtropical climate, such as those developed at higher altitudes.

Lateritic bauxites are economic ores of aluminum accumulated as hydroxide (gibbsite) or oxi-hydroxide (boehmite) developed on quartz-poor materials. Several types are distinguished, according to their mineralogical compositions and to their kind of organization. *Protobauxites* are red latosols (*ferralsols*), yielding significant amounts of gibbsite. *Orthobauxites* result of the development with time of such protobauxites, generally under cooler and wetter subtropical climates for which altitude could be the determinant factor. In this case the top of the profile could be dark-red and bearing relicts of ancient *granules* or *microgranules* inherited from the ancient latosol called *conakryte*. Laying below the conakryte and above the lithomarge, the bauxite *sensu stricto* is a thick horizon, pale-pink in color and made of massive gibbsite crystallizing as septaria around pores of large size and conferring to this material a kind of consolidation which has nothing to do with concretion hardening. *Cryptobauxites* are bauxitic horizons developing in between at the top a yellow latosol (kaolinite, goethite and quartz) several meters thick,

and at the bottom with a very thick lithomarge. The characteristics of the bauxitic horizon are the same except that the color may be yellow-white in this case. *Metabauxites* are ancient orthobauxites evolving under warmer and dryer climates. The red superficial horizon of conakryte has disappeared and being replaced by a ferricrete horizon located not above but below the bauxite accumulation. The bauxitic horizon, white in color, very hard and dense in consistency, is essentially made of *concretions* of boehmite (from a centimeter up to several meters in diameter), in some cases dissociated and underlined by rings of hematite (called pisolites). Metabauxites begin to form when orthobauxites are displaced in the climatic zone of ferricretes. This evolution slow down but prolongs under semiarid climates.

Gibbsitic Podzols are laterites by a strict application of the mineralogical definition, developing as ultisols at the expanse of quartz-rich parent rocks and under per-humid tropical climates. The superficial horizon is totally white (albic), rose-pale or ash colored, most of the time very thick, looking like the "Dover cliffs" in the Congo. Down below the albic horizon a layer of gibbsite cementing the quartz grains is very often observed.

Laterites are excellent indicators of continental climates and paleoclimatic successions, due to uplift, subsidence, continental drift, and relative migrations of the equator and its associated climatic zones.

Continental drift and paleoclimatic successions

One has first to realize that the equatorial zone of the great tropical forest is and was always bordered by a series two zones (N and S symmetrical) of seasonally contrasted tropical climates colonized by savannah. Those two are bordered by the two steppe and desert zones of semiarid and arid climates, farther surrounded by two other zones of subtropical climates. During the Cretaceous, the Sahara was located under the equator; bauxites were formed in Saudi Arabia, while Nigeria and Guinea were in the southern climatic zone of ferricretes which today appear as relicts in some places covering the Post-Gondwana old and high surface. At that time Congo and Amazonia were deserts covered by sand dunes. During the Eocene, continents moved northward and the equator moved southward. Furthermore the global humidity and temperature were at their maxima. Ferricretes were also at their maximum of extension in southern zones of Amazonia, Congo, Central Africa and the northern domains of the Sahara, where they still persist today but more or less dismantled. However, at higher altitudes, orthobauxites form at the expanse of red latosols on the uplifted panafrikan surface of Guinea, South Mali and Burkina Faso. Europe is located in the northern zone of the subtropical climates where karst bauxites are widespread. From the Miocene to the Present, climatic zones continued to move southward while the global climate became cooler. South-Eastern Africa and Andes were uplifted. Southern ferricretes transformed into latosols in central Amazonia, Guyana, Tanzania, Congo, Gabon, while new ferricretes formed in the northern belt but on the lower surfaces (Haut-Glakis) in Burkina Faso, Ivory-Coast, and Mali. However ancient orthobauxites of Southern Mali and Northern Burkina, localized on older surface were submitted to aridity accompanying the progression southward movement of the Sahara. Orthobauxites of high surfaces were transformed into metabauxites. At the present time, Amazonia and Congo are

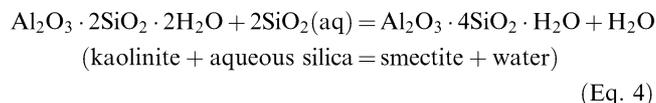

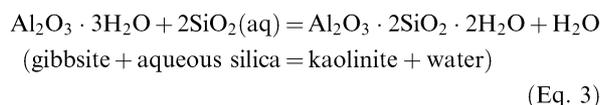

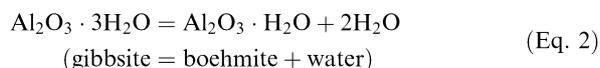

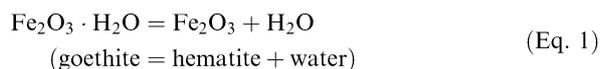

in the equatorial zone. The uplift of Andes and of the East-African Rift makes the climate very humid on the ancient quartz-sand dune deposits, so that gibbsitic Podzols develop in the Rio Negro and Zaire basins.

Because of the continental drift and changes in the global climate, almost all the old lateritic profiles are polygenic. Laterites by their diversity remain excellent indicators of paleoclimatic successions all over Australia, South-east Asia, Africa, Brazil, and even the United States and Europe.

Hydration-dehydration, key to laterite stability and transformations

For many years, mineralogical criteria have served as a base of soil classifications and interpretations of the leaching dynamics of cations and silica, responsible for the variety of observed soils. The hydroclimatic parameters P (rainfall) and D (drainage) as well as the P/D ratio (overall concentration factor of the weathering solutions submitted to evaporation, $E = P - D$) regulate pH and silica activity, $[\text{SiO}_2]$, in waters draining the profiles. However two other parameters: T (temperature) and $[\text{H}_2\text{O}]$ (activity of water, defined by the relative humidity of the air) are essential to control hydration-dehydration reactions occurring within the superficial horizons, and having both petrographic and climatic significance.

The equilibrium reactions among laterite minerals (formulae written, to simplify, as a sum of oxides) are the following:

Compared to gibbsite and goethite, which are hydrated minerals, hematite and boehmite are simply dehydrated, while kaolinite and smectites are dehydrated but silicated mineral phases. Hydration is favored in humid and cool climates in which $[\text{H}_2\text{O}]$ is elevated and $[\text{SiO}_2]$ lowered. Excretions of gibbsite and goethite are observed in bauxites and latosols where ferricrete dismantles under wetter and cooler climates. In contrast, dehydration is favored under dry and hot climates, where $[\text{H}_2\text{O}]$ is lowered and $[\text{SiO}_2]$ elevated. Concretions of hematite and kaolinite, insuring the hardening of ferricretes, and concretions of boehmite and hematite are characteristic of the transformation of orthobauxites into metabauxites under dryer and warmer climates.

Thus, beside temperature and the activity of aqueous silica in solution, which controls the reactions of silication-desilication, temperature and the activity of water also controlled the reactions of hydration-dehydration, and finally the hardening

and the dismantling conditions of the lateritic mantle, through the last 150 million years of continental drift.

LEPISPHERES

Lepispheres (from the Greek, meaning “spheres of blades”) are 3-micron to 20-micron-diameter rosettes of authigenic silica (SiO_2) formed during low-temperature diagenesis (Figure L5). Coined by Wise and Kelts (1972) as a term to describe a secondary siliceous cement viewed by light and scanning electron microscopy in an Oligocene deep-sea chalk, lepispheres are now regarded as morphologic expressions of the incipient mineral phase in the formation of deep-sea chert (Wise *et al.*, 1992). As such, they form in a variety of deep- to shallow-marine settings where precursor materials of amorphous silica such siliceous microfossil tests and volcanic glass are present. The unstable amorphous silica (opal-A of Jones and Signet, 1971) is converted to lepispheres (opal-CT) by a zero-order dissolution–diffusion–reprecipitation reaction. The metastable lepispheres may eventually convert to the more stable mineral phase, quartz (opal-C). In rock terms, the

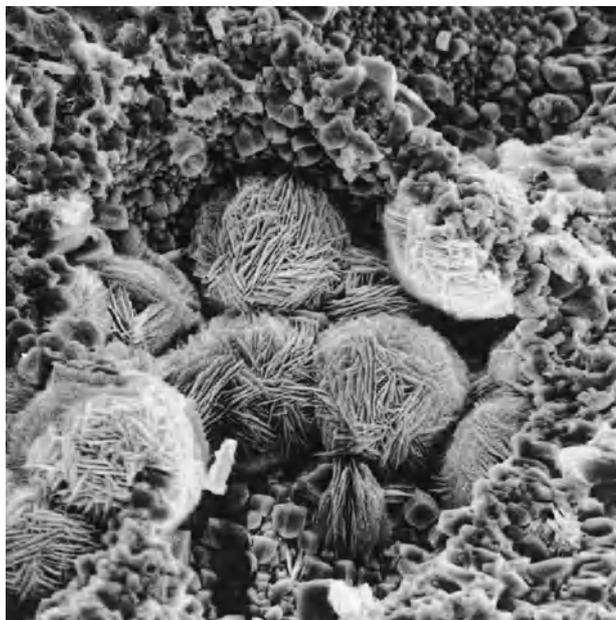

Figure L5 Cluster of opal-CT lepispheres filling a recrystallized foraminiferal test chamber in a partially silicified deep-sea chalk (scanning electron micrograph from Wise and Weaver, 1974, figure 5a, 1600X).

lepispheres may coalesce to form porcelanite, the intermediate phase in the formation of true quartz chert from a siliceous precursor material.

Opal-CT lepispheres are distinguished by a somewhat broad X-ray diffraction pattern centered about a strong cristobalite peak with a minor peak between 4.25Å and 4.30Å (Wise *et al.*, 1992, figure 1). Their mineralogy is best described as an unidimensionally disordered structure of low cristobalite with low tridymite domains (Florke *et al.*, 1976). In the light microscope, lepispheres are extinct under crossed nicols (due to the pseudoisotropic nature of the mineral), although the many fine blades diffract nonpolarized light sufficiently to produce an apparent (but not real) high refringence.

Lepispheres have been reproduced in laboratory experiments where wet diatomaceous sediment has been subjected to moderately high temperatures for a number of months (Kastner *et al.*, 1977). Nucleation of lepispheres is favored by the presence of carbonate (such as calcareous microfossils), magnesium (as is found in ordinary seawater), and high concentrations of dissolved silica in the pore fluids. Because siliceous microfossils such as diatoms have a large surface area, their dissolution proceeds rapidly, quickly bringing the pore fluid concentration of silica above the equilibrium solubility of opal-CT. Because opal-CT precipitates at a silica concentration well below the equilibrium solubility of opal-A, however, the growth of the lepispheres drives the reaction by constantly drawing silica from the pore fluids, causing further dissolution of the parent material until the supply is virtually exhausted.

Although no gel or colloidal phase has ever been observed in the formation of lepispheres, such phases have been detected by high-resolution transmission microscopy in the formation of some zeolites. Whether or not such colloidal phases exist in the formation of lepispheres is a subject for future research.

A survey of non-marine environments in which they might form would also be in order.

LIQUEFACTION AND FLUIDIZATION

Liquefaction is a process by which a liquid saturated soil loses its solid characteristics and for a short time acts like a viscous fluid. The most dramatic examples are observed during earthquakes. Buildings will then sink or fall over as their foundations are no longer supported; pipes and buried tanks rise to the surface buoyed up by the liquefied soil; buried utility lines may rupture; ground becomes displaced and slopes fail; sand-boils, the remnant of geyser-like upwelling of the liquefied material, cover the surface. Despite these dramatic effects, there are sometimes beneficial aspects to fluidization. The liquefied soils cannot transmit the earthquake's elastic waves and as result protect buildings from damage. There are many examples of buildings that, while they may have sunk slightly, survived the earthquake because the soil around them liquefied.

Two conditions are required for soil liquefaction. The first is that the soil be saturated. This means that the entire interstitial pore space between the particles is filled with liquid. Such is the condition of soils below the water table and liquefaction is a particular problem in areas with high water tables. The second condition is that the soil must be loosely packed or *under-consolidated*. When sheared, an under-consolidated soil will contract or reduce the pore space between particles.

(Conversely an *over-consolidated* soil will expand, increasing the pore space.) When saturated the pore space is filled with a nearly incompressible liquid so that reducing the pore space requires forcing out the liquid. In a porous material the liquid flowrate is proportional to the pressure gradient *via* Darcy's law. The only place for the liquid to go is the surface so that forcing the fluid from the shrinking pore space requires very large fluid pressures to push the liquid toward the low pressure at the ground surface. Quickly the pressure can rise to the weight of the overburdening soil, (which is the maximum value to which the pressure can rise), at which point the entire weight is supported by the fluid pressure and the fluid dominates the behavior of the particle/liquid mixture.

The process of liquefaction can be summarized as follows. Shaking by the earthquake causes the saturated soil to compact. To do so, it builds up pore pressure to force out the interstitial liquid. The pressure builds until the liquid supports the entire weight of the overburden. This leaves no pressure on the interparticle contacts which allows the particles to slip freely. The soil then behaves as a viscous fluid. This continues until enough liquid has been driven out of the pore space to allow the particles to come back into contact and again support the applied loads elastically. Following a liquefaction event, the surface of the ground is often covered with puddles of the water driven out of the pore space.

The ground under critical structures, is often compacted to an over-consolidated state in order to prevent liquefaction. Generally over-consolidated soils are stronger than under consolidated soils, and they are less likely to shear during an earthquake. But even if the earthquake manages to shear an over-consolidated soil, the soil would expand, not contract. In this case nearly the opposite of liquefaction occurs. To expand the soil, liquid must be sucked into the additional pore space. This requires a low liquid pressure, so that during this period, more weight is supported by the particle contacts which actually strengthens the soil. But this exercise is often futile if the surrounding soil is left in an under-consolidated state. When an earthquake occurs, the surrounding soil will liquefy causing a pore pressure rise that is initially confined locally. However the pore pressure will quickly diffuse into the surrounding unliquefied soil including the material that was purposely over-consolidated. Thus, the over-consolidated material can still be put into a weakened state which may result in damage to overlying structures.

The large viscosity of a liquefied soil arises from two sources. First of all, when the bulk material is sheared, the fluid shears only within the small spaces between particles. In this way the actual shear rate experienced by the actual fluid is many times larger than that experienced by the material as a whole and results in a proportionally larger viscosity. But the largest contribution to the apparent viscosity will come from the internal momentum transport due particle collisions which results in apparent viscosities that are many orders of magnitude larger than those for the pore fluid alone. Liquefaction also causes an increase in the apparent density. The fluid/solid mixture will behave as a single fluid with a density equal to that of the mixture density which may be several times that of the pore fluid alone. In such a situation, light rocks that would sink in the pore fluid alone, may rise to the surface of the liquefied material.

Fluidization is a similar phenomenon. A fluidized bed is a common device used in chemical processing (in fact, the catalytic crackers used in petroleum processing are fluidized

beds). These blow fluid up through a bed of solid particles until the pressure drop across the bed equals the weight of the bed. Then as for liquefaction, the particles are completely supported by the fluid and, with no pressure on the particle contact points, behave much like a fluid. Heavy objects placed on fluidized beds will sink while lighter objects rise to the surface and bubbles that are strikingly similar to gas bubbles in a liquid, form within the bed, rise and break on the surface.

Similar phenomena can be observed in geological systems whenever there is an upwelling of fluid through a particle bed. Even if the fluid flow is not large enough to completely fluidize the material, it may still weaken it to a large extent. A well-known example of geological fluidization is quicksand. Quicksand is composed of a fine sand through which there is an upwelling of water that makes the sand behave like a very viscous fluid into which people and animals can become trapped in much the same as in the very viscous asphalt of a tarpit. It has been speculated that fluidization is also responsible for the emplacement of pyroclastic flows. These may be fluidized by the outgassing of recently released volcanic material or by air entrained by the motion of the flow. As the fluidized material behaves as if it has the large density of solid, lighter materials are buoyed to the surface while heavier materials sink. This explains why lighter materials such as pumice are found near the surface and heavier materials at the lower levels of the deposits.

LOAD STRUCTURES

This name is most appropriately given to a sub-class of syndepositional to postdepositional, soft-sediment deformation structures which result from the partial to complete inversion of one or more pairs of discrete layers of granular sediment, the uppermost of which in each pair, in some cases deforming while continuing to be deposited, arguably had the greater bulk density (Allen, 1982). Load structures therefore record the action of essentially vertical forces, although the simultaneous influence of a body force related to a depositional slope is not excluded. They arise almost exclusively in aqueous environments and represent a movement within the sediment toward a state of minimum potential energy. Convolute stratification is excluded from the sub-class because these structures are restricted to single layers in which there may have been a continuous, positive gradient of bulk density, evidence for which may have survived.

Like soft-sediment deformation structures generally, the production of load structures calls for the operation of trigger mechanisms, deformation mechanisms and driving mechanisms (Allen, 1982; Owen, 1987, 1995; Harris *et al.*, 2000; Jones and Omoto, 2000). There is a predisposition or potential for their formation if one or more of a number of prior conditions are met in the sediments to be affected. Each of the layers involved should have experienced little or no compaction and be fully water-saturated. In each layer the pore-fluid pressure should be high and the grain fabric in or tending toward a metastable state, a circumstance favored by rapidity of deposition and a high water-content. The vertical arrangement should see layers of high bulk density overlying those of lower density; it is well-known that muds, with a comparatively high water content on deposition, have a significantly lower bulk density than sands, which are deposited with a closer packing. The chief trigger mechanisms are: (1) a sufficiently powerful earthquake; (2) aseismic events in the region which raise pore-fluid pressures in confined sedimentary layers; (3) the sudden appearance of an agent from which coarse sediment is very rapidly deposited on a finer substrate (e.g., density currents in lakes/ oceans, floods due to ice dam-breaks); (4) changes in hydrostatic pressure and bed shear-stress related to the passage of progressive water waves or tsunami; (5) changes in pressure and shear stress on a bed resulting from the advection of large-scale turbulence; and (6) the seasonal melting of layered alluvium in periglacial regions, remembering that water expands on freezing. These triggers act by rendering the sediments in the layers, or parts of the layers, fluid-like for a period. Such a state can persist, however, only for so long as the grains have failed to resettle. The deformation mechanisms are two-fold, as in soft-sediment deformation generally. Layers that have become effectively viscous respond to the driving forces by folding, occasionally on more than one wavelength where contrasting, minor layers are involved; those that are effectively brittle fail by faulting. Almost all load structures exhibit evidence of folding, but some show minor faulting as well. Recalling that water-saturated sediments can behave as complex non-Newtonian fluids, the occurrence of faults may record the rapid development of extreme strains during deformation. Alternatively, it may be evidence that the grains had resettled sufficiently to make the sediment again solid-like. Driving forces have already been touched on. As their action is essentially vertical, they should be expressed in load structures by geometrical patterns symmetrical about essentially vertical axes. Systematic departures from such symmetry may be expected only when a directed body force, as on a depositional slope, also came into play.

In essence, the formation of load structures reduces to the problem of the instability in the field of gravity of layered materials capable of behaving as non-Newtonian fluids for a limited period. Theoretical and experimental work on simple systems of this kind (Ramberg, 1964, 1968, 1981) suggests that the scale and geometrical character of load structures is a function largely of the scale of the layers made temporarily fluid-like and the rheological contrast between them, controlling the strength of the chief driving force and the rate of deformation. A general limit on the extent of strain is imposed by the duration of the fluid-like state. In particular, the scale of the deformation increases with the thickness of the affected layers. Thus the spatial patterns or wavelengths discernible in beds showing load structures can range in scale from millimeters and centimeters to tens or hundreds of meters, as

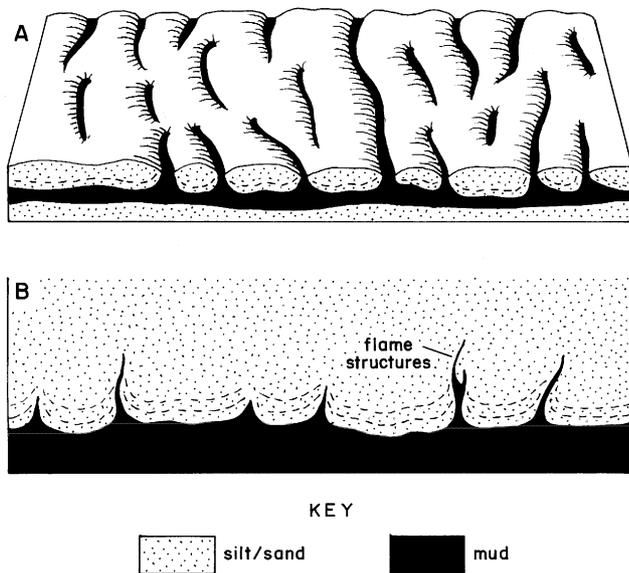

Figure L6 Schematic representations of (A) wrinkle marks, in vertical section and plan view, and (B) load casts on the underside of a sandstone bed, in vertical section.

the affected layers increase in thickness. For this reason, and because of the range of possible triggers, the occurrence of load structures has few restrictions related to depositional environment.

Amongst the smallest of load structures are the *wrinkle marks* widely found in the estuarine intertidal zone (Allen, 1984). These seem to be triggered by the action of waves as the tide retreats across a surface on which a pair of tidal laminae had just been deposited. Typically, the pair is a few millimeters thick, involving a lower, clayey-silty lamina which is overlain by one that is silty-sandy. During loading, the clayey-silty sediment penetrates upward through the coarser lamina at intervals of the order of 10 mm to define in plan a mosaic of roughly equant to elongated, silty-sandy pods (Figure L6(A)). A marked elongation parallel with the contours is observed where deposition had occurred on a significant slope and a subhorizontal body-force also came into play. Slope-parallel microfaults may in such cases slightly displace the pods relative to each other.

Load casts (Figure L6(B)) are probably the commonest and most widespread form of load structure, occurring in fluvial, lacustrine, deltaic, shallow-marine and deep-water environments (Allen, 1982). In deep water, turbidity currents suddenly emplace sand beds centimeters to meters thick upon substrates of soft mud. Either at the time of deposition or shortly afterward, the lower part of the sand sinks down some way into the mud, which rises upward for some distance between the pockets of sand as a series of what have been called flame structures. A freshet spreading across an already-drowned river floodplain on which mud has settled, or a river flood entering a muddy lake, can have a similar effect. Where deformation affects the whole thickness of the coarse layer, breaking it up into discrete portions, or where multiple coarse layers are so affected, the structures called pseudo-nodules (Macar, 1948) and ball-and-pillow (Cooper, 1943; Kuenen,

1948) can arise, as in many near-shore deltaic and shallow-marine environments. In some varieties of load cast, especially where trains of isolated sand ripples or small dunes had moved across a surface of mud, the presence internally of truncated laminae shows that deformation proceeded episodically. In this case the magnitude of the driving force varies spatially, being greatest beneath the crests of the bedforms. The largest load structures of all are those expressed most dramatically by huge mudlumps or mud diapirs, as seen in the rapidly advancing Mississippi birdsfoot delta, where sandy mouth bars are advancing across shallow-marine, largely under-consolidated muds at rates of tens of meters annually (Morgan and Andersen, 1961).

Load structures are widely observed proof that sediments freshly deposited in many kinds of aqueous environment can be temporarily changed from solid-like to fluid if certain preconditions are met and if a trigger mechanism is activated. They provide no information on current directions but can provide evidence of depositional slopes.

LUNAR SEDIMENTS

Introduction

The surface and surficial deposits on the Moon are radically different from Earth's. The Moon is completely dry and does not have an atmosphere; it is devoid of an internally driven magnetic field and plate tectonics is absent; large and small impacts through time have produced a thick regolith, and sediments so produced are transported ballistically. Regolith may be shock-indurated by fresh impacts, or may be buried under fresh ejecta that may be hot and may sinter unconsolidated grains together, to produce regolith breccias. All lunar samples are from the regolith; and, all remote sensing signals (*albedo*, *UV-Vis-IR reflectance* [of sunlight], *natural γ -ray*, and *X-ray fluorescence* [by solar X-rays] *spectra*) of the Moon are from its regolith. Most of the signals come from the uppermost 0.5 μm layer, that is, almost entirely from the dusty veneer of the Moon. Because the composition of the finest fractions of lunar soils is different from the bulk composition of any lunar soil, it is essential that all calibration be corrected back to the compositions of bulk soils. The remote sensing techniques and their lunar calibrations are used to explore all atmosphere-free rocky bodies in the solar system; hence the extreme importance of precise and accurate characterization of lunar soils in planetary exploration.

In the initial days of lunar sample return by Apollo missions, the sub-centimeter fraction of the samples was informally termed "fines" and then "lunar soil" came in vogue. In lunar science literature and in the community, "soil" is now entrenched with an informal size connotation; the word has no significance *vis a vis* its use for Earth materials in agricultural, engineering, geological, and hydrological sciences. In general, lunar soils are gray in color and consist of angular and irregularly shaped grains with a mean size of about 60 μm . Grains cemented with fresh glass produced by micrometeorite impacts on lunar soils produce a type of constructional particle called *agglutinate* (a term adapted from terrestrial pyroclastic vocabulary). Except for a minor (<2 percent) meteoritic component, lunar soil composition varies between anorthositic and basaltic. McKay *et al.* (1991) summarize lunar soil data gathered up to about 1990.

Petrographic composition

Two principal terrains configure the lunar surface. One is a high mountainous terrain (*highlands*) consisting of light colored anorthositic rocks that are 4.4 billion years or older in age. Flat lowlands, essentially impact basins (*mare*) filled with dark Fe-rich basalt flows ranging in age from about 3 billion years to 4 billion years in age, comprise the other. Impacts have mechanically disintegrated these rocks and have also indurated some of the clasts together. The regolith on the surfaces of these units generally reflects the composition and the color of the rock units below although there has been some mixing of distant impact ejecta in all local soils. The majority of lunar soils consist of five major grain types: mineral fragments (10–40 percent), igneous and metamorphic rock fragments (5–20 percent), breccias with various degrees of coherence (10–40 percent), and agglutinates (20–50 percent). Glass spherules of either impact or volcanic fire fountain origin make up a minor component (usually <5 percent) except in a

few unusual soils and in some restricted size ranges. Genetically, lunar soil components may also be classified into two groups: bedrock derived and regolith derived. Agglutinates, regolith breccias, and glass spherules are regolith-derived components.

Orange soil

An orange layer in the regolith near the Shorty Crater in Mare Tranquillitatis consists of more than 90 percent high-titanium (up to 16 percent TiO_2) glass beads ranging in color from orange and red to black in hand specimen. At the bottom of a nearby drill core the soils consist of nearly 100 percent black beads in which skeletal crystals of olivine and ilmenite abound. These beads are products of volcanic fire fountaining with remnants of condensed volcanic gases on their surface. Beads of high magnesium iron-poor green volcanic glass are also found in significant amounts a few soils from the Apennine Mountains but not in layers.

Chemical composition

Chemical compositions of lunar soils also range from basaltic to anorthositic. Mixing of mare and highland components in different proportions give rise to diverse soil compositions. Differential comminution and differential agglutination of lunar soils have rendered different size fractions to be compositionally different from each other. The extent of mare ejecta mixing with highland soils and vice versa can be estimated better from the chemical compositions of soils than from modal compositions, partly because a few minor and trace element concentrations are characteristic of certain pristine igneous rocks. Average compositions (wt percent) of a few typical mare and highland soils are given below.

	Mare	Highland
SiO_2	40.6	45.0
TiO_2	8.4	0.54
Al_2O_3	12.0	27.3
Cr_2O_3	0.45	0.33
FeO	16.7	5.1
MnO	0.23	0.30
MgO	9.9	5.7
CaO	10.9	15.7
Na_2O	0.16	0.46
K_2O	0.14	0.17

Crustal composition of the moon

With no bedrock sampled so far, direct evidence of rock types in the crust of the Moon comes from regolith samples. Rock fragments from boulder sizes to sand sizes have been analyzed for chemical and mineralogic compositions, crystal chemistry, isotopic systematics, radiometric age dating, experimental petrology, and nuclear and ferromagnetic resonance measurements, to name a few. It is a tale of incredible provenance sleuthing. The crust of the Moon is inferred to be made mostly of ferroan and gabbroic anorthosites, norites enriched in K, REE, P, U, and Th, various kinds of Fe-rich (~20 percent FeO) basalts that have large ranges of K_2O (0.06–0.36 percent) and TiO_2 (0.4–13.0 percent), and a low-Fe basalt (~10 percent

FeO) with higher concentrations of K₂O (~0.5 percent or more), P (~2500 µg/g), and REE.

Grain size

Lunar regolith samples are not plentiful. NASA allocated approximately 0.5 g or 0.25 g of the submillimeter fraction of lunar soils for determining their grain size distribution. Sieving with minimal loss required more than 20 hours spanned in about 4 to 5 workdays per sample. The results were then combined with those of the subcentimeter fraction of the rather hastily sieved lunar regolith at NASA's curatorial facilities (Graf, 1993). The mean grain size (M_Z) of lunar soils range between 3ϕ and 4ϕ (125–62.5 µm) and their inclusive graphic sorting (σ_{IG}) generally vary between 2ϕ and 3.0ϕ , that is, they are poorly sorted by terrestrial standards. Many soils are coarsely skewed; much of the fine dust is locked up in agglutinates.

Vertical profile

Several trenches, drive tubes, and drill cores have penetrated and sampled the lunar regolith up to a depth of about 3 m. Understandably none has reached bedrock. Each section of the regolith shows evidence of layering, by way of color (shades of gray), grain size, chemical and mineralogical composition, and maturity. However, layers in closely spaced drill cores and in adjacent trenches (within a few meters) do not correlate indicating that impacts have moved the regolith considerably. Nearly all vertical profiles of soils show that the topmost layer is more mature (see below for the concept) than those below.

Origin and evolution

Large meteorite impacts up to about 1 b.y. ago have produced most of the regolith of the Moon. Impacts by micrometeorites (<1 mm) have continuously comminuted the regolith and are largely responsible for the production of lunar soils. Micro-meteoritic impacts on lunar soils melt a miniscule amount, mostly the finest dust, at the point of impact. The melt incorporates soil grains as clasts and quenches quickly to produce agglutinates, that is, glass bonded aggregates. Micro-meteoritic impacts affect only the topmost millimeters of the lunar regolith. With continued exposure, that is, increasing maturity, the soil in this layer becomes finer and finer simultaneously producing agglutinates that are larger. Over time the rate of comminution and agglutination becomes

equal. In this steady state, continued exposure of lunar soils at the surface increases the abundance of agglutinates but does not reduce the mean grain size any more. However, slightly larger impacts excavate material from below, which may not be as mature, and mix the two together. Such events disturb the steady state. Most lunar soils presumably are not in a steady state but may be close to one.

Because the Moon does not have any magnetosphere or any atmosphere, energetic particles of the solar wind freely bombard the lunar surface and implant solar wind elements (SWE), especially hydrogen ions, in the outer rinds (~150 nm) of exposed soil grains. Abundance of SWE in lunar soils increases with maturity. Apart from melting a small fraction of lunar soil grains, micrometeoritic impacts also vaporize a part of the target and much of itself. Elemental dissociation takes place in the high temperature vapor from which nanophase Fe⁰ metal condenses and is deposited on surfaces of soil grains. Additionally, the melt itself may undergo reduction reactions with implanted hydrogen and produce nanophase Fe⁰ globules that are strewn in agglutinitic glass. The two processes not only darken lunar soils but also increase the abundance of nanophase Fe⁰ with increasing maturity (Hapke, 2001; McKay *et al.*, 1991).

A robust correlation between the abundance of agglutinates, SWE, nanophase Fe⁰ (measured by ferromagnetic resonance), inverse grain size, and to some extent with soil color strongly supports the inferred processes of lunar soil evolution.

Sediments Produced by Impact

M

MAGADIITE

Magadiite is a hydrous sodium silicate mineral that was discovered by Hans Eugster (1967) in late Pleistocene lake sediments at Lake Magadi in the southern Kenya Rift Valley. Although rare, magadiite is a well-known precursor of non-marine chert. Quartzose "Magadi-type cherts", which have formed by the diagenetic alteration of magadiite, have been reported from rocks of Precambrian to Holocene age. Magadi-type chert is generally considered diagnostic of saline, alkaline lacustrine environments.

Magadiite [$\text{NaSi}_7\text{O}_{13}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$] and the related sodium silicates, kenyaite $\text{Na}_2\text{Si}_{22}\text{O}_{41}(\text{OH})_8 \cdot 6\text{H}_2\text{O}$, makatite [$\text{Na}_2\text{Si}_4\text{O}_8(\text{OH})_2 \cdot 4\text{H}_2\text{O}$], and kanemite [$\text{NaHSi}_2\text{O}_4(\text{OH})_2 \cdot 2\text{H}_2\text{O}$], form mainly in hypersaline, sodium carbonate-rich brines that have a pH > 9 and consequently have high concentrations of dissolved silica (up to 2,700 ppm). Sodium silicate minerals are present at Lakes Magadi and Bogoria in Kenya, Lake Chad, and in some alkaline lakes in California and Oregon. When fresh, magadiite is white, soft, puttylike, and easily deformable, but it dehydrates rapidly on exposure to air, and hardens irreversibly to form a fine chalky aggregate. At high magnification, magadiite typically displays minute aggregates of thin platy monoclinic crystals (<10 μm) that may be equant or have a spherulitic habit (Icole and Perinet, 1984; Sebag *et al.*, 2001).

At Lake Magadi, magadiite form beds a few decimeters thick, lenses, and concretions with irregular protrusions, and veins that transect bedding in zeolitic lacustrine silts (Figure M1). Elsewhere, magadiite also fills cracks in large (meter-scale) polygons (e.g., Alkali Lake, Oregon), or replaces plants (Sebag *et al.*, 2001).

Formation of magadiite

Two general pathways have been proposed to explain the formation of magadiite in silica-rich NaCO_3 brines: a decrease in pH and evaporative concentration. At Magadi,

subhorizontal beds have been explained by seasonal precipitation in a stratified saline, alkaline lake. Magadiite has been inferred to precipitate when dilute inflow waters flow across a dense, sodium carbonate brine rich in dissolved silica and lower the pH at the fluid interface (chemocline). At Lake Chad and in some American examples, magadiite may have precipitated by evaporative concentration or by capillary evaporation of saline, alkaline brines at a shallow subsurface water table. Other inferred mechanisms include subsurface mixing of dilute and saline, alkaline groundwaters, a reduction in pH of an alkaline brine resulting from an influx of biogenic or geothermally sourced CO_2 , and precipitation from interstitial brines. Different sodium silicate minerals may form according to the concentrations of Na and SiO_2 in the brine.

Conversion to chert

At Magadi, beds of magadiite pass laterally into quartzose cherts confirming their genetic relationship. Magadi-type cherts form beds, plates, and lobate nodules, commonly with features indicating soft-sediment deformation upon compaction. Reticulate fine cracks, salt crystal pseudomorphs or molds, and relict spherulites are also common.

The conversion of magadiite to quartz is rapid and involves a loss of sodium, water, and volume. Leaching by percolating meteoric water, dehydration, and spontaneous recrystallization due to sorption of silica by clays, have been proposed. Intermediate diagenetic products, including kenyaite, amorphous silica and moganite, may form during the transformation (Icole and Perinet, 1984; Sheppard and Gude, 1986). Both magadiite and the associated cherts have a distinctive trace element signature unlike other cherts.

Although the genetic models are well established and magadiite is easily synthesized in the laboratory, few natural examples of modern precipitation have been documented. Recently Behr (2002) has shown that many of the cherts at Lake Magadi may have been precipitated as amorphous silica by bacteria and may not have had a sodium silicate precursor. Similarly, many ancient continental cherts resemble Magadi-type cherts in morphology and fabric, but are unlikely to have had a magadiite precursor. The discovery of magadiite in

Figure M1 *In situ* magadiite in the High Magadi Beds at the southern end of Lake Magadi, Kenya. Soft white masses and thin streaky lenses of magadiite are present in darker lacustrine silts that were deposited when Lake Magadi was a deeper, fresher, and probably stratified lake.

cavities in volcanic rocks in Namibia and Quebec, and in hot springs deposits at Lake Bogoria in Kenya, shows that it is not restricted to lacustrine environments. Much remains to be learned about natural sodium silicates and their diagenesis.

Siliceous Sediments

MAGNETIC PROPERTIES OF SEDIMENTS

Introduction—classes of magnetism

Sediments are aggregates of minerals, including silicates, carbonates and trace amounts of various oxides and sulfides. The magnetic properties of sediments can therefore be traced

back to the magnetic properties of their mineralogical constituents which obviously may vary with sediment type, provenance area, and depositional setting. Magnetic properties of any material are directly related to its electronic structure, notably the presence or absence of uncompensated electron spins, and the presence or absence of collective spin behavior. Any moving electric charge creates a magnetic field; thus also electrons that orbit atomic nuclei and spin around their own axes, are microscopic magnets. The magnetic moment of an individual electron spin is termed the Bohr magneton.

The basic classes of magnetism are diamagnetism, paramagnetism and ferromagnetism. If there are no uncompensated electron spins, a material is *diamagnetic*. This situation occurs for example in calcite (CaCO_3), dolomite ($\text{CaMg}(\text{CO}_3)_2$), quartz (SiO_2), or forsterite (MgSiO_3). The *susceptibility* is the magnetic moment of a substance measured in an applied magnetic field divided by the applied field. Diamagnetic minerals have a small and negative susceptibility (Table M1), that is, the direction of the sample's magnetic moments opposes that of the applied field. Diamagnetism is independent of temperature.

If there are uncompensated electron spins in a crystal structure that behave independently of each other, the material is *paramagnetic*. This occurs for example in silicates and carbonates that contain iron or manganese (or some other transition elements). Biotite and clay minerals like illite often contain at least some Fe, and are therefore paramagnetic (Table M1). Also ankerite $\text{Ca}(\text{Mg, Fe})\text{CO}_3$, is paramagnetic because the magnetic moment of uncompensated electron spins is much larger than the diamagnetic moment due to the orbit of the electrons around their respective atomic nuclei. Paramagnetic minerals have a small and positive susceptibility because magnetic moments tend to align to an applied field. The susceptibility of paramagnets is small because thermal jostling randomizes the electron spins. Paramagnetism is inversely proportional to (absolute) temperature.

Ferromagnetism “sensu lato” and permanent or remanent magnetization are restricted to minerals that have collective spin behavior. In certain crystalline solids that contain transitional elements in large amounts, the atomic nuclei are sufficiently close to each other to have the orbits of the outermost electrons overlapping with each other. In this situation, the uncompensated spins may line up and their individual magnetic moments can be added to get macroscopic magnetism. This situation can occur in metals, oxides and sulfides. The corresponding minerals are referred to as magnetic minerals. In nature, the transition element of most interest is iron. Various types of collective spin behavior are distinguished (Figure M2). Ferro- and ferrimagnetic material have a very high susceptibility while antiferromagnets have a susceptibility comparable to paramagnets (*cf.* Table M1). The field and temperature dependence of the susceptibility is complex. At a certain temperature—named the *Curie temperature*, characteristic of the material—thermal jostling becomes stronger than the collective spin interaction changing the ferromagnetic structure into a paramagnetic structure. On cooling through the Curie temperature, the ferromagnetic structure is restored.

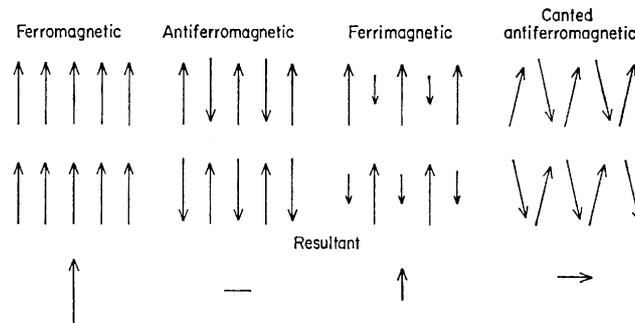

Induced and remanent magnetization

Diamagnetic and paramagnetic moments are “induced” magnetic moments: they only exist in an applied magnetic field. The magnetic moment is proportional to the applied

Table M1 Typical magnetic properties of some natural minerals

	T_C	M_s	χ	ARM	IRM
Fe_3O_4 (soft)	578	92	560	18	9
Fe_3O_4 (hard)	578	92	400	110	22

quartz			-0.0062		
$CaCO_3$			-0.0048		

soft = magnetically soft, i.e., multidomain; hard = magnetically hard, i.e., single domain. T_C = Curie temperature ($^{\circ}C$). Values for M_s , χ , ARM and IRM are referring to values at room temperature. M_s = saturation magnetization (Am^2kg^{-1}); χ = low-field susceptibility ($10^{-6}m^3kg^{-1}$); ARM = anhysteretic remanent magnetization grown in a 100 mT peak alternating field with a 100 μT direct current bias field ($10^{-3}Am^2kg^{-1}$); IRM = isothermal remanent magnetization acquired in a 1T direct current field (Am^2kg^{-1}). * : greigite decomposes before its Curie temperature is reached. For paramagnets and diamagnets a few examples are given.

**Figure M2** Schematized collective spin structures. Resultant indicates the resulting macroscopic magnetism.

field. The proportionality constant is the susceptibility (χ , also χ_{in} or κ), a material property. In low applied fields it is named the low-field or initial susceptibility. The susceptibility of individual diamagnetic and paramagnetic minerals add linearly to yield an overall susceptibility. For sediments which contain only trace amounts of magnetic minerals, the same holds for the low-field susceptibility due to ferromagnetism. The measured susceptibility is therefore a composite signal. It may be equated to the concentration of ferrimagnetic spinel, when its concentration is $> \sim 1\%$ χ is frequently used as a proxy for the magnetic mineral concentration, because χ variations due to grain size are comparatively small. In some sedimentary settings the *anisotropy of magnetic susceptibility* yields information for example concerning bottom currents, whereas in lithified sediments it may yield information on deformation patterns (e.g., Tarling and Hrouda, 1993). As a rule, comparatively slowly accumulating marine sediments are bioturbated and the sedimentary anisotropy information is lost.

Remanent magnetic moments remain in a zero field. Depending on the size of the magnetic particles, remanent magnetizations—once acquired—may last for geological times. This forms the foundation for the paleomagnetic signal recorded in rocks (e.g., Butler, 1992). When the magnetization of magnetic minerals is measured as function of the applied

field, a so-called hysteresis loop (Figure M3) results. It requires energy to change the magnetic state of an ensemble of magnetic particles. Therefore, the response of the sample lags the field change, it shows hysteresis. The area contained in the loop represents the energy of the magnetic particles in the sample. The shape of the loop depends on the grain size of the magnetic particles, while the values for the coercive force (Table M1, M2) can be related to magnetic mineralogy. The concentration can be inferred from the saturation magnetization and saturation remanence. Thus, these loops contain information concerning the grain size, magnetic mineralogy, and the concentration of magnetic particles in a sample. Hysteresis parameters and other mineral-magnetic parameters yield information specifically concerning the magnetic minerals present in a sample. They are useful proxy parameters for (paleo)climate and (paleo)environmental processes (e.g., Maher and Thompson, 1999).

Natural magnetic minerals and mineral-magnetic parameters

By far the most important terrestrial magnetic mineral is magnetite (Fe_3O_4), one endmember of the titanomagnetite solid solution series. It may occur in trace amounts in virtually

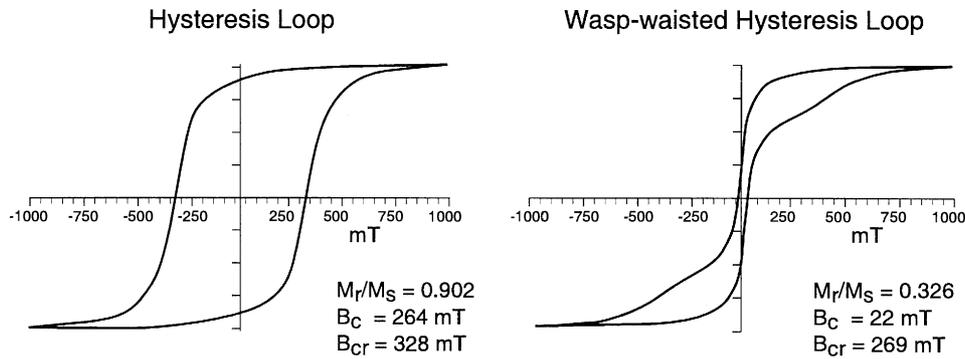

Figure M3 Examples of hysteresis loops. Left panel: typical single domain loop characterized by a high M_r/M_s ratio. Right panel: so-called wasp-waisted loop (narrow central part and wider loops in higher fields before closure in highest fields) generated by two distinct coercivity fractions, due to a soft magnetite-like magnetic mineral and a much harder antiferromagnetic mineral.

Table M2 Acronyms and definitions of some mineral-magnetic parameters

M_s	saturation magnetization expressed per unit volume (Am^{-1}); σ_s when expressed per unit mass ($\text{Am}^2 \text{kg}^{-1}$).
M_r	remanent saturation magnetization per unit volume (Am^{-1}); σ_r when expressed per unit mass ($\text{Am}^2 \text{kg}^{-1}$).
B_c	coercive force (mT). The oppositely directed magnetic field strength required to reduce the magnetic moment of a sample (assemblage of grains) to zero after saturation, measured in that applied field.
B_{cr}	remanent coercive force (mT). The oppositely directed magnetic field strength required to reduce the remanent magnetic moment of a sample to zero after saturation. By its virtue of being a remanence, its measurement takes place in zero field.
χ_{in}	low-field or initial susceptibility, the magnetic moment of a sample measured in a low applied magnetic field divided by the field value (mass-specific units m^3kg^{-1} ; volume-specific units are dimensionless). Also χ or κ .
χ_{hf}	high-field susceptibility, the magnetic moment of a sample measured between two field-values higher than the fields needed to saturate the ferrimagnetic contribution to the magnetization. Also referred to as the paramagnetic susceptibility (units are the same as for χ_{in}).
ARM	Anhyseretic Remanent Magnetization (Am^2), acquired by the decay of an asymmetric alternating field (AF) from a peak value to zero (usually). In practice, AF demagnetization equipment is used, a small direct current (DC) bias field is imposed. ARM intensity is linear with the DC bias field for low concentrations of magnetic minerals to field values of $\sim 50 \mu\text{T}$ to $80 \mu\text{T}$ (i.e., to values comparable to the intensity of the geomagnetic field). σ_{ARM} : ARM intensity per unit mass ($\text{Am}^2 \text{kg}^{-1}$). Also κ_{ARM} .
χ_{ARM}	ARM intensity per unit volume divided by the value of the DC bias field (dimensionless SI units).
(S)IRM	(Saturation) Isothermal Remanent Magnetization. IRM is acquired by imposing a certain DC field to a sample at a constant temperature (usually room temperature), the maximum possible remanence value (after magnetic saturation of the sample) is termed SIRM, M_r , or M_{rs} .

any sediment or soil. Other natural magnetic minerals include hematite ($\alpha\text{Fe}_2\text{O}_3$), maghemite ($\gamma\text{Fe}_2\text{O}_3$), goethite (αFeOOH), and the sulfides greigite (Fe_3S_4) and pyrrhotite (Fe_7S_8). Pyrite (FeS_2), ubiquitous in anoxic sediments, is not magnetic.

Mineral-magnetic measurements involve determination of the field- and temperature-dependence of various types of induced and remanent magnetizations. The techniques are sensitive, require little sample preparation, are rapid, often grain-size indicative, and usually non-destructive. The magnetic properties describe bulk properties of the sample, so they are complementary to micro-analytical techniques that usually analyze only a fraction of a total sample. The field-dependent parameters offer most grain-size dependent information,

essential for a paleoclimatic and paleoenvironmental reconstruction. In addition they are comparatively easy acquired, thus suited for the processing of large numbers of samples.

Information concerning particle size can be gathered from magnetic measurements because the size of a particle is related to its magnetic domain structure. In very small grains ($< \sim 30 \text{ nm}$, all ranges refer to magnetite at room temperature) no stable domain structure can exist, these particles are termed superparamagnetic. Slightly larger equant particles ($\sim 30 - \sim 100 \text{ nm}$) are single domain, whereas particles larger than $\sim 10 \mu\text{m}$ are multidomain, they contain many magnetic domains separated by domain walls. The grain-size range between single domain and multidomain is termed

pseudo-single-domain. Single domain grains respond to a changing magnetic field by rotation of their magnetic moments, while multidomain grains basically respond by movement of domain walls, two processes that are characterized by a different field dependence. This very fact allows deduction of grain size from field-dependent measurements. The more commonly used mineral-magnetic parameters are summarized in Table M2.

For low concentrations (i.e., in the absence of magnetic interactions) mass-dependent parameters are linear with concentration at least to a first-order approximation which is applicable to the situation in sediments. By dividing two mass-dependent parameters, a concentration-independent variable is obtained which allows interpretation of grain-size trends. Field values, such as the coercivity parameters, are concentration-independent to a first-order approximation.

Large multidomain particles acquire comparatively low ARMs and IRMs. IRM, by its nature, is a much stronger remanence than ARM (Table M1). Single domain magnetite particles are particularly prone to acquire ARM, so the ARM/IRM ratio may be used to trace grain size if magnetite is magnetically the dominant mineral. Different coercivity fractions in a single sample may be quantified utilizing the IRM component analysis procedure that fits an optimal number of coercivity components to a measured IRM acquisition curve (Kruiver *et al.*, 2001).

Sediment magnetism

In sediments, the magnetic mineral suite is a mixture of particles with two main origins: detrital particles and particles that were formed *in situ*. The detrital particles are eroded and subsequently transported from a source area by eolian, riverine, lacustrine or marine processes (only in very slowly accumulating abyssal plain sediments cosmogenic particles may constitute a significant source). Iron oxides are chemically sufficiently stable during transport to survive, although the particles abrade and superficially oxidize. Iron sulfides do not survive transport conditions, they are formed in the sediment column at the depositional site.

In situ formed authigenic particles are a consequence of diagenetic processes. These processes may also change the detrital input to some extent. Biological factors often are important. Biomineralization is a widespread phenomenon; for example a major part of the global calcium carbonate mass is of biogenic origin. In virtually all sedimentary environments and water-logged soils, bacteria which use iron in their metabolism are known to occur. The bacteria may use iron as a terminal electron acceptor: magnetite is formed outside the cells (extracellular magnetite) as a consequence of its low solubility product. The crystals are very fine-grained and usually are poorly crystalline. Alternatively, other bacteria may produce chains of highly crystalline SD magnetite grains (magnetosomes) inside their cells; these are referred to as magnetotactic bacteria (e.g., Hesse and Stolz, 1999).

The distinction between authigenesis and biogenesis is arbitrary. Authigenesis refers to inorganic chemical, rather than biological processes. However, usually at least one of the reactants in an "inorganic" chemical reaction process is bacterially produced or mediated. The sulfide in the pyrite formation process, which usually has a profound impact on the assemblage of magnetic minerals in sediments, is produced by sulfate-reducing bacteria. The sulfate reacts with available

ferrous iron to form intermediate monosulfides, which usually react completely to form pyrite. Greigite and pyrrhotite have been reported as intermediate products in these reactions. Especially greigite is increasingly documented in a wide variety of (lake and marine) sediments (e.g., Snowball, 1997; Roberts *et al.*, 1996). The reaction pathway which leads to the formation of pyrrhotite, is not yet clearly established. Both sulfides may form authigenically in sediments. Greigite in particular is documented in a variety of lake sediments that are characterized by much lower sulfate contents than marine conditions. Sulfate reduction under anoxic conditions usually does not lead to the formation of pyrite, the final product in marine sediments. Instead greigite or pyrrhotite, intermediate products, often remain. The hysteresis properties are very similar to those of magnetite and thermal methods are often required to unambiguously diagnose greigite (and pyrrhotite) with magnetic means. Because greigite may occur in magnetotactic bacteria as well its occurrence can be used as a biomarker (Pósfai *et al.*, 1998).

From the many examples that show the usefulness of magnetic properties to document paleoclimate and paleoenvironmental processes two are shown here: (1) the influence of diagenetic processes due to cyclic redox conditions in sediments from the Mediterranean Sea; and (2) the observation of climate variability in the North Atlantic including Heinrich events. Noteworthy as well are the well-known loess-paleosol records from the Chinese Loess Plateau that have been shown to be a continuous recorder of paleoclimate throughout the Quaternary (e.g., Maher and Thompson, 1999) with the paleosols having higher magnetic susceptibility than the intercalating loess. Although it has been known for a long time that the paleosols are correlated to warmer and moister climatic periods, only recently a robust orbital chronology could be formulated for the loess/paleosol sequence (Heslop *et al.*, 2000).

The Mediterranean Sea

Apart from sulfide formation, the influence of diagenesis on the mineral-magnetic record can be substantial because iron through its two redox states is an important element in many diagenetic reactions, including biologically mediated ones. From the Miocene into the Quaternary many Mediterranean sediments are characterized by astronomically controlled sequences of anoxic and suboxic sediments (e.g., Hilgen, 1991). The dominant source of the original magnetic minerals is thought to be dust from the Sahara with minor riverine input depending on the location in the Mediterranean Sea. The role of biogenic magnetite in oxic sediment seems to be minor. Under anoxic conditions, layers enriched in organic material may be deposited, so-called sapropels. During sapropel deposition, below each sapropel there is a zone where the formerly existing magnetic minerals have been by and large reductively dissolved; the iron is precipitated as pyrite (Figure M4). When oxic conditions are restored in the water column these sapropels are (partially) reoxidized starting from their top parts. During this oxidative diagenesis, pyrite and other sulfides are oxidized; the iron precipitates amongst others as magnetic oxides in the zone of the sapropel that is slowly oxidizing away. Compared to "average" sediment, the zones straddling sapropels are thus characterized by low magnetic intensities below the visible sapropel and higher magnetic intensities in the zone directly above the sapropel. In

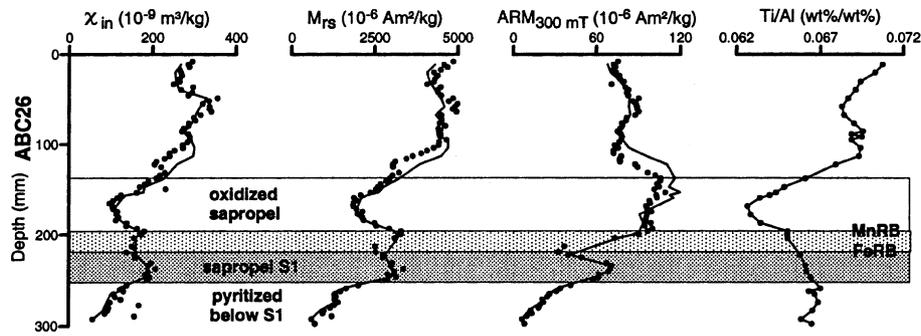

Figure M4 Susceptibility (χ_{in}), saturation remanence (M_{rs}), ARM acquired in 300 mT peak alternating field (ARM_{300mT}) and Ti/Al as a function of depth in box core ABC26 (lat 33°21'; lon 24°55'E) from the eastern Mediterranean. χ_{in} and M_{rs} follow the Ti/Al ratio that is a proxy for dust content. ARM is indicative of the precipitated magnetite in the oxidized sapropel. MnRB = manganese redox boundary; FeRB = iron redox boundary (after Passier *et al.*, 2001).

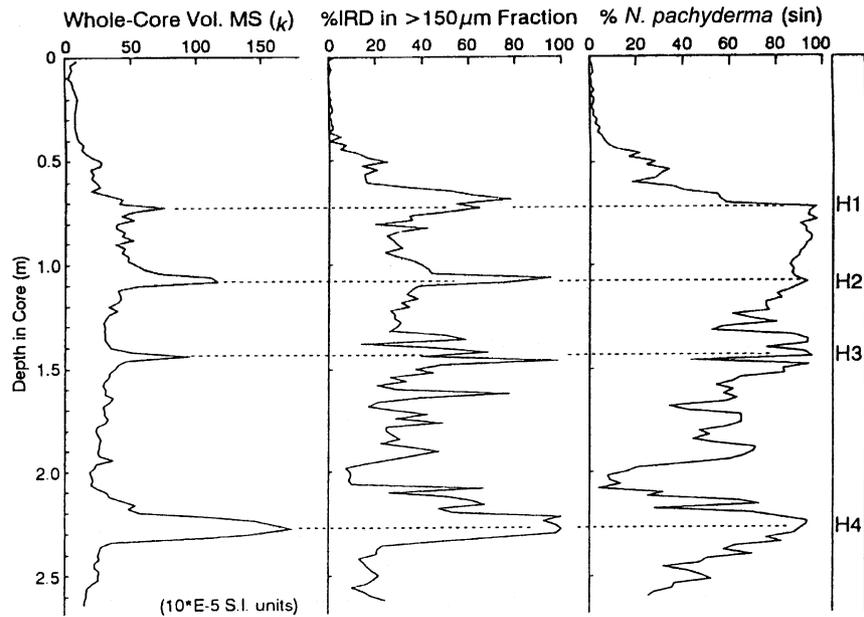

Figure M5 Downcore profiles of magnetic susceptibility (κ), the percentage of ice-rafted debris (IRD) in the $>150\mu\text{m}$ fraction, and the percentage of *N. pachyderma* in relation to the Heinrich events in core BOFS-5K (lat 50°41'N, lon 21°52'W). Susceptibility is most easily acquired and offers best discrimination in this oceanographic setting (after Robinson *et al.*, 1995).

particular the ARM record traces the diagenetic enrichment. Part of the precipitated magnetite has properties that makes a biogenic origin likely.

Most research has focused on the youngest sapropel (e.g., Passier *et al.*, 2001) but older sapropels have a similar signature. Undoubtedly, sapropels represent extremely varying redox conditions; similar, albeit less extreme magnetic changes have been reported in other sedimentary systems as well (e.g., Tarduno and Wilkinson, 1996).

The north Atlantic

The circum-Atlantic bedrock is often composed of highly magnetic crystalline basement rocks and basaltic volcanics.

Weathering of these rocks provides comparatively magnetic detritus which makes the detritus-rich North Atlantic sediments eminently suited for paleoclimate studies with magnetic methodology. The contrast with biogenic carbonate and opal that are both diamagnetic is very strong. The orbital periods of *c.* 100, 41 and 21 k year are reflected in many sediment records. The glacial sediments are characterized by higher concentrations and the presence of coarser-grained pseudo-single-domain to multidomain magnetite (Robinson, 1986). Superposed on this periodicity much more rapid, millennial-scale, climate changes may be recorded as well, if the sedimentation rate is sufficiently high ($> \sim 10\text{ cm/k year}$) and the influence of diagenesis on the magnetic properties can be shown to be insignificant (Stoner and Andrews, 1999). Heinrich layers are

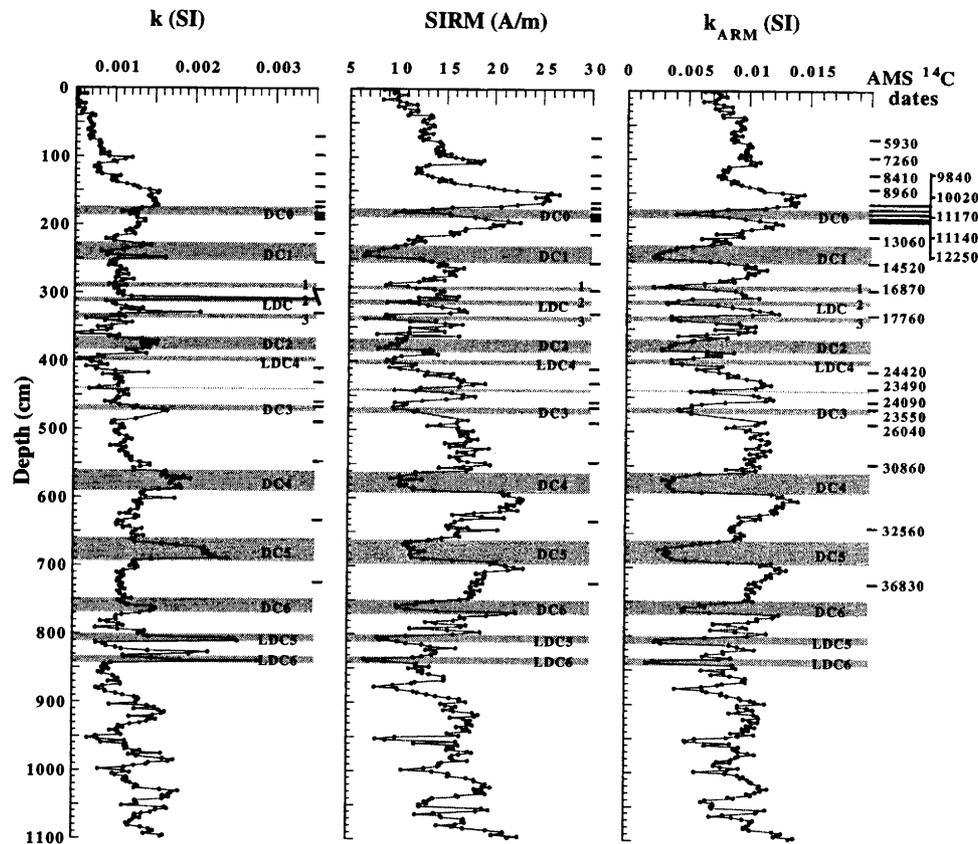

Figure M6 Downcore profiles of magnetic susceptibility (k), saturation remanence (SIRM), and anhysteretic susceptibility (k_{ARM}) in piston core P-094 (lat 50°12'N; lon 45°41'W) from the Labrador Sea. DC = detrital carbonate content between 20 wgt percentage to 60 wgt percentage; LDC = low detrital carbonate (<10 wgt percentage). All layers are associated with increased magnetic grain size whereas only part of them are identified by increased susceptibility, showing the merit of proxy parameters based on remanent magnetization properties (after Stoner *et al.*, 1996).

characterized by a high content of iceberg-rafted debris (IRD) and can therefore be traced easily by magnetic susceptibility measurements (Figure M5).

Comparatively far out of the glacier margins IRD and Heinrich layers are closely associated. However, approaching those margins, this relationship becomes less clear: many more sediment layers contain at least some IRD. The IRD in the Heinrich layers and the “background” IRD appear to be different. When normalized for carbonate, the concentration and size of the magnetic grains in Heinrich layer IRD is larger than in “background” IRD (Robinson *et al.*, 1995) which makes mineral-magnetic parameters attractive proxies. A piston core taken at Labrador rise (Figure M6) shows at least 13 distinct rapidly deposited layers. Note that expression of the low-field susceptibility of the layers differs through the core whereas the profiles of the remanent magnetization parameters SIRM and k_{ARM} offer much more structure than would be gathered from visible lithological changes only (Stoner *et al.*, 1996).

MASS MOVEMENT

Introduction

Mass movement refers to processes by which soil and rock materials move downslope under their own weight (Selby, 1993; Turner and Schuster, 1996). The six principal movement mechanisms are creep, sliding, flow, toppling, free-fall, and rolling. Given the spectrum of possible processes, mass movement deposits exhibit a wide range of sedimentological features and surface morphology. Most deposits are typically poorly sorted, unstratified clastic aggregates (i.e., diamictons) with predominantly angular clasts of local provenance.

Deposits associated with rapidly flowing events, such as debris flows and rock avalanches, often exhibit crude stratification and inverse grading. The typical morphologies of mass movement deposits are colluvial cones and fans, planar colluvial blankets, linear ridges and lobes, and complex hummocky forms. The latter have often been confused with glacial drift deposits. Given the shear strength of many landslide materials, some are emplaced at relatively steep angles (5° – 15°) and therefore violate the Principle of Original Horizontality. Such deposits require cautious structural interpretation when encountered in ancient lithified assemblages.

Strength of hillslope materials

Detachment of material from a slope as a slide or fall requires that shear stress, due to the downslope component of the bulk weight of the material, equals shear strength along a plane of detachment, as described by the Mohr–Coulomb equation:

$$s = c' + (\sigma - u)\tan \phi' \quad (\text{Eq. 1})$$

where s is shear strength, c' is cohesion, σ is total normal stress, u is pore water pressure, and ϕ' the angle of shearing resistance. Term $(\sigma - u) = \sigma'$ is effective normal stress (Craig, 1997). Cohesion is associated with either clay or cementing material. Clay cohesion is a function of the load history of a material, being relatively low (<10 kPa) in recently deposited muddy deposits, and relatively high (>100 kPa) in over-consolidated clay-shale formations (Selby, 1993; Craig, 1997). Angle of shearing resistance, ϕ' , controls the steepest stable slope for a dry frictional material, and depends on particle angularity, mineralogy, and packing density. It is highest in dense deposits of angular quartz-feldspathic grains (35° – 45°), and lowest in low-density deposits of clay (5° – 15°) (Kenney, 1984). Clay mineral species also controls frictional strength, being highest in kaolinite, intermediate in illite, and lowest in montmorillonite. Shear strength also depends on material displacement history. First-time failures in soil and rock mobilize peak strength, comprising *in situ* cohesion and friction due to maximum grain or rock-joint interlocking (Craig, 1997). Small shear displacements, of the order 0.1 m, cause substantial loss of cohesion and a reduction of frictional resistance due to shear dilatancy and the development of preferred grain alignments. The resultant ultimate or residual strength is appreciably lower than the original peak value (Craig, 1997). This means that surfaces which have experienced past movements are predisposed to continued movement. Similar reduced strength commonly occurs along tectonically sheared rock surfaces.

On slopes where soil is significantly reinforced by tree roots, a third strength component termed root reinforcement, c'_r , exists. It is significant on slopes with relatively thin (<2 m) mantles of colluvial material or weathered glacial drift. Since most mountain soils are relatively thin, landslide events, and hence regional sediment flux to depositional areas, are strongly regulated by plant cover and its degree of anthropogenic disturbance (Sidle *et al.*, 1985).

Causes of mass movement events

Slope failure as a landslide may be induced by an increase in shear stress, a decrease in shear strength or both. Shear stress increase, coupled with shear strength decrease, typically occur when materials are water saturated by rainfall or snowmelt.

Wetting increases bulk weight and hence shear stress, while changing effective stress as the groundwater table rises above the level of the potential slip plane. Such concomitant changes in stresses may occur within a few hours, explaining why many slope failures occur during major storms (Selby, 1993).

On a longer timescale, slope undercutting by rivers and glaciers causes slope steepening and hence shear stress increase. This induces slow creep movements within a slope, causing a progressive reduction in both cohesion and frictional resistance over time and hence long-term material fatigue. Seismic shock often provides the final trigger for many catastrophic slope failures in a wide range of materials, ranging from hard, jointed rock to unconsolidated clays.

Types of mass movement

A common failure type is the *translational slide*, involving a slab-shaped detachment along a well-defined rupture surface. In rock slopes, *rock slides* typically follow discontinuities such as bedding, joints, foliation and faults. Sliding is feasible only where the dip of the discontinuity is less than the slope angle, allowing the critical plane to crop out on a slope (Hoek and Bray, 1981). Large rock slides (20 Mm^3 to 200 Mm^3) are often seismically triggered and produce *rock avalanches*, since total disintegration of the mass allows flow to occur. Entrainment of saturated valley-floor material provides a liquefied base for the avalanche, allowing velocities of 10 m per second to 30 m per second. Exceptionally large liquefied failures, termed *lahars*, result from collapse of stratovolcanoes (Vallance and Scott, 1997). The largest lahar deposits approach 10^9 m^3 , cover tens of km^2 , and rank as the largest landslides on Earth. High mobility of lahars is caused by saturation by melting of ice and snow, drainage of volcanic crater lakes, and entrainment of saturated alluvial material.

On soil and debris covered slopes, translational *debris slides* occur along the soil–bedrock interface since soil shear strength is lower than that of rock. Debris slides are typically 10^2 m^3 to 10^3 m^3 and are triggered mainly by rainstorms. Scour of saturated material along a stream channel transforms many debris slides into *debris flows* (Iverson *et al.*, 1997). Debris flows occur in every climatic zone, attaining velocities of 5 m per second to 10 m per second and typical volumes of 10^3 m^3 to 10^5 m^3 .

On slopes cut into thick clay or shale, deep-seated *slumps* are common, involving a roughly cylindrical-arc slip surface oblique to the stratification with backward rotation of the landslide mass. Slumping creates a steep, debuttressed head-scarp prone to further slumping, a process termed retrogression. Prolonged retrogression may produce an elongated *earth flow*, up to several kilometers in length, moving at 1 m a^{-1} to 5 m a^{-1} , with a total volume exceeding 10^8 m^3 . In low density saturated silts and clays, liquefaction may occur at depth as the deposit collapses under shear loads. Frictional strength declines notably as pore pressure rises, allowing rapid acceleration as a *quick clay flow-slide* (Turner and Schuster, 1996). Flow-slide retrogression may occur at meters per minute, with flow velocity attaining 1 m per second to 5 m per second.

In permafrost areas, seasonal thaw of ice-rich soil produces a 0.5 m to 1.0 m thick water-saturated active layer above permafrost material. *Solifluction* involves movement of the active layer at 10^{-2} m a^{-1} to 10^{-1} m a^{-1} on slopes as low as 2° . Movement on slopes well below the theoretical lowest angle

predicted by Mohr-Coulomb theory occurs by a combination of *frost creep* and *gelifluction* (Harris, 1987). Frost creep is soil movement by alternating cycles of frost heave and thaw-settlement in soils subjected to ice segregation. Gelifluction is a type of soil flow, occurring during seasonal thaw, in which high water pressures develop during melting of low density, ice-rich soil. Overburden pressure is largely borne by the pore-water, allowing low effective stress to develop. A transient phase of negligible frictional strength occurs, allowing soil to move on slopes substantially flatter than possible in saturated, consolidated soils. On steeper slopes in permafrost areas, *skin flows* involve rapid downslope detachment of the entire active layer. Retrogressive *thaw slumps* are triggered by river undercutting of slopes and exposure of ice-rich sediments. Thaw slumps are the largest slope failures found in permafrost areas.

MATURATION, ORGANIC

Organic maturation refers to the progressive and mainly irreversible transformation of organic matter (OM) in response initially to biological and later to thermal energy. Organic

maturation is also referred to as organic diagenesis, organic metamorphism, and as coalification when referring to coal.

Organic matter is a minor component in most sedimentary rocks, however its importance by far outweighs its abundance. Organic matter comprises the fossil fuel resources petroleum and coal. The products of OM diagenesis govern many mineral reactions and are important in the transport and deposition of many ore minerals. Studies of organic maturation have mainly been pursued from two separate avenues: organic geochemists have investigated the chemical reactions and products of organic maturation particularly from the perspective of petroleum whereas coal petrologists have studied organic maturation of coal mainly microscopically.

Introduction

Diagenesis of OM has been considered in terms of three or four stages by various authors (e.g., Tissot *et al.*, 1974; Bustin, 1989; Diessel, 1992). *Eogenesis* has been used in reference to biological, physical and chemical changes in OM that occur at low temperatures where reactions are mainly biologically mediated. *Diagenesis*, at higher temperatures normally associated with greater depths of burial, is successively referred to as *catagenesis* and *metagenesis*. Diagenetic reactions of OM due to contact with free oxygen or meteoric water has been referred to as *teloogenesis*. The boundary between different diagenetic stages is gradational as a result of the heterogeneity of the OM and biological processes. The different coal ranks from peat to lignite, subbituminous, high-, medium-, and low-volatile bituminous coal, semi-anthracite and anthracite, are names sequentially assigned to successively more carbon-rich and volatile-poor coals that form in response to progressive diagenesis.

Substantial research exists on the kinetics of organic diagenesis because of the importance of predicting the timing and volume of hydrocarbon generation from the diagenesis of kerogens. As well, sophisticated numerical models have been proposed that attempt to predict organic maturation based on the thermal history of the strata and the activation energy of various kerogen types. Because many of the products of organic diagenesis are metastable and rocks are open to migration of products (hydrocarbons), thermodynamic equilibrium is rarely ever established.

Eogenesis

Eogenesis refers to low temperature diagenesis of OM, where reactions are at least in part biochemical resulting from metabolic processes of organisms, and the effects of temperature and pressure are subordinate (Figure M7). Due to the diversity of microbial processes and organic substrates, reactions during eogenesis are complicated and poorly understood. Different depositional settings give rise to different diagenetic processes and sources of OM, which in turn influence the type and rate of degradation of the OM mainly by bacteria, actinomycetes and fungi. For OM to be preserved at all to further undergo diagenesis requires rather specific depositional conditions. It is clear that in subaerial environments chemical oxidation and aerobic microbial decomposition invariably leads to complete decomposition of the OM. Anaerobic microbial processes are generally slower and hence eogenetic reactions are commonly retarded such that there is greater potential for a portion of the OM to be preserved. For

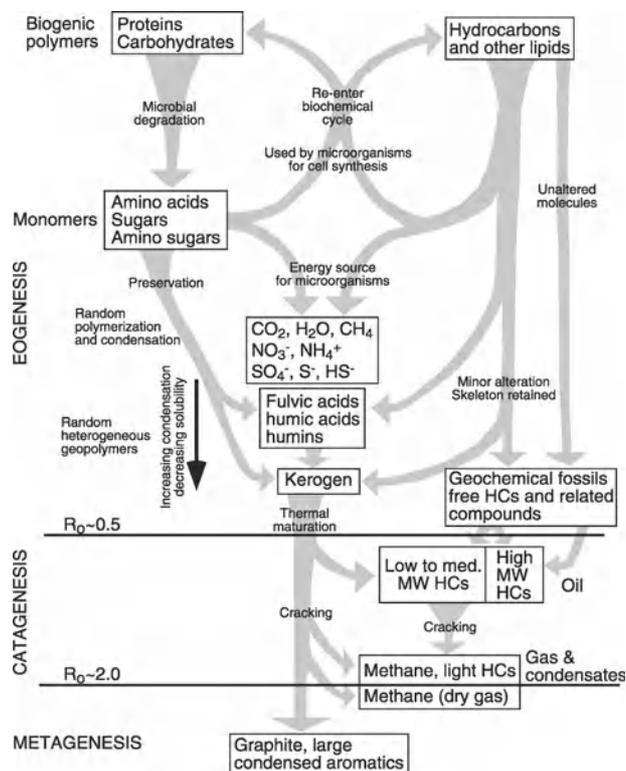

Figure M7 Schematic diagenetic pathway of organic matter in sediments. Modified after Barnes *et al.* (1990).

OM to survive eogenesis and to move on to catagenesis, it must be rapidly removed from oxic conditions. Proteins, carbohydrates (sugars, cellulose, and chitin), lipids (fats, waxes, and steryl esters) and lignins are the main biopolymers contributed by organisms to the sediment. Biopolymers are variously depolymerized during eogenesis forming what is colloquially referred to geopolymers, which are essentially fulvic and humic acids, humins and kerogens (Bustin, 1999). Geopolymers are defined on their solubility, their molecular weight and, because they form by random recombination, their structures. Geopolymers vary depending on available monomers and diagenetic conditions. With increasing cross-linkage and loss of acidic functional groups (carboxyl and phenolic hydroxyl groups), the humic and fulvic acids lose their base solubility and form an insoluble humin/kerogen residue. The term humin is used for base insoluble fraction of the OM in soils, whereas kerogen refers to the organic fraction in rocks, which is insoluble in organic solvents. The details of diagenetic reactions leading to kerogen formation remain poorly understood. Some kerogen forms through loss of functional groups and cross-linkage formation early in diagenesis, but others later during catagenesis and still other kerogen appears to arise directly from monomers without an intervening humic stage particularly under anoxic conditions. The lipid-rich components are particularly resistant to biochemical processes and unless degradation is particularly intense, these components survive eogenesis. An important product of eogenesis is the formation of mainly methane (up to 99 percent), carbon dioxide (0 percent to 8 percent) and minor

heavier gases by fermentation reactions. This biogenic gas may source significant economic accumulations both in the coal (coalbed methane) and conventional reservoirs. Carbon dioxide generated together with organic degradation products influences the Eh, pH, and ionic composition of pore waters and thus plays a role in diagenesis of minerals.

The end of eogenesis generally occurs when the microscopic reflectance of coal maceral vitrinite is about 0.5 percent, which also corresponds to the boundary between subbituminous coal and high-volatile bituminous coal. At this stage base-soluble compounds are usually negligible and thermal energy is required for further diagenesis.

Catagenesis

Diagenesis beyond the eogenetic stage is in response to thermal exposure (temperature and time), generally accompanying burial in a sedimentary basin or high heat flow adjacent intrusive or extrusive bodies (Figure M7). The rate of organic diagenesis is exponential with temperature and linear with time. Confining pressure has little effect during organic diagenesis apart from compaction during the peat and lignite stages and some experiments suggest high confining pressure retard catagenetic and metagenetic reactions. Catagenetic reactions take place at temperatures of around 40°C to 150°C and moderate pressures (30–150 MPa), often producing significant amounts of petroleum, methane and carbon dioxide. The amount and type of liquid hydrocarbons generated varies with the type of kerogens present. Generally most coals are considered to have little liquid hydrocarbon potential whereas algal-rich, fine-grained rocks are excellent liquid hydrocarbon source rocks. During catagenesis coal rank progressively increases from subbituminous to anthracite and kerogen increases in carbon content, decreases in volatiles, aliphatic chains are cleaved and the size of aromatic clusters grows through condensation and development of ordering. Coincident with the generation of gas, the surface area of the kerogen increases such that significant quantities of the generated gas are adsorbed in the matrix (up to about 30 m³/tonne for coal) giving rise to coalbed methane. Coalbed methane (and gas shale), is an important energy resource, however, it is also a potential explosive hazard during coal mining. The exact level of catagenesis for liquid hydrocarbon generation (oil birth line) varies with the chemical composition of the kerogen. The catagenetic level at which liquid hydrocarbons begin to crack is referred to as the oil death line. The zone of catagenesis between the birth and death “lines” is referred to as the *oil window* or oil kitchen (Figure M7).

Organic matter undergoes noticeable transformations that are observable microscopically even at the beginning of the eogenetic stage. The fraction of the OM derived from higher plants, mainly cellulose and lignin, give rise to the microscopically defined maceral huminite (at low maturation levels) and later vitrinite. The reflectivity of huminite/vitrinite progressively increases, as observed microscopically in reflected light through diagenesis. This degree of reflectance can be measured with a specially designed microscope and is referred to as vitrinite reflectance. Vitrinite reflectance is the most widely used method for determining the degree of diagenesis of coals and OM in rocks. During catagenesis vitrinite reflectance progressively increases from about 0.5 percent to 2.0 percent (Figure M7). Liptinite components

change little until the oil birth line which corresponds to a vitrinite reflectance of about 0.5 percent and then it become progressively brighter and merge in brightness with vitrinite at a reflectance of about 1.4 percent (the death line of oil). The fraction of the OM rich in lipids is microscopically darker than vitrinite and is referred to as liptinite. The liptinite macerals change little with diagenesis until the onset of the oil window at which time there is a “jump” in diagenesis as HCs are generated (Figure M7). That microscopically defined fraction of the OM that is semi charred or charred at the site of deposition (charcoal) is referred to respectively as semi-fusinite and inertinite. These materials being variously pre-coalified undergo little change during diagenesis.

Metagenesis

Metagenesis refers to the level of diagenesis of the OM at which crystalline ordering of the OM begins (Figure M7). Aromatic clusters increase in size and C–C bonds are broken generating additional methane. Any remnant aliphatic molecules and any previously formed heavier hydrocarbons are cracked to methane. The remaining kerogen becomes further enriched in carbon with loss of volatiles. Microscopically the reflectance of vitrinite progressively increases from about 2.0 percent to 10 percent or more and the liptinite component and lower reflecting inertinite components become visually indistinct from vitrinite. Early studies argued that graphite is the end point of coal diagenesis however field and experimental evidence now suggest that the activation energy for formation of graphite is so high that it is unlikely that it will form in nature by thermal exposure alone (Figure M7).

Telogenesis

Organic matter diagenesis is progressive and for the most part irreversible. Organic matter at all stages of diagenesis is reduced and subsurface environments are typically anaerobic. Where, however, OM is uplifted to the surface or comes in contact with oxygenated meteoric water, it is subjected to oxidation. Oxidative processes are collectively referred to as telogenesis and result in marked changes in the OM. During oxidation nonaromatic groups are selectively removed and acidic functional groups such as carboxyl, carbonyl and phenolic hydroxyl are formed leading to production of humic acids. The oxidative diagenetic processes have a deleterious effect on coal quality: coking coals lose their ability to form coke, thermal coals decline in calorific value and coal particles lose their hydrophobicity and thus are difficult to separate from mineral matter during coal processing (Copard *et al.*, 2002; Teichmüller, 1982). If oxidation is intense it may be microscopically evident by distinctive darkish halo along boundaries of organic particles. With pooled hydrocarbons two distinct telogenesis processes occur: (1) water washing which results in selective removal of lighter hydrocarbons by groundwater; and (2) bacterial degradation which can lead to loss of normal alkanes and isoprenoids leaving a heavier oil residue enriched in cycloalkanes and aromatics. These two processes are considered responsible for formation of the heavy oil deposits.

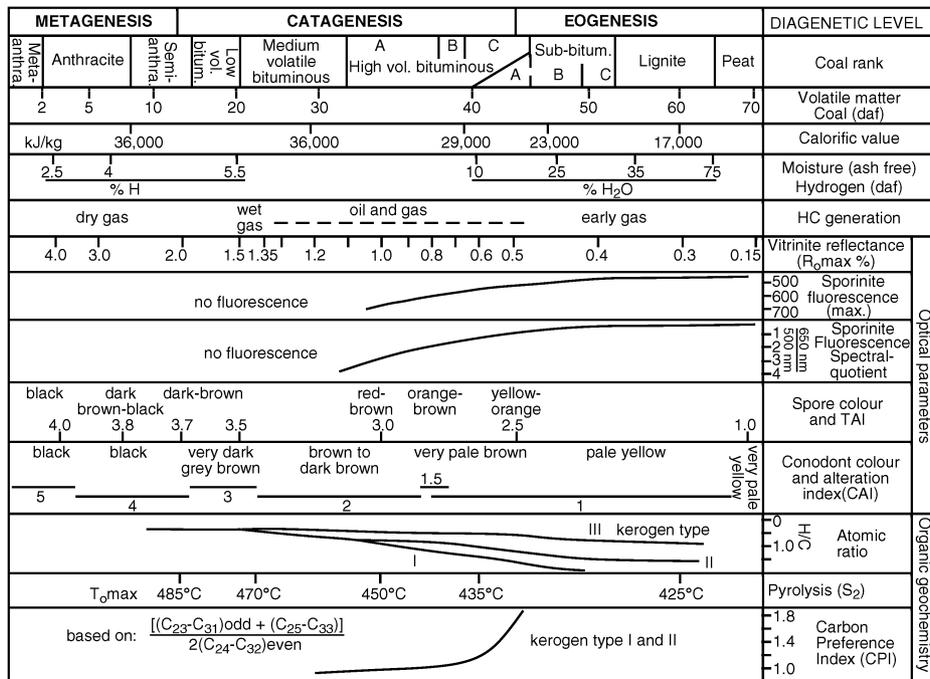

Figure M8 Correlation of major organic maturation indices. The correlation shown is based on vitrinite reflectance. Modified after Bustin *et al.* (1990).

Quantifying organic diagenesis

Both the kerogens and bitumen fraction of the OM have been used to quantify diagenesis by chemical, physical and microscopic methods (Bustin *et al.*, 1990; Tissot and Welte, 1978). In Figure M8, the correlation between the major different diagenesis indices is provided. A few of the more common techniques are summarized below. The reflectance of vitrinite, and its precursor huminite is the most widely accepted method of quantifying organic diagenesis and the method to which all others are compared. Vitrinite reflectance is measured microscopically using a highly polished specific and a specialized microscope equipped with a photometer. With increasing levels of diagenesis the reflectivity of vitrinite increases in a predictable fashion. Characteristics of coal have often been used as diagenetic indicators. The volatile matter, moisture, and hydrogen content of coal decrease with increasing diagenesis and the carbon content and calorific value increase in a predictable manner (Figure M8). The chemistry of kerogens has also been found to be useful indicator. For example the hydrogen to carbon ratio and pyrolysis yield of kerogens decrease with increasing diagenesis. The carbon preference index (ratio of odd to even n-alkanes) also progressively decreases with diagenesis from values greater than 1 (due to initial organic selectivity) to values approaching one as diagenesis progresses.

The fluorescence of lignite macerals has been utilized in some studies. With increasing levels of diagenesis the intensity of fluorescence decreases and the wavelength of maximum fluorescence progressively increase. Such measurements require a microscope equipped with a scanning monochromatic filter and sensitive photometer.

Kerogen coloration in transmitted light including pollen, spores and conodonts has been successively used to quantify maturation. As with toast, the OM darkens with increases with degree of thermal exposure and specialists attribute the colors to various numerical schemes based on visual examination. The color of kerogens has been referred to as the *Thermal Alteration Index*, whereas the color of conodonts is referred to the *Conodont Alteration Index* (CAI) (Figure M8).

MATURITY: TEXTURAL AND COMPOSITIONAL

Maturity refers to the degree to which clastic sediment has been modified by physical and chemical processes at Earth's surface. *Textural maturity* refers to the degree to which physical characteristics of grains and populations of grains approach the "ultimate end product" (Pettijohn, 1975, p.491). *Compositional maturity* (stability) refers to the degree to which chemical characteristics approach the "ultimate end product," so that grains are more in equilibrium with Earth's surface conditions.

Textural maturity

As rocks approach Earth's surface during removal of overlying rocks, individual fragments of rock are defined by diverse physical, chemical and biologic weathering processes. Joints and other structural discontinuities tend to define gravel clasts, whereas preexisting grain size tends to define sand and silt clasts. Intensity of chemical weathering largely controls clay mineralogy (*q.v.*). Chemical weathering causes the least stable components in go into solution and/or to combine into more stable minerals during weathering. The result of these varied processes is the creation of sedimentary clasts of diverse grain size, shape and composition. As the clasts are eroded, transported and deposited (possibly through several cycles), they are modified by diverse physical and chemical processes. Most of these processes produce increased textural maturity through time.

Various measures of textural maturity have been developed. *Roundness* is a measure of the degree to which a grain has attained a continuously curving surface. *Sphericity* is a measure of the degree to which a grain has attained a spherical shape (equidimensional). These characteristics can be determined by painstaking measurements of curvature and dimensions of individual grains, or more commonly, by visual comparison with standard charts. A more sophisticated method for analyzing large populations of grain shapes utilizes Fourier analysis (e.g., Ehrlich and Weinberg, 1970).

Grain-size distributions reflect diverse processes at work during erosion, transportation and deposition. Some depositional environments tend to concentrate certain grain sizes; in the case of high-energy beaches, coarser clasts are left at river mouths and finer clasts are transported offshore, resulting in a

concentration of fine to medium sand along beaches. Such an environment produces a narrow range of grain sizes, and is, therefore, texturally mature. In contrast, mass wasting and flash floods produce texturally immature deposits.

Standard petrographic methods of studying sandstone have shown a strong correlation between grain size and composition (e.g., Boggs, 1968). As rock fragments break into their constituent minerals (especially quartz and feldspar), QFR compositions change from dominantly R to dominantly Q and F. Thus, finer-grained sandstone (texturally more mature; higher QFR percent Q and F) is produced by the breakage of coarser grains (texturally less mature; higher QFR percent R). Interpretation of compositional maturity of sandstone is complicated by this artifact of method because of the dependence of composition on grain size, but interpretation of textural maturity is straightforward. Thus, the use of QFR petrographic methods is more useful for paleoclimate and other studies, where textural maturity is diagnostic (e.g., Suttner *et al.*, 1981; Suttner and Basu, 1985). Where reconstruction of original source rocks is the goal, the Gazzi-Dickinson method (QFL) is recommended (see below).

Compositional maturity (stability)

Most minerals and rocks are unstable at Earth's surface because they originated at higher pressures and temperatures, and in different geochemical environments. As a result, surface conditions are continuously acting on these minerals and rocks in ways that create more stable assemblages. Metastability is common at Earth's surface due to slow reaction rates at low temperatures; nonetheless, given the immensity of geologic time, even metastable minerals are gradually altered.

In general, minerals crystallized at higher pressures (P) and temperatures (T) are less stable at Earth's surface than are lower-PT minerals. Thus, the inverse of Bowen's reaction series is Goldich's weathering series, which indicates that, for example, albite is more stable at Earth's surface than is anorthite, and biotite is more stable than olivine. Thus, one measure of compositional maturity is the stability of mineral assemblages relative to their parent assemblages in their provenance areas.

The ZTR index (Hubert, 1960) is a commonly used mineral-stability measure. It is determined by dividing the quantity of zircon, tourmaline and rutile (super-stable accessory minerals) by the quantity of total accessory minerals. Thus, super-stable mineral assemblages have ZTR values close to unity.

Petrographically determined measures of stability include the proportion of total quartz in the QFL population (using the Gazzi-Dickinson method, which lessens the dependence of composition on grain size; Ingersoll *et al.*, 1984). Sub-populations also indicate relative stability; for example, $Q_m / (Q_m + Q_p)$, $Q_p / (Q_p + L_m + L_v + L_s)$, $L_s / (L_m + L_v + L_s)$, $Q_m / (Q_m + F_k + F_p)$ values all tend toward unity in super-stable sandstone. Polycrystallinity and undulosity tend to weaken quartz grains, so that ultra-quartzose sandstone tends to have relatively low proportions of both (Basu, 1985). Super-stable conglomerate consists predominantly of quartzite clasts, analogous to super-stable quartz arenite (including ortho-quartzite).

Stability of mudrock is highly dependent on climate because stability of clay minerals is determined primarily by chemical weathering regime. Thus, light leaching produces montmorillonite and illite, and related clays, depending on starting

material. With increased leaching, kaolinite is favored. With extreme leaching, aluminum and iron oxides are the primary residuum (laterites, *q.v.*), thus representing extreme compositional maturity (super stable).

Ratios of major oxides also indicate compositional maturity because the oxides behave differently at Earth's surface. MgO, CaO, and Na₂O tend to decrease, whereas K₂O, SiO₂, TiO₂, and Fe₂O₃ tend to increase during weathering (Pettijohn, 1975). Various ratios of the latter oxides to total oxides approach unity with increasing stability.

Discussion

Textural maturity and compositional maturity are distinctly different measures of the degree to which sediment has been modified during the diverse processes of weathering, erosion, transportation and deposition. Distinction between these two attributes, however, has not always been clear. The "graywacke problem" is an informative example of possible confusion.

Geosynclinal theory equated "graywacke" (poorly sorted sandstone, with abundant "fine-grained matrix") with "eu-geosynclinal sedimentation" (e.g., Kay, 1951). When most "graywackes" were recognized as turbidites, it was said that turbidites were poorly sorted mixtures of sand and mud. The presence of abundant "matrix" in "graywackes" was cited as evidence. Detailed petrographic study of "graywackes" has shown that, in almost all cases, most of the "matrix" is pseudomatrix, that is, physically deformed and chemically altered detrital grains (Dickinson, 1970). Recognition of pseudomatrix allows for the correct interpretation of provenance (based on assignment of pseudomatrix to detrital-grain categories) and the correct interpretation of textural maturity (little original detrital matrix, which means that sand was well sorted prior to diagenetic alteration). Recognition of pseudomatrix as detrital grains is consistent with the observation that modern turbidites are well sorted, that is, have less than 5 percent matrix (e.g., Hollister and Heezen, 1964). Thus, the "graywacke problem" resulted from the confusion of compositional maturity (unstable lithic grains and micas readily become pseudomatrix during diagenesis) with textural maturity (pseudomatrix was interpreted as detrital matrix, which led to the inference that turbidites were poorly sorted). Careful petrographic study is needed to recognize the original detrital texture and composition of sandstone, and for the correct interpretation of both textural and compositional maturity.

MEANDERING CHANNELS

The planform of rivers—the channel pattern as seen from an overflying aircraft—is quite varied and has invited many attempts at classification by river scientists. An important early planform classification by Leopold and Wolman (1957) divided rivers into three categories: braided, meandering and straight. Braided channels are multiple-thread patterns and contrast with the single-thread meandering and straight channels; meandering channels are distinguished from their straight counterparts by their sinuously winding course. The term "meander" has become part of our everyday language and derives from the apparently aimless wandering habit of the Maiandros in Phrygia, a winding river named by the ancient Greeks in what is now modern Turkey.

More recently river scientists have recognized the limitations of this simple tripartite river-planform division and have stressed instead the continuum of river planforms. Nevertheless, the meandering channel remains an important end-member in all modern classifications of river planform and is one of the most common patterns found in nature. It may be defined as a single-thread river channel consisting of a continuous series of channel bends of alternating curvature together displaying elements of both periodic and random geometry.

The planform and channel geometry of river meanders

One of the most intriguing properties of meandering channels is the sometimes remarkably regular periodic waveform they display (see Figure M9). In its purest form this regular sinuous waveform has a characteristic shape (sine-generated) and a geometry that scales with channel width so that meanders tend to be geometrically self-similar regardless of the size of the river. For example, on average, meander wavelength typically

Figure M9 (A) Aerial photograph of the freely meandering Pembina River, Alberta, Canada; (B) aerial photograph of confined meandering Beaver River, Alberta, Canada.

is 8–12 times the bankfull channel width and meander-bend curvature is about 2–3 times the channel width. Because channel width (W) is related to discharge (Q), meander wavelength (L) is also related to river discharge

$$L = k\sqrt{Q}$$

(where k ranges from 30 to 60, depending on the return period of Q), a relationship which has been exploited in paleo-hydrologic studies of ancient rivers (see Dury, 1964).

Initially river scientists were preoccupied with the periodic character of river-meander traces and only more recently have acknowledged their non-periodic, intermittent, or random behavior. In most meandering channels the orderliness of highly periodic sinuosity is blended with, and disturbed by, a variety of planform disorder that relates to channel migration processes. For example, regular meander-bend development can be distorted by heterogeneities in the alluvium through which bends are migrating, meander bends can migrate laterally to form complex meander loops which are much

larger than the associated meander bends, and high sinuosity meander bends can erode back on themselves to form meander cutoffs. Typical variations in the relative importance of these two planform elements led Kellerhals *et al.* (1976) to distinguish three categories of meandering: irregular, strongly repeating, and tortuous.

Although the shape of channel bends in a freely migrating meander train can be symmetrical and sinusoidal, even slight river confinement commonly leads to bend asymmetry as the train migrates downvalley. In cases of pronounced confinement (e.g., meanders formed in the confines of abandoned glacial meltwater channels of the Canadian Prairies), meander asymmetry is extreme and is an indicator of flow and migration direction (Figure M9(B)).

Channel cross-sections at or somewhat downstream of the axis of meander bends are distinctly asymmetrical with deeper flow occupying the outer bank zone and the deposition of a point bar causing shoaling at the opposite inner bank. At points of meander inflection flow typically is shallower over a

channel-wide bar called a *riffle*. This “pool and riffle” sequence is a distinctive morphological characteristic of all meandering channels.

Flow in meandering channels

Although much debated, there is no generally accepted universal explanation for why meanders form in rivers (see reviews by Callander, 1978 and Knighton, 1998). Whatever the cause of meandering, however, the general pattern of flow through the alternating channel bends of meanders is well-known and understood. In the absence of secondary flow, bend flow seeks to conserve angular momentum so that it tends to conform to that of a free vortex with high velocity at the smaller radius of the inner bank and lower velocity at the outer bank where radial acceleration is lower. But secondary flow redistributes momentum in the bend to achieve a reversal of this relationship in the zone of fully developed bend flow. Near the water surface where velocity is highest, secondary flow is dominated by centrifugal “forces” and flow moves toward the outer bank. Near the bed, where velocity and thus the centrifugal effects are lowest, the balance of forces is dominated by the inward hydraulic gradient of the super-elevated water surface and secondary flow moves toward the inner bank. The three-dimensional expression of these forces is helical flow which has an alternating sense through successive meander bends. One of the important consequences of helical flow in meanders is that sediment eroded from the outside of a meander bend tends to be moved to the inner bank or point bar of the next downstream bend.

The process of meander formation and maintenance

Meander planform geometry is controlled by the process of lateral migration. Meandering channels erode the outer banks of channel bends and maintain a constant channel width by achieving a matching rate of deposition on the point bar

forming the inner bank. Rates of migration may be exceedingly slow (a small fraction of channel width/year) or very rapid (several channel widths/year) depending on the ratio stream power/bank strength, and on the degree of bend curvature (Hickin, 1974; Hickin and Nanson, 1975, 1984). Depending on the particular pattern of bend erosion and deposition, meanders can exhibit a variety of evolution. Simple bends can increase in amplitude by extension until decreasing bend curvature deflects or constrains the direction and rate of motion. Phase differences in the flow and bend alignment can lead to bend rotation, lobing and compound meander loops. Where confinement constrains meander development, bend motion is mainly restricted to downvalley translation. These motions are further modified by the formation of gooseneck and chute cutoffs which short-circuit the meandering channel path, sometimes forming ox-bow lakes.

The deposits of meanders: meander floodplains

The nature of sediments deposited to form the floodplains of most meandering rivers is intimately related to the sediment available for point bar deposition and to the process of lateral migration. The classical point bar model of deposition in sand- and gravel-bed rivers, originating primarily from the work of Allen (1963), is illustrated in Figure M10. Within-channel lateral accretion deposits of gravel overlain by sand are capped by overbank fines deposited during flood discharges. Lateral accretion deposits consist of a basal gravel platform of bed material on which are deposited upward-fining sands and silts representing the declining energy of the depositional environment as the point bar aggrades to less frequently inundated elevations. Internal sedimentary structures vary from dune to ripple related cross strata and trough cross-lamination in the lateral accretion deposits to horizontal strata in the overbank deposits. This upward-fining sediment column with its associated upward downscaling of sedimentary structures, is

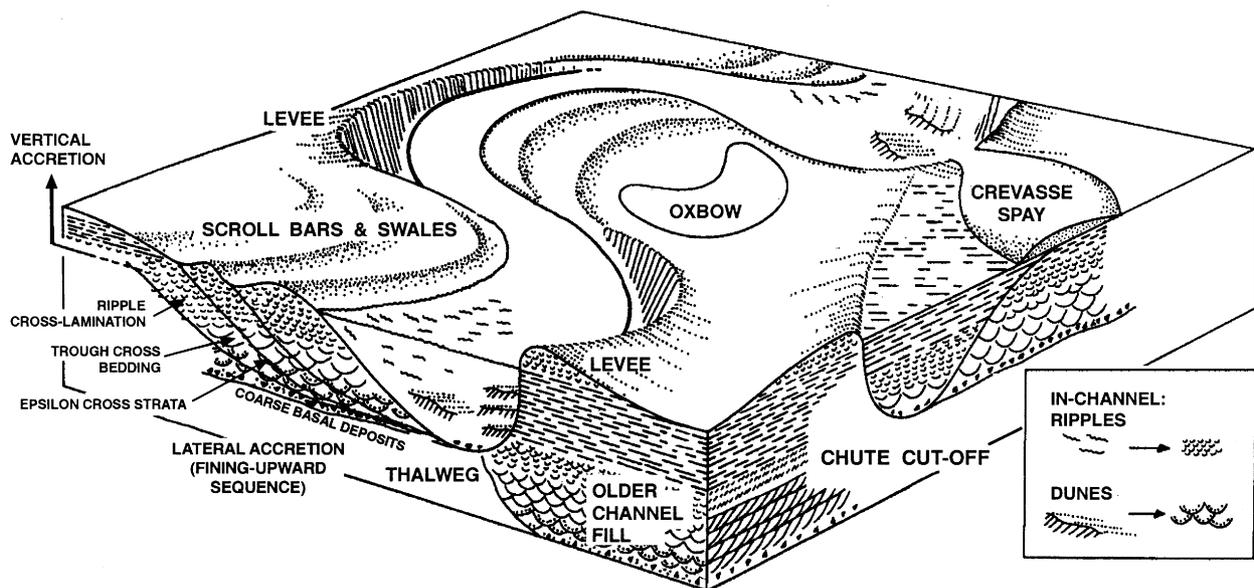

Figure M10 The geomorphic setting and sedimentological elements of the upward-fining sequence, the basis of the classical meandering-river facies model (modified from Walker and Cant, 1984).

packaged in units bound by sigmoidal epsilon cross strata (ECS), corresponding to distinct phases of channel migration and point bar deposition. These packages of sediment often form arcuate ridges or scroll bars, separated one from the other by troughs in the surface of the floodplain.

More recent investigations, however, have recognized many variations on this classical model of meander deposition and still others describe floodplain sedimentology which seems to be entirely unconventional. For example, in Miall's (1985) models of meandering river floodplain (gravel meandering, gravel-sand meandering, sand meandering and fine-grained meandering) he recognizes the important control of sediment type on the details of floodplain sedimentology. These river channel styles reflect a progressive increase in the abundance of fines although coarser basal lateral accretion deposits are common to all models. Floodplains with lateral accretion deposits consisting of sandy silt with negligible upward fining have been described by Nanson (1980). Others have also noted that meandering river floodplains formed in environments where silt is abundant and gravel and sand are much less available, particularly in low-gradient tropical regions, also do not appear to be adequately described by the classical Allen model (Jackson, 1981; Smith, 1987). Similarly, the negligible role played by lateral accretion in some steep upland valleys formed in non-cohesive sediments, as well as in low-gradient channels in cohesive sediments, is formalized in the genetic classification of floodplains by Nanson and Croke (1992).

The floodplains of meanders may also include a significant proportion of counterpoint (or eddy-accretion) sediments of horizontally bedded silt and fine sand deposited in flow separation zones at points of abrupt direction change in the channel. In confined meanders the abrupt angle bends that occur where the channel impinges on the valley wall (Figure M9(B)) form systematically alternating zones of flow separation downstream at the valley walls. These alternating gyres trap eddy accretion sediments which form concave bank benches with a curvature opposed to that of the convexly curved scroll bars on the adjoining point bar (Hickin, 1979, 1986; Nanson and Page, 1983; Burge and Smith, 1999).

River planform facies and architectural element models of meander deposits

Attempts to characterize meandering river sediments in terms of bedform-scale sedimentary structures and assemblages (planform facies models) that would distinguish them with some certainty from other river types (especially braided) have not fulfilled early promise. Although general sedimentological properties for sand/gravel-bed rivers are well represented by these facies models, overlap among planform groups is so significant that their diagnostic utility is weak and often misleading (Jackson, 1978; Brierley and Hickin, 1991; Hickin, 1993; Miall, 1996). In recent years some fluvial sedimentologists have advocated the development of bar-scale or architectural element-scale models to characterize fluvial sediments (Miall, 1985). It has been argued that such planform element models may be far more effective diagnostic tools than are bedform-scale facies models. This development represents a return to earlier geomorphic concepts such as those developed by Happ *et al.* (1940) and Fisk (1944, 1947) and espoused by Leopold, Wolman and Miller (1964) who recognized that floodplains of rivers such as the Mississippi consist of an assemblage of distinct morphological and

sedimentological elements (such as channel fills, point bars, meander scrolls, sloughs, levees, backswamp deposits, and crevasse splays). But such an element approach to the depositional record requires three-dimensional mapping of such features and the typically poor access to exposures in the field is rarely adequate for this purpose. There is some prospect, however, that remote sensing of the subsurface architecture by means such as ground-penetrating radar (GPR), shallow seismic and electrical resistivity surveys, may yield the necessary data to allow this approach to be developed further (Alexander *et al.*, 1994; Leclerc and Hickin, 1997).

Summary

Meandering channels, single-thread river-channels consisting of a continuous series of channel bends of alternating curvature, are an important end-member in all modern classifications of river planform and is one of the most common river patterns found in nature.

River meanders tend to have a sinuous waveform of characteristic shape (sine-generated) and a geometry that scales with channel width so that meanders tend to be geometrically self-similar regardless of the size of the river. The regularity of this sinuous pattern, also reflected in a corresponding "pool and riffle" bed geometry, can be disturbed by such effects as floodplain heterogeneities, meander cutoffs, complex loop development, and channel confinement.

In the classical point bar model of deposition in sand-bed and gravel-bed rivers within-channel lateral accretion deposits of gravel overlain by sand are capped by overbank fines deposited during flood discharges. This upward-fining sediment column with its upward downscaling of sedimentary structures, is packaged in units bound by sigmoidal epsilon cross strata (ECS), corresponding to distinct phases of channel migration and point bar deposition.

More recent investigations have recognized many variations on this classical model of meander deposition, encompassing the broader range of sediments actually found in nature, including counterpoint deposits common in confined meanders. Mud-dominated floodplains remain poorly studied and the subject of current research.

Planform facies models at the bedform scale have enjoyed limited diagnostic success. Bar-scale or architectural element-scale models of floodplain sedimentology hold more promise but require three-dimensional data dependent on remote sensing of the subsurface by techniques such as ground-penetrating radar.

MÉLANGE; MELANGE

Mélange (spelled melange in much English-language literature) describes heterogeneous rock units that contain blocks, typically of hard or structurally competent lithologies, surrounded and supported by a fine-grained matrix of shale, slate, or serpentinite. Considerable controversy has surrounded the term *mélange* since its first use by Greenly (1919), in the description of a unit from Anglesey in the British Isles. Interest in *mélanges* was revived during the development of plate tectonics, when *mélanges* were identified as tectonic products of subduction (e.g., Hsu, 1968). Controversy has surrounded both the definition of the term *mélange*, and the interpretation and origin of units so described.

Definitions

Almost all definitions of *mélange* include as critical components the presence of blocks of varied sizes and lithologies, not in contact with each other, and surrounded by a finer-grained matrix. Most geologists have also agreed that a *mélange* has to be a unit that is mappable, typically at a scale such as 1 : 25,000 (Silver and Beutner, 1980) or 1 : 24,000 (Raymond, 1984). Authors have differed as to whether the presence of a tectonic fabric in the matrix is essential to the definition of *mélange*. Most described examples do have a fabric of some sort; rock bodies in which blocks are present in a clearly untectonized matrix are typically labeled using more interpretive terms such as “olistostrome” or “debris flow” (*q.v.*), which imply specifically sedimentary processes of origin. Some authors have suggested that such sedimentary units be excluded from the definition of *mélange* (Hsu, 1974). Nonetheless, the term has been applied to many units entirely lacking tectonic fabric, and the type example described by Greenly (1919) locally lacks fabric. A purely descriptive definition is therefore preferable; units of known tectonic origin are commonly distinguished as “tectonic *mélanges*.”

Also in dispute is whether the blocks have to include “exotic” lithologies, such as the blueschist and ultramafic units in the well-known Franciscan *mélanges* of California. Although exotic blocks were regarded as essential in the definition adopted by Raymond (1984), it is often difficult to decide what lithologies are truly “exotic”, and close textural and fabric similarities exist between chaotic units with and without exotics (Brandon, 1989). Thus a definition consistent with most modern usage is: “an internally disorganized unit that is mappable at 1 : 25,000 scale, that is characterized by the

presence of blocks of varied lithologies and sizes supported by a fine-grained matrix.”

Interpretations

Proposed mélanges origins fall into three large categories. In the first group are interpretations that appeal to gravitationally driven movement on slopes to disrupt bedding in sedimentary components and to mix the blocks and matrix. Such processes include slides, slumps, and debris-flows. The term “olistostrome” (Flores, 1955, 1956), literally “slide layer,” describes a mélange, with or without fabric, interpreted to be formed by slope processes. In the second category are processes, such as fluid overpressuring and diapirism, that occur within a pile of sedimentary rocks, and result in disruption and mixing without necessarily penetrating to the Earth’s surface. Thirdly, there are processes related to faults that are rooted at depth in the lithosphere, including subduction zones and transform faults.

In attempts to distinguish between these potential origins, investigators have typically appealed to a variety of lines of evidence, studying both the internal fabric and structure of mélanges, and the external contacts and geometry of mapped mélange bodies.

Features and origin of blocks

Observations of the internal fabric of mélanges can provide information on the rheology of the blocks and matrix and may therefore help to constrain the mode of formation.

Many mélanges preserve evidence for the process of fragmentation that has produced blocks. In some cases it is possible to observe partially fragmented beds cut by brittle surfaces. These surfaces may be either extensional or shear fractures, that produce irregular shapes and trains of fragments derived from an original block or bed (e.g., Cowan, 1982). If fractures cross-cut grains, cements or veins in the blocks, this may indicate a post-lithification origin for the structures, and that fragmentation occurred at depth. Where extensional fractures occur, matrix may penetrate into the blocks producing veins that are partially or completely filled by shale. This has been interpreted as an indication of the presence of a fluid matrix, but in other cases it has been shown that matrix was already in a compacted state, with strong fissility, before it penetrated into veins (e.g., Waldron *et al.*, 1988). Whatever the state of lithification, it is clear that elevated fluid pressures can play a role in promoting brittle fracturing by reducing the effective normal stress on potential fracture planes.

Not all blocks are produced by fracturing. In some cases, disruption of bedding in sedimentary protoliths leads to the dispersion of individual grains or highly attenuated beds into the mélange matrix. Fragments produced in such circumstances have less angular outlines, typically appearing as lens shapes or “phacoids.” The presence of phacoids is an indication of deformation that was ductile at mesoscopic scale; however, phacoids in unmetamorphosed mélanges do not typically show evidence for intracrystalline plastic deformation at microscopic scale. In some mélanges, blocks are connected by highly thinned “wisps” representing attenuated beds (e.g., Byrne, 1984); microscopic examination indicates that such wisps are typically formed by disaggregation, and not by grain breakage or plastic flow (Brandon, 1989).

Some mélanges contain blocks from diverse sources, including intrusive igneous and metamorphic lithologies (e.g., ophiolites and blueschists) that cannot have formed in proximity to a lower grade or purely sedimentary matrix. Cloos (1982) suggests that such “exotic” blocks are incorporated by large-scale flow within an accretionary wedge. However, incorporation as large sedimentary clasts derived from fault scarps or mass flows that incorporate older rocks at the Earth’s surface is a possibility that is difficult to eliminate, especially in tectonically active environments such as subduction complexes and collision zones.

Fabric and origin of matrix

Matrix fabrics in mélanges are extremely variable. Some mélanges lack matrix fabric; in these cases it is generally clear that the matrix formed by flow of wet sedimentary material. In most cases some fabric is present, and typically this takes the form of a scaly foliation (Moore *et al.*, 1986), characterized by anastomosing planes surrounding lenticular bodies of fine-grained, fissile material. Foliation surfaces are typically polished and may show slickenside striations that indicate sense of shear. Some such surfaces may be traceable into faults or shear zones that dismember blocks. Larger scale fabrics may be present: in many mélanges the matrix is heterogeneous, and can be divided into domains of varying color, texture, etc., reflecting different protoliths. The domains are typically highly elongated in map outline, and may contribute an overall foliation to the map pattern, and an overall stratification to the mélange. Such stratification has been used as an indicator of sedimentary origin (Steen and Andresen, 1997), but it is quite possible to envisage the development of large-scale foliation during accretion and deformation in a subduction zone, so such inferences are probably unwarranted. Other mélanges display more continuous fabrics such as slaty cleavage or metamorphic foliation; in many cases it can be shown that these fabrics post-date the mixing and fragmentation processes and may be unrelated to the formation of the mélange.

Overall geometry of mélange units

Given the difficulty of using arguments based on internal fabric to distinguish between possible origins, arguments based on contacts and the overall geometry of mélanges often provide a better basis for distinguishing between possible modes of origin.

Most helpful are clear stratigraphic contacts either at the base or top of a mélange body. Brandon (1989) emphasizes evidence from depositional basal stratigraphic contacts in attributing an olistostromal origin to mélanges of the Pacific Rim Complex of Vancouver Island. Swarbrick and Naylor (1980) describe interbedded sediments between mélange units in Cyprus, that indicate that the mélange is clearly stratified. Pini (1999) describes tabular bodies with fabric that form part of a stratigraphic succession and are therefore identified as of sedimentary origin, despite the presence of scaly fabrics.

Mélanges of diapiric origin may also be identified based on large-scale geometry. Orange (1990) describes the variations in fabric within the Duck Creek mélange of the Olympic Peninsula, Washington, tracing a transition from margins with pervasive scaly foliation and inequant phacoidal blocks, to a core with poorly developed foliation, and equant, angular blocks. Using fold asymmetries, Orange (1990) is able to

demonstrate opposing senses of shear on opposite sides of the mélange, further supporting an origin by diapirism.

Mélange formation by tectonic processes in fault or shear zones is most easily demonstrated by regional scale cross-cutting relationships along fault zones. Pini (1999) was able to show such relationships for units in the Apennines, termed tectonosomes. Orange (1990) described the Hogsback mélange of the Olympic Peninsula, concluding that shear-zone origin is indicated by a combination of: consistent foliation in map-pattern, consistent fold vergence, increase in foliation intensity toward the center of a mélange, and tight clustering of clast long-axis directions throughout the unit.

Conclusion

Units described as mélange undoubtedly have a variety of origins. Field and thin-section evidence may provide information about the lithification state of the material at the time of fragmentation and/or mixing, but only in cases where there is clear evidence for prior burial and lithification can a deep-seated, tectonic origin be inferred. Many mélanges involve some process of deformation of wet or incompletely lithified material, either within a gravity-driven slump or debris flow, within a diapir, or within a tectonic accretionary terrain in which effective stresses are reduced by high fluid pressures. The products of these processes (boudinage, brittle fracturing, scaly fabrics) appear similar in all three settings. Under such circumstances, determining the origin of a mélange depends on careful recording of variations across the mélange body and documentation of contact relationships.

MICRITIZATION

Bathurst (1966) coined the term “micritization” in reference to a process of alteration of original skeletal grain fabric to a cryptocrystalline texture by repeated algal microborings and subsequent filling of the microborings by micritic precipitates. Bathurst was simply applying Folk’s (1959) term for cryptocrystalline carbonate (<4µm) micrite—a contraction of the words microcrystalline calcite—to describe a process of textural diminution in carbonate grains. In fact, Wolf (1965) used the term “grain-diminution” to describe the early alteration of crustose coralline algal cellular skeletons to micrite. Bathurst, however, did not accept recrystallized micrite in his definition of “micritization”, which he wanted to restrict to referring to the process of microboring and subsequent precipitation of micrite infill. Bathurst’s idea became very popular (e.g., Lloyd, 1971; Gunatilaka, 1976; Kobluk and Risk, 1977). Subsequently, Friedman (1985), pointed out that Folk (1959, 1962) introduced the term micrite to describe microcrystalline ooze matrix, not textural alteration. He felt that Bathurst and others were misusing Folk’s terminology.

Despite the concerns about the original intentions of authors when they introduced the terms micrite and micritization, Alexandersson (1972) indicated that there was a need for the broadest use of both terms. He proposed that the term micrite should no longer have “any mineralogical implications” (p.206) and it should be used simply as a textural term. Alexandersson further suggested that micritization should refer to an alteration “of a pre-existing fabric to micrite” with “no genetic implications” (p.206). To him, micritization

included all processes involving the destruction of an ordered crystallographic fabric to a disordered micritic texture, with either a decrease or increase of crystal size. Most recent studies of the alteration of carbonate grains have accepted Alexander's broad definitions (e.g., Land and Moore, 1980; Reid *et al.*, 1992; Reid and Macintyre, 1998).

As mentioned earlier, Bathurst (1966) suggested that the process responsible for micritization of carbonate grains was algal microboring and subsequent precipitation of micrite in open borings. Earlier studies based on light microscopy had concluded that the cryptocrystalline textures in many shallow-water carbonate sediments were the result of recrystallization (e.g., Illing, 1954; Purdy, 1963, 1968; Pusey, 1964; Winland, 1969). However, for almost two decades after Bathurst's initial report, shallow-water marine carbonates were generally thought to be stable, with micritic textural alterations formed by boring and infilling.

More recently, pore-water chemical studies have indicated that extensive alteration of carbonate sediments is taking place in shallow tropical waters (e.g., Morse *et al.*, 1985; Walter and Burton, 1990; Rude and Aller, 1991; Walter *et al.*, 1993; Patterson and Walter, 1994). In addition a series of detailed petrographic and mineralogical studies have illustrated that micritization by recrystallization is widespread in carbonate grains found on the seafloor of tropical shallow waters (Reid *et al.*, 1992; Reid and Macintyre, 1998). Macintyre and Reid also discovered that the original skeletal needles of the green alga *Halimeda incrassata* (Macintyre and Reid, 1995) and the porcelaneous foraminifera *Archaias angulatis* (Macintyre and Reid, 1998) are recrystallizing to *minimicrite* (crystals <1 μm

after Folk, 1974) while these organisms are still alive (Figure M11(A),(B)). *In vivo* micritization of carbonate skeletons is a textural alteration only and does not involve changes in mineralogy. In both of these studies the micritization process was thought to be related to the breakdown of the skeletal needles into their original polycrystalline aggregates or domains, which were deposited in organic envelopes that controlled the needle shape. Degradation of these organic envelopes and alternating conditions of precipitation and dissolution caused by reversals on CO_2 partial pressures associated with changes in photosynthesis and respiration in *Halimeda* (Macintyre and Reid, 1995) and algal symbionts in the foraminifera (Macintyre and Reid, 1998), may have resulted in the micritization of the skeletons of these living organisms.

Further studies of *Halimeda* and porcelaneous foraminifera grains deposited on the shallow tropical seafloor indicate that the micritization of skeletal needles continues after death, with extensive formation of *minimicrite* (Reid and Macintyre, 1998). As the micritization process continues, the anhedral equant *minimicrite* tends to increase in size to form subhedral blocky crystals of micrite (Figure M12). This continuing micritization of carbonate sediment grains can involve mineralogical changes and "together with concomitant cavity filling results in the gradual obliteration of skeletal elements and the formation of micritized grains with little evidence of original skeletal structure" (Reid and Macintyre, 1998, p.945). The processes responsible for this micritization of carbonate sediment grains may include organic alteration of pore-water chemistry, or reduction of high free surface energies associated with the increase in crystal size.

The role of microborers in the micritization process of sediment grains was re-introduced when lightly etched polished sections of micritized grains examined using scanning electron microscope (SEM) revealed the presence of multi-cyclic boring and concurrent filling of bore holes (Macintyre *et al.*, 2000; Reid and Macintyre, 2000). The endolithic cyanobacterium responsible for this boring and infilling activity is *Solentia* sp. This microborer does not limit its activity to the edge of grains but eventually reworks the entire grain with minimal damage the grain's outer walls (Figure M13(A)). The infilling cement consists of fibrous *minimicrite* crystals, which form banded patterns extending across the 5–10 μm diameter boreholes (Figure M13(B)) (Macintyre *et al.*, 2000). With the lack of open boreholes and the well preserved grain boundaries, it is very difficult in SEM and light petrographic microscope studies to distinguish between concurrent infillings of microborings and recrystallization

(B) Detail of cyanobacterial microborings showing banded minimicrite infillings.

in the formation of micritized carbonate grains (Reid and Macintyre, 2000).

Summary

- (1) Micritization of carbonate sediment grains in shallow-water tropical seas is widespread forming micritic grains, which commonly show no evidence of original structure.
- (2) Micritization of carbonate skeletons can be initiated when the organism is still alive.
- (3) The breakdown of original skeletal needles to form minimicrite in living organisms likely involves both the destruction of the organic envelopes, in which the needles are originally formed and changing internal chemical conditions. No mineralogical changes of the skeleton occur during this *in vivo* micritization.
- (4) The micritization of skeletal grains continues after skeletons are deposited on the seafloor. Postmortem micritization involves the formation of anhedral minimicrite and subhedral micrite and may include changes in mineralogy.
- (5) Driving forces for the micritization of sediment grains may include biological alteration of pore-water chemistry and inorganic reduction in free energy of crystal surfaces.
- (6) Microboring activity can also be an important factor in the micritization of carbonate grains. This can involve (a) formation of open boreholes and later precipitation of infilling cement, as described by Bathurst, or (b) concurrent infilling with little evidence of open boreholes. In the latter case, micritization by microboring is difficult to distinguish from micritization by recrystallization.

MICROBIALLY INDUCED SEDIMENTARY STRUCTURES

Coastal sedimentary systems of moderate climate zones are governed not only by physical dynamics like erosive tidal flushing or reworking by wave action, but also by biotic factors like sediment stabilizing or accumulating by epibenthic bacterial communities. The shallow-marine environments are colonized by benthic microorganisms, amongst those photoautotroph cyanobacteria are an abundant group (ecology: Whitton and Potts, 2000). With the aid of their adhesive and slimy “extracellular polymeric substances” (EPS, see for introduction Decho, 1990), epibenthic species attach to mineral grains, and they can even form thick, tissue-like, organic layers covering extensive areas of the sedimentary surface. Such bacterial “carpets” are termed “microbial mats” (definition of term see Krumbein, 1983; overview also in Gerdes and Krumbein, 1987; Cohen and Rosenberg, 1989; Stal and Caumette, 1994; Stolz, 2000).

Colonizing at the interface between sediment and water, cyanobacteria are able to react to sediment-affecting physical agents in different ways.

Responsive behavior of epibenthic cyanobacteria to physical sedimentary dynamics

During periods of no or low rates of sediment deposition, thick microbial mat layers develop. By growth, they smoothen out or level the original tidal surface morphology, and form flat bedding surfaces (compare Noffke and Krumbein, 1999). In close up on vertical sections through thick mat layers, the growing biomass drags upward mineral grains from the sedimentary substrate. The grains are separated from each other, and become oriented with their long-axes perpendicularly to the loading pressure (microbial grain separation; Noffke *et al.*, 1997).

Slow moving, suspension-rich bottom currents induce a vertical orientation of cyanobacterial filaments that trigger fall-out of sediment by “baffling, trapping, and binding” (Black, 1933). Over time, the sediment agglutinating microbial community grows upward (Gerdes *et al.*, 1991). In vertical section, this produces laminated intrasedimentary patterns.

In depositional areas of higher hydrodynamic energies, only thin microbial mats can grow. They cover surface structures, like ripple marks, without altering the original shape of the relief. Buried depositional surfaces are “imprinted” by the thin, former mat layers (Gerdes *et al.*, 2000, and references therein).

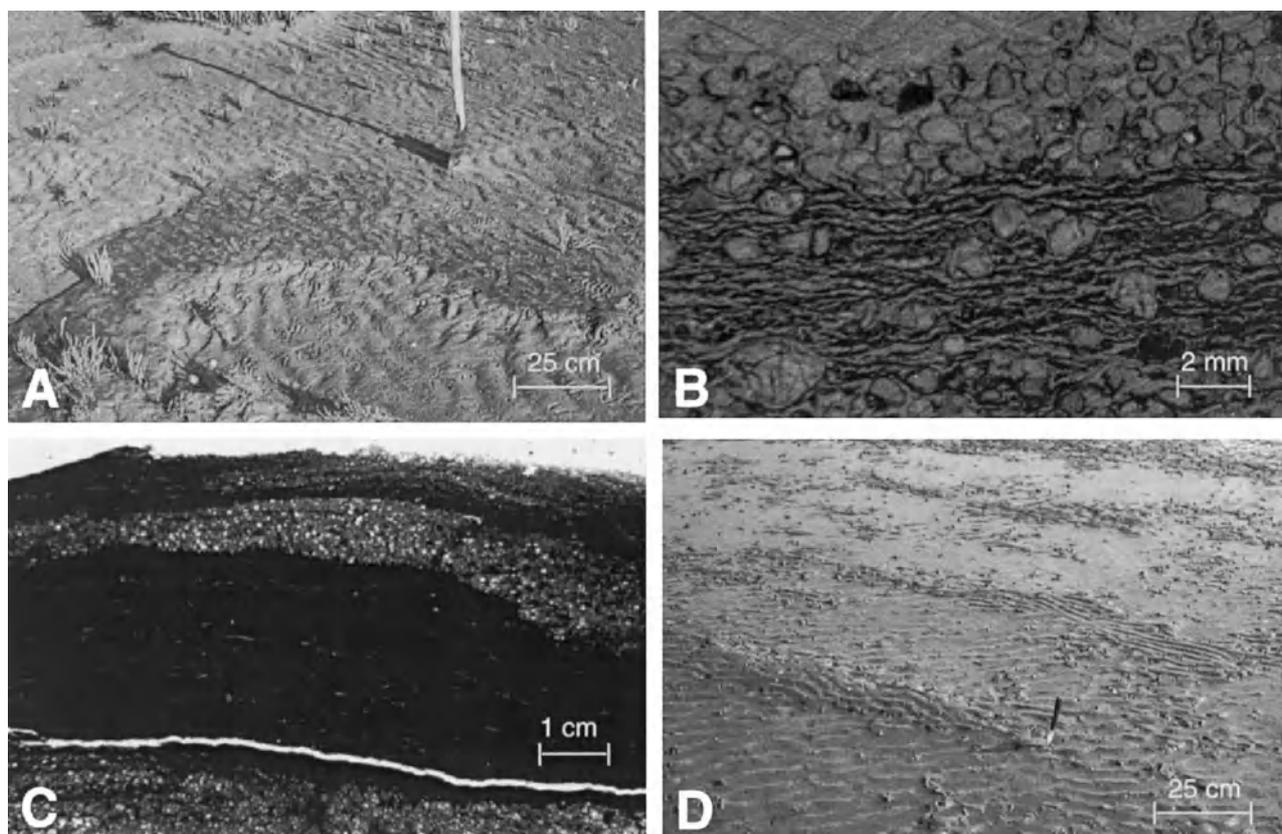

Figure M14 Microbially induced sedimentary structures in physical depositional areas of moderate climate zones—examples. (A) Sedimentary surface smoothened by microbial mat cover; (B) “Oriented grains” within microbial mat layer; thin section; (C) “Biolaminite”; thin section; (D) “Multidirected ripple marks”.

Only when subjected to strong bottom currents, mat-secured sedimentary surfaces are eroded, because the dense and coherent microbial mats seal effectively their substrate and increase resistance against erosion. Additionally, cyanobacterial layers prohibit exchange of gas between sediment and water. These effects are known as “biostabilization” (Paterson, 1994; Krumbein *et al.*, 1994; Paterson, 1997; Noffke *et al.*, 2001).

Microbially induced sedimentary structures

The responsive behavior of the mat-constructing microepibenthos generates a great variety of characteristic sedimentary structures. The structures differ significantly from biogene stromatolites we are familiar from chemical lithologies, and mineral precipitation plays no role in their formation.

Flat bedding planes originated by immense mat growth are termed “leveled surfaces” (Noffke, 2000; Noffke *et al.*, 2001), Figure M14(A). In the fossil record, they can be recognized as “wrinkle structures” (Hagadorn and Bottjer, 1997), where they document pauses in sedimentation (Noffke, in press). Characteristically, thin-sections through leveled surfaces reveal “mat layer-bound oriented grains”, that is mineral particles floating independently from each other in the organic matrix like a chain of pearls, Figure M14(B). They document former microbial grain separation, and pressure-related orientation (Noffke *et al.*, 1997).

Laminated intrasedimentary pattern caused by baffling, trapping, and binding are well-known as “biolaminites”, or, after consolidation, as “planar stromatolites” (discussion of terms by Krumbein, 1983), Figure M14(C).

Typical surface morphologies that are shaped by biostabilization interfering with erosion are “erosional remnants and pockets” (Noffke, 1999; fossil example: MacKenzie, 1968), or “multidirected ripple marks” (Noffke, 1998; fossil counterparts: Pflueger, 1999), Figure M14(D). Internal features are “fenestrae fabrics” (Gerdes *et al.*, 2000). “Sinoidal structures”, visible in vertical sections through the sediment, imprint former ripple mark valleys (Gerdes *et al.*, 2000; Noffke *et al.*, 2001; fossil example: Noffke, 2000).

Because the structures are formed syndepositionally by biotic-physical interference, they were grouped as an own category “microbially induced sedimentary structures” into the Classification of Primary Sedimentary Structures (Noffke *et al.*, 2001).

MILANKOVITCH CYCLES

Variations in the Earth's orbital parameters cause quasi-periodic, 10^4 – 10^6 year scale changes to occur in the incoming solar radiation, or insolation. These insolation changes are commonly known as *Milankovitch cycles*, after the Yugoslav mathematician who first described the cycles (Milankovitch, 1941). Milankovitch cycles have been linked to large-scale climate cycles and, in turn, to climate-mediated sedimentary cycles (e.g., Berger *et al.*, 1984; Einsele *et al.*, 1991; Shackleton *et al.*, 1999).

Earth's orbital parameters

The Earth's rotating axis of figure is tilted with respect to the Sun, Moon and the other planets. Consequently, the axis precesses mainly in response to the luni-solar gravitational attraction on the Earth's equatorial bulge, at a rate governed primarily by the Earth's shape, rotation rate, and Earth–Moon distance. In addition, the axial precession experiences gravitational perturbations from the motions of the other planets acting on the Earth's orbit (e.g., Laskar 1988, Berger and Loutre, 1990). Some perturbations modulate the distance and timing of the Earth's closest annual approach to the Sun (orbital eccentricity and longitude of perihelion), which together affect the year-to-year duration and intensity of seasonal insolation, or *climatic precession*, also called precession parameter, precession index, or precession–eccentricity syndrome. Variations in the Earth's *orbital eccentricity*, generated by interactions among these perturbations, give rise to small changes in the Earth's total annual insolation. Other perturbations cause the Earth's orbital plane to tip and precess (orbital inclination and longitude of the ascending node), thereby modulating the Earth's axial tilt angle, or *obliquity*,

relative to the Sun, and consequently, the Earth's latitudinal distribution of insolation.

The evolution of the Earth's orbital parameters over the past 10 myr is shown in Figure M15. The parameters exhibit quasi-periodic behavior with many closely spaced frequencies that are traceable to modulating effects from the planetary perturbations discussed above (see also Laskar, 1988, 1990). The relatively short time spans (<10 million years) covered by most stratigraphic sequences will usually involve analysis that averages over some of the more closely spaced modes. Current astrodynamical theory provides an accurate ephemeris back to *ca.* 16 Ma; for times prior to this, the theory can be used only in limited ways and then with extreme caution (Laskar, 1999).

Geophysical phenomena related to the Earth's tidal dissipation may have played a significant role in the long-term evolution of the orbital parameters. Specifically, the faster rotation rates, closer Earth–Moon distances, and higher ellipticities predicted for remote geologic ages would have involved faster precession rates, hence shorter periodicities for the climatic precession and obliquity (e.g., Berger *et al.*, 1992). On the other hand, some of the orbital eccentricity modes, for example, the 404 kyr cycle, are thought to have remained stable over the past 200 Ma, raising the possibility that they can be used as high-precision geochronometers (Shackleton *et al.*, 1999).

Earth's orbitally forced insolation

The insolation received at a specific terrestrial horizontal surface is determined by the Earth–Sun distance and elevation of the Sun in the sky, which together depend upon geographical latitude, time of day and position of the Earth along its annual orbit. From year to year, the orbital parameters alter the Earth–Sun distance and solar elevation angle on any given calendar day. The relative contributions of the parameters that force the insolation depend upon latitude and effective time(s) of forcing. This was first recognized by Milankovitch (1941), who showed that summer-time “caloric insolation” in the tropics is driven mainly by precession, but

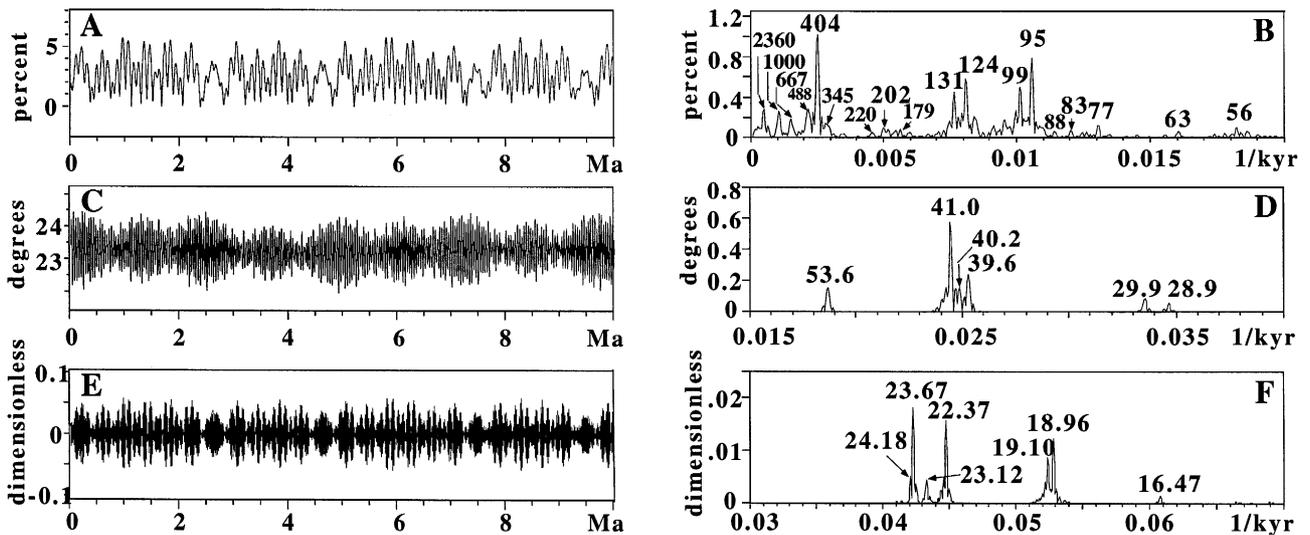

Figure M15 Earth's orbital parameters, 0 Ma to 10 Ma, according to the LA90 model (Paillard *et al.* 1996). (A) eccentricity series; (B) eccentricity spectrum; (C) obliquity series; (D) obliquity spectrum; (E) climatic precession series; (F) climatic precession spectrum. Labels indicate periodicity in kyr of significant harmonic components.

poleward mainly by obliquity. In fact, there are an infinite number of ways to compute orbitally forced insolation. For example, in the illuminated latitudes of Northern summer solstice, noon-time instantaneous insolation is characterized interannually by dominant precession forcing (Figure M16(A)). In contrast, insolation integrated over all daylight hours has increased obliquity forcing toward the North Pole (Figure M16(B)), and insolation integrated over midday solar elevations only results in dominant obliquity forcing everywhere (Figure M16(C)). These and other insolation calculations for equinoctial times and over other time intervals are discussed in Berger *et al.* (1993). How the orbital parameters are ultimately captured in the sedimentary record depends on what form of orbitally forced insolation drives the climatic variables that control sedimentation.

Milankovitch cycles in stratigraphy

Evidence for orbital forcing in the stratigraphic record is found in the geochemistry and lithology of sediment in both marine and continental deposits. In Milankovitch studies, the most intensely researched sedimentary parameter is the oxygen isotope ratio ($\delta^{18}\text{O}$) in foraminifera, which is thought to track global ice volume and, to a lesser extent, ocean temperature and salinity. The Plio–Pleistocene benthic $\delta^{18}\text{O}$ record in sediments cored from the tropical eastern Atlantic seafloor shows predominant obliquity forcing that would be expected of high-latitude insolation-forced glaciation cycles (Figure M17(A)). Eolian dust variations in the same sediment

are dominated instead by climate precession (Figure M17(B)), which is interpreted as evidence for low-latitude insolation forcing of the monsoon over Africa. At same time, continental loess sequences of north central China developed with an oscillating concentration of iron-rich minerals linked to pedogenesis, detected as a magnetic susceptibility signal. At the Xifeng-1 locale, the signal exhibits a strong obliquity mode up to *ca.* 600 ka, when it abruptly gains an extremely high amplitude ~ 100 kyr mode—possibly a response to the rapid expansion of the Northern continental glaciations—causing the power spectrum to be heavily weighted in the eccentricity band (Figure M17(C)). These records represent only three of many scores of Plio–Pleistocene sedimentary sequences collected over the past 20 years that have yielded signals consistent with Milankovitch forcing.

While knowledge about the orbital parameters prior to ~ 16 Ma is uncertain, all indications are that the parameters were operating in a recognizable form at least as long ago as the Triassic. For example, the Ca/Fe ratio of Late Eocene

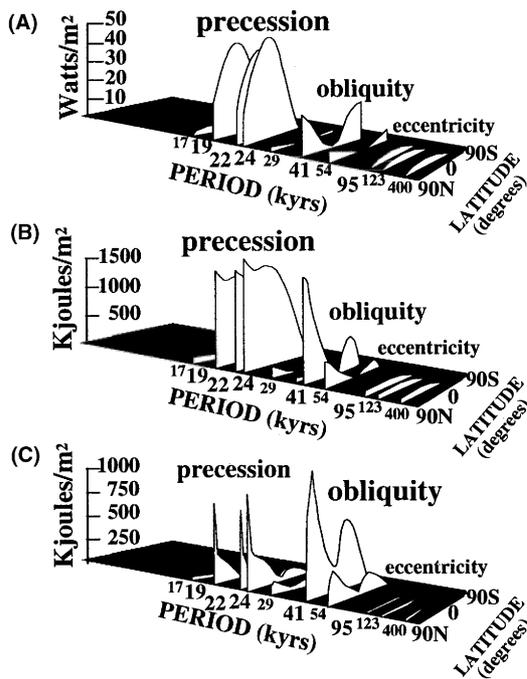

Figure M16 Global variability of the interannual insolation on 21 June, 0 Ka to 150 ka, in spectral amplitude, as a function of latitude ϕ . (A) instantaneous insolation at noon (zenith angle $z=0$); (B) daily integrated insolation; (C) noon zenith-class ($z=[\phi-\delta, 90^\circ-\phi]$, where δ is solar declination on 21 June) integrated insolation. Locations $\phi > 90^\circ\text{S}$ — δ experience polar winter night and receive no insolation. Redrawn from Berger *et al.* (1993, Figure 14).

(E) Late Cretaceous magnetic susceptibility series, DSDP site 516F, untuned, ~ 81 Ma to 82 Ma, referred to the GPTS of Cande and Kent (1992) (Park *et al.*, 1993). (F) Late Triassic depth rank series, Lockatong formation, Newark Basin, *ca.* 5 myr long, untuned (Olsen and Kent, 1996).

sediments from offshore Florida tracks carbonate versus terrigenous content, and shows a mixed obliquity–precession response consistent with middle latitude insolation forcing (Figure M17(D)). Late Cretaceous carbonate-rich sequences from the Brazil Basin were deposited with a strong climatic precession signature (Figure M17(E)). Other basinal sequences extending back into the Early Cretaceous have also been found to contain depositional patterns with orbital modes (e.g., Herbert *et al.*, 1995). Likewise, evidence for orbital forcing occurs in Jurassic stratigraphy (Shackleton *et al.*, 1999). Finally, one of the most striking examples of Milankovitch cycles occur in the Triassic continental deposits of eastern North America. Here, lacustrine cycles occur as facies alternating between deep perennial lake to playa, and have been interpreted as flooding-drying responses to climatic precession. The spectrum of the depth rank series constructed from the facies logs indicates that the cycles were strongly modulated by the orbital eccentricity (Figure M17(F)).

Summary

The Earth's orbital parameters dictate the amount of insolation received at the Earth's surface. The orbitally forced insolation that comes to affect climate change can take on many different forms that depend on the latitude and time of forcing of the responding climate; these are the Milankovitch cycles. Geochemical and lithological variations of many ancient cyclic sedimentary sequences have signals that are consistent with Milankovitch cycles.

MIXED SILICICLASTIC AND CARBONATE SEDIMENTATION

Introduction

Every student of the sedimentology and stratigraphy of carbonates early on appreciates the unique aspects of carbonate deposition and the fundamental differences between carbonate and siliciclastic (or clastic) deposition (e.g., Wilson, 1975; Walker and James, 1992). The majority of carbonate deposits forming today in tropical and sub-tropical settings and their ancient counterparts (e.g., rimmed shelves, ramps, etc.) require warm, shallow (within the photic zone), clear water (low turbidity) of near normal salinity which is well circulated by currents, waves and tidal processes to insure proper oxygenation and nutrient levels. The requirement of low turbidity, clear water generally means that where clastic sediment is supplied coevally to a carbonate environment, deposition of the two sediment types is generally mutually exclusive, such that the “carbonate factory” favors or is restricted to areas free of “polluting” clastic materials. However, the mixing of clastic and carbonates occurs today in several Holocene settings, including the Belize shelf, the northeastern shelf of Queensland, Australia (landward of the Great Barrier Reef), and along coastal environments within the Persian Gulf (Wantland and Pusey, 1975; Maxwell and Swinchart, 1970; Purser, 1973). In addition, the mixing and interbedding of carbonate and clastic sediments is extremely common throughout the stratigraphic record (Mount, 1984; Budd and Harris, 1990; Doyle and Roberts, 1988; Lomando and Harris, 1991; Dolan, 1989), where mixing occurs in a

variety of environments: coastal and inner shelf; middle and outer shelf (reef); slope to basin environments. Mixed deposits occur in temperate as well as tropical shelf environments.

Late Paleozoic mixed clastic-carbonate successions have probably received the most study of all mixed deposits. For example Carboniferous "cyclothem" of the Midcontinent and southwestern USA and Europe (e.g., Weller, 1930; Duff *et al.*, 1967; Wilson, 1967; Rankey, 1999) provide the underpinnings of models for cyclic stratigraphy at all scales. From these and additional studies of mixed clastic-carbonate strata of the Permian Basin in the New Mexico and Texas, the concept of "cyclic and reciprocal sedimentation" (Van Siclen, 1958; Wilson, 1967; Silver and Todd, 1969; Meissner, 1972) was introduced to explain the origin of mixed clastic-carbonate shelf-to-basin cyclic deposits. This critical concept has evolved to provide the foundation upon which present-day "sequence stratigraphy" is predicated (e.g., Sarg, 1988). From an economic viewpoint, mixed deposits are significant reservoirs of oil and gas (e.g., the Permian Basin, USA), and studies of the high-resolution stratigraphic architecture of mixed clastic-carbonate sequences has led to the discipline of reservoir characterization (e.g., Kerans and Tinker, 1997).

An insightful approach to the problem of mixed deposits has been set forth by Budd and Harris (1990) who recognize basically two types of mixed deposition: (1) mixtures due to spatial variability, where mixing occurs principally by lateral facies mixing of coeval sedimentary environments (see also Mount, 1984); and (2) mixtures due to temporal evolution in sedimentation, induced by sea-level changes and/or variations in sediment supply, causing a vertical variation in the stratigraphic succession. Mixing can occur through a wide range of scales, from millimeters to kilometers, respond to a wide range of processes, and can be influenced by all orders of cyclicity. Trends of mixing can vary along both depositional strike and dip, ranging from coastal environments to deep basinal settings.

Important factors that influence mixing include: (i) climate: humid (fluvial-deltaic clastic input onto a carbonate shelf; e.g., the Belize shelf) versus arid (eolian influx; e.g., the Persian Gulf); (ii) sediment supply of clastic material and source terrain (proximal clastic marine shelf with a linear source versus distal tectonically active, uplifted source terrain with a fluvial, point-sourced input); (iii) transport mode (episodic storm mixing versus lowstand-induced sediment by-pass of a carbonate shelf); (iv) shelf width and paleobathymetry (carbonate ramp, distally-steepened carbonate ramp, reefal rimmed high-relief platform, etc.) (v) oceanographic factors such as prevailing wind- and storm-driven currents, tidal range, etc.; (vi) relative changes in sea-level which will act to either trap clastic sediments updip on the shelf during relative highstands or promote clastic influx onto and across a carbonate shelf during relative lowstands (Van Siclen, 1958). The rates and magnitudes and of such relative sea-level changes will determine the amount and style of mixing, such that mixed clastic-carbonate cycles and sequences will vary markedly from "ice-house" periods in geologic history to "greenhouse" periods.

Styles of clastic and carbonate mixing

Depositional mixing and stratigraphic partitioning occurs at all scales and to all degrees. For instance, such mixing may occur: (1) within a single bed whereby minor amounts of

clastic material are dispersed within a carbonate bed with a low degree of "lithologic separation" (e.g., Cambro-Ordovician peritidal facies of North America, Read and Goldhammer, 1988; Goldhammer *et al.*, 1993); (2a) within a single heterolithic bed ("ribbon rocks") whereby carbonate material (ooids, peloids, etc.) comprises coarser-grained planar and ripple lamination which alternates with fine-grained clastic material (shale; e.g., Cowan and James, 1993, 1996); (2b) within a single heterolithic bed ("ribbon rocks") whereby clastic material (mature quartz sand) comprises coarser-grained planar laminations and ripple lamination which alternates with thin intercalations of finer-grained carbonate mud (e.g., Demicco and Hardie, 1994); (3a) between vertically juxtaposed beds within high-frequency cycles (meter-scale; "fifth"- and "fourth"-order) with a high-degree of lithologic separation (e.g., Pennsylvanian "cyclothem"; Wilson, 1975; Driese and Dott, 1984; Atchley and Loope, 1993; Yang, 1996; Rankey *et al.*, 1999); (3b) between vertically juxtaposed bedsets within low-frequency sequences (decameter-scale, "third-order") with a high-degree of lithologic separation (e.g., basinal portions of "composite sequences" of the Permian of west Texas; Silver and Todd, 1969; Meissner, 1972; Tinker, 1998); (4a) between vertically juxtaposed beds within high-frequency cycles (meter-scale; "fifth"- and "fourth"-order) with a low degree of lithologic separation, such that vertical contacts between clastics (typically shale and carbonates are gradational within a cycle (e.g., Grotzinger, 1986; Osleger, 1991; Cowan and James, 1993); (4b) between vertically juxtaposed beds within low-frequency sequences (decameter-scale, "third-order") with a low degree of lithologic separation, such that vertical, as well as lateral contacts between clastics (typically shale) and carbonates are gradational within a cycle (e.g., Grotzinger, 1986; Chow and James, 1987; Sonnenfeld and Cross, 1993); (5) laterally within a single bed as time-equivalent facies changes (spatial mixing; Houlik, 1973; Shinn, 1973; Mount, 1984; Brett and Baird, 1985; Grotzinger, 1986; Calvet and Tucker, 1988; Adams and Grotzinger, 1996; Cowan and James, 1996); and (6) as regionally extensive km-scale depositional systems that can replace one another in time and space (Aitken, 1978; Byers and Dott, 1981).

Models of clastic and carbonate mixing

Spatial variations in coeval environments

In his summary of mixed clastic-carbonate systems, Mount (1984) highlighted four types of mixing of spatially separated carbonate and clastic environments for shallow Holocene shelf settings: (i) punctuated mixing—where sporadic storms and other extreme, high-intensity periodic events transfer sediment across highly contrasting environmental boundaries separating clastics from carbonates; (ii) facies mixing—where sediments are mixed along diffuse borders between contrasting facies, for example nearshore clastic belts and offshore carbonate reefs or ooid shoals; (iii) *in situ* mixing—where the carbonate fraction consists of the authochthonous death assemblages of calcareous organisms that accumulated on or within clastic substrates, for example foram-mollusc assemblages within a subtidal clastic shelf; and (iv) source mixing—where admixtures of carbonates into a clastic-dominated setting are generated in response to uplift and erosion of proximal carbonate terrains.

Punctuated and facies mixing are the most prevalent, and both will lead to the lateral mixing of coeval juxtaposed environments, producing lateral interfingering of clastics and carbonates. Spatial mixing invokes local autocyclic processes, and thus occurs along a timeline in an ancient deposit. Spatial mixing requires no changes in relative sea-level.

Holocene examples that are affected by spatial mixing include: (a) humid fluvio-deltaic systems proximal to a carbonate shelf, such as the nearshore clastic belt and offshore barrier reef of the Belize shelf (Wantland and Pusey, 1975), and the northeastern Australian shelf and offshore Great Barrier Reef (Maxwell and Swinchart, 1970; Flood and Orme, 1988); (b) Arid eolian dunes proximal to carbonate ramp system, such as along the leeward southeast coast of the Qatar Peninsula in the Persian Gulf (Shinn, 1973); (c) the deep axial trough of Persian Gulf, where fine-grained clastics (clays and silts) from the Tigris-Euphrates delta accumulate adjacent to fine-grained carbonates of the Persian Gulf carbonate ramp system (Purser, 1973). Ancient examples include Cambrian ramp-to-deeper shale shelf transitions in the Upper Cambrian intra-shelf basin of the Virginia Appalachians (Markello and Read, 1981), and the Upper Muschelkalk (Triassic) outer ramp deposits of the Catalan Basin (Spain; Calvet and Tucker, 1988), among others (Houlik, 1973; Mount, 1984; Brett and Baird, 1985; Grotzinger, 1986; Sonnenfeld and Cross, 1993; Adams and Grotzinger, 1996; Cowan and James, 1996).

Temporal variations in environments or evolution in sedimentation

Over geologic time, mixtures may occur as a result of relative sea-level change and/or variations in sediment supply, which causes vertical variations in the stratigraphic succession of facies. The concept of "cyclic and reciprocal sedimentation" (Van Siclen, 1958; Wilson, 1967; Silver and Todd, 1969; Meissner, 1972) which invokes changes in relative sea level was developed to explain the origin of mixed clastic-carbonate shelf-to-basin cyclic deposits. This model suggests that carbonate sedimentation dominates during relative sea-level highstands and rises in sea-level, when clastics are trapped updip in flooded fluvial valleys and narrow clastic shelves while the carbonate factory is fully operational. Additionally, during such highstands, rates of carbonate sedimentation (between 20 cm to 30 cm/1000 years in lagoons to greater than 1 m/1000 years in reefs and shoals) are sufficient to keep pace with typical background subsidence rates such that the subtidal factory outcompetes any clastic influx. Shelfal carbonate deposits are typically thick and the coeval carbonate basin is starved and only thin carbonate deposits are preserved.

Clastic sedimentation dominates during lowstands when carbonate shelves are subaerially exposed and thus largely shut down. During a relative fall in sea-level, widespread braided fluvial systems, shallow deltas or nearshore shallow marine clastics may migrate across the shelf completely and ultimately source deep-water clastic deposits (Van Siclen, 1958; Wilson, 1969; Meissner, 1972; Rankey *et al.*, 1999), or clastics may migrate laterally by longshore processes. During true lowstands, fluvial-deltaic systems may incise the antecedent shelf (e.g., the Pleistocene of Belize, Choi and Ginsburg, 1982) and funnel clastic sediments to point-sourced submarine canyons into the basin in humid climates, or in arid climates, eolian dunes may migrate across subaerially deflated carbonate shelves, often truncating older carbonate features (Goldhammer *et al.*, 1991;

Borer and Harris, 1991; Atchley and Loope, 1993). During such lowstands, the subaerially exposed carbonate shelf may be karstified and often completely by-passed such that clastic material is deposited on adjacent slopes and basinal areas as onlapping sheets, wedges and fans that terminate against the defunct carbonate slope, for example the Upper Permian Capitan depositional system of west Texas and New Mexico (Bebout and Kerans, 1993; Tinker, 1998). Such basinal deposits may be then subject to reworking by contour-hugging bottom currents. The cyclic and reciprocal model further suggests that lowstand shelfal clastics will be thin and coeval basinal clastics (submarine fans, turbidites) will be much thicker. However, the height and steepness of the underlying carbonate slope is an important consideration in determining the character of any lowstand clastic sand body. Alternatively, if an updip clastic source is limited, basinal settings may receive little or no clastic material and only record the shutdown of the carbonate platform in the form of submarine diastems (e.g., mineralized, cemented hardgrounds).

The character of the lowstand clastic sediments reflects both proximity to the source area and depth of deposition. For example in the late Devonian of the Canning Basin (western Australia), Southgate *et al.* (1993) record the evolution of several Frasnian-Famennian "third-order" depositional sequences whereby the shelfal carbonates are completely bypassed. Within the basin, however, there exist several sequences of lowstand clastics each composed of basin-floor fans, slope fans, and prograding complexes, which overall form a fining-upward trend from basal coarse clastics to fine-grained mudstone and shales vertically within a particular lowstand. This grain-size trend is interpreted to depict initial stream rejuvenation upon initial subaerial shutdown of the carbonate shelf, followed by subsequent waning of coarse proximal sediment supply as renewed transgression of the shelf occurred.

An unequivocal and detailed example of mixed clastic-carbonate sedimentation driven by sea-level changes is provided by the Quaternary reefs in the southernmost Belize lagoon (Choi and Ginsburg, 1982). During the last glacial maxima, eustatic sea-level was about 120 m beneath its present day level, exposing and karstifying much of the Belize carbonate shelf. As coastal rivers advanced seaward onto the shelf, they created morphological features including fluvial and submarine channels, fluvial channel bars, levees and deltaic lobes. Subsequently, when eustatic sea-level rose, such clastic features with positive morphologic relief served as nucleation sites and nodes for the initial development of Holocene reefs and other biogenic carbonates. Another example, provided by Davies *et al.* (1989) illustrates the cyclic and reciprocal nature of Cenozoic clastic-carbonate sequences developed in response to eustasy along the northeastern shelf of Australia (Figure M18).

Conclusions

Mixed siliciclastic and carbonate sedimentation is a common theme throughout the stratigraphic record. Holocene systems enable us to examine mixtures due to spatial variability, where mixing occurs principally by lateral facies mixing of coeval sedimentary environments. Studies of spatial mixing emphasize process and provide clues to examining ancient mixed successions. Where such examples are cyclically interbedded, they are often attributed to temporal evolution in

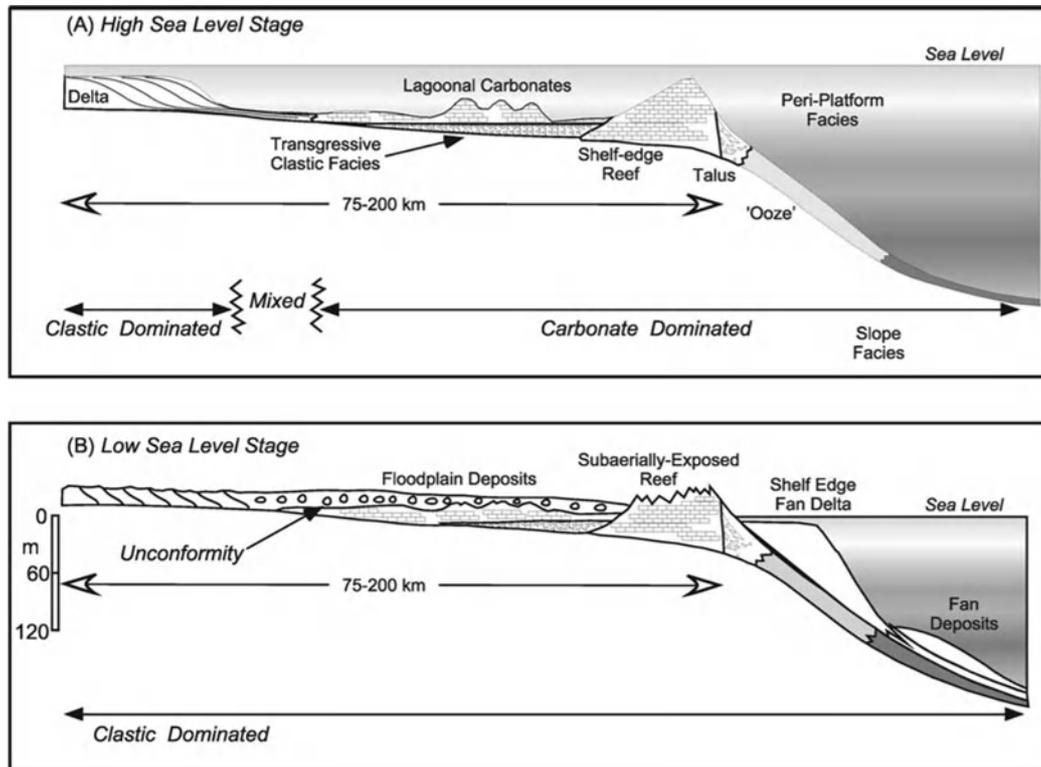

Figure M18 Schematic sections showing high (A) and low (B) sea-level control on the stratigraphic evolution and sedimentary geometry of shelf facies in the central Great Barrier Reef province. Note the predominance of siliciclastic facies in the lowstand. Modified from Davies *et al.* (1989).

sedimentation, induced by sea-level changes and/or variations in sediment supply, causing a vertical variation in the stratigraphic succession. Many, if not most, ancient mixed successions can be interpreted as examples of cyclic and reciprocal sedimentation, controlled by cyclic variations in relative sea-level.

MIXED-LAYER CLAYS

Clay mineral crystals contain from a few to few hundred silicate layers (1:1 or 2:1, dioctahedral or trioctahedral, see figure 1 in *Illite Group Minerals*), spread over tens to thousands

of nm in the a^* and b^* crystallographic directions and stacked parallel in the c^* direction. Layers are either electrically neutral or they have a negative charge, resulting from isomorphous substitutions within the tetrahedral and/or octahedral sheet. The charged layers are bounded by interlayer cations or sheets of interlayer hydroxide. If the interlayer cations are hydrated, the interlayer (smectite or vermiculite type) has swelling properties (i.e., it may change thickness and accept organic molecules). Clay crystals may contain non-identical layers and/or interlayers, that is, be mixed-layered (interstratified). Mixed-layering is defined as random and characterized by the ordering parameter (Reichweite) R_0 if there is no preferred sequence in stacking of layers (or interlayers) A and B. If some sequences are privileged, such mixed-layering is called ordered (R_1 if ABAB... , R_2 if AABAAB... etc.; details in Moore and Reynolds, 1997). If only one type of sequence is present, the mineral is called regular. Such minerals (only of R_1 type) exist in nature; they are given separate names, and their origin is explained by different mechanisms. Other names of mixed-layer clays are combinations of the components' names, for example, illite-smectite.

Mixed-layering is identified and quantified by means of X-ray diffraction (XRD), supplemented by chemical analysis and electron microscopy. OOI XRD reflections of mixed-layer minerals appear between positions of corresponding reflections of pure components. The nature of layers and swelling interlayers is revealed by XRD of specimens heated or treated with different exchange cations or organic solvents. Computer modeling of such diffraction effects is used to measure layer ratios and ordering (Moore and Reynolds, 1997). If the imaging conditions are properly selected, and a distinctive and stable under vacuum spacing of the swelling interlayer achieved, the nature of layers can be identified in transmission electron microscope by measuring the layer spacings and obtaining AEM chemical analyzes of the bulk crystal.

Mixed-layer clays with smectitic interlayers can be separated in dilute suspensions, by infinite osmotic swelling along these interlayers, into individual layers or blocks of layers bounded by stable interlayers (fundamental particles, see figure 1 in *Illite Group Minerals*). When such separation is stabilized in the solid state, the mixed-layering diffraction effect is destroyed and such blocks of layers (individual layers do not diffract coherently) can be studied by XRD, as if they were pure end member clays (Eberl *et al.*, 1998).

Mixed-layer clay minerals are most often intermediate products of reactions altering pure end-member clays. Mixed-layer minerals occur in natural environments ranging from surface to low-grade metamorphic and hydrothermal conditions (see review by Šrodoň, 1999). The majority of mixed-layer clays have been synthesized in the laboratory. Most often, the mixed-layering is 2-component, but more complicated interstratifications have also been documented. Mixed-layer clays are either di or trioctahedral; di/trioctahedral interstratifications are very rare. Most mixed-layer clays contain swelling interlayers of smectite type (typical of diagenetic alteration) or vermiculite type (typical of weathering alteration). In general, the weathering reactions producing mixed layering are reversals of the corresponding high temperature reactions, but the reaction paths are quite different. Solid-state transformation and dissolution/crystallization are the two mechanisms responsible for the formation of different mixed-layer clays.

Dioctahedral mixed-layer clays

Kaolinite–Smectite (K–S)

K–S is known from Recent soils developed on acidic to alkaline parent rocks and from the corresponding paleosols (Hughes *et al.*, 1993). If present in sedimentary rocks, K–S is most often a detrital component, which survives burial temperatures of at least 100°C. Its further evolution has not been traced. Most probably, the abundance of K–S is underestimated, because it is difficult to detect and also can be misidentified by XRD as halloysite.

K–S is typically very fine-grained, randomly interstratified, and it always evolves from smectite (origin from kaolinite has not been reported). The reaction has been reproduced in laboratory and is promoted by a high supply of Al.

Illite–Smectite (I–S)

I–S is the most abundant, most ubiquitous and the most studied mixed-layer clay. I–S can be detected by XRD in the $<0.2\ \mu\text{m}$ fraction of almost every sample of sedimentary rock. Smectite or recycled I–S is stable in sedimentary environments and starts to react toward more illitic composition at about 70°C. This reaction has been originally interpreted as fixation of potassium in smectitic (swelling) interlayers plus solid-state transformation of layers, but currently it is explained as dissolution of smectite layers and simultaneous nucleation of 2 nm illite particles in the swelling interlayers and subsequent growth of these particles (see *Illite Group Minerals*).

Evolution of I–S is continuous, always from R_0 (decreasing to ca. 45 percent smectite), through R_1 (down to 20 percent S), to $R > 1$, and finally to illite. Regular 1 : 1 interstratification (K-rectorite) is rare, known mostly from hydrothermal environments. Chemical evolution involves enrichment of I–S in K (and in some cases NH_4) and Al, a decrease in cation exchange capacity, and liberation of Ca, Mg, Fe, and Si, which contribute to quartz and carbonate cementation. I–S crystals have a lognormal distribution of thickness with the mean of 5–6 layers/crystal, which increases below 20 percent S.

The percent S in I–S is an indicator of diagenetic grade, analogous to organic indicators (see *Maturation, Organic*), and can be used for evaluation of maximum paleotemperatures and their K–Ar dating (see *Illite Group Minerals*). Because of its abundance and swelling layers, I–S controls mechanical, electrical and exchange properties of most shales.

Weathering of illite or I–S is not a simple reversal of diagenetic reaction and is not well understood. Smectite can be produced directly by dissolution-precipitation (Šucha *et al.*, 2001) or by transformation *via* ordered illite-vermiculite and vermiculite (Wilson and Nadeau, 1985).

Glaucanite–Smectite (G–S)

Minerals in monomineral glauconite pellets are iron-rich analogues of I–S. Glauconitization (see *Glaucony and Verdine*) proceeds at the sediment/water interface, through the same steps of random and ordered interstratifications as illitization. Regular interstratification has not been observed. Anomalous chemical characteristics of some samples may result from interlayering with berthierine (iron serpentine). Data are lacking on the evolution of G–S during burial diagenesis.

Na-illite–smectite (rectorite)

This mineral is reported only as a regular variety, called rectorite (allevardite in older literature), and its geological occurrence is restricted to hydrothermal alteration zones and low-grade metamorphic rocks. In both cases, it is associated with pyrophyllite and occasionally with cookeite, which indicates crystallization temperatures of ca. 280°C. Sometimes, Ca may prevail over Na, which is expressed by the presence of margarite-like layers. Rectorite crystals are always very thick, as is evident from their very sharp diffraction peaks and electron microscope images.

Chlorite–smectite (tosudite)

This clay is known only as a regular interstratification (named tosudite) of beidellite (Al-smectite) and di-dioctahedral chlorite (donbassite), or di-trioctahedral chlorite (sудоite, Mg-rich; or cookeite, Li-rich). Likewise, only regular interstratification was produced in hydrothermal experiments. Tosudite is known from hydrothermal, pneumatolytic, or low-temperature metamorphic alteration zones, in association with dioctahedral chlorite, serpentine, rectorite, and pyrophyllite. This association suggests that tosudite forms during acid hydrothermal alteration, at temperatures well below 350°C.

Mica (Illite)–Vermiculite (I–V)

I–V is a product of potassium removal during weathering of micas and illite. It occurs as thick crystals, with tri-dimensional order, frequently with almost regular interstratification. The vermiculitic layer may evolve toward smectite, giving rectorite-like clay (Wilson and Nadeau, 1985). Partial chloritization of vermiculitic interlayer is, however, more common. Clays of this type are called soil vermiculites, soil chlorites, chlorite intergrades, or swelling chlorites (Barnhisel and Bertsch, 1989). Formation of soil vermiculites is a massive phenomenon in temperate climates and this material has been identified in fresh sediments. Its further evolution during diagenesis remains obscure.

Trioctahedral mixed-layer clays

Serpentine–Chlorite (Sp–C)

Sp–C is exclusively Fe-rich clay (berthierine-chamosite). It is known to form in Recent “verdine facies” sediments in very shallow tropical seas (see *Glaucony and Verdine*), often as sandstone grain coatings. Either both layers crystallize simultaneously, or chloritization starts at the sea bottom. During burial, the berthierine content decreases and disappears completely at the transition zone between shales and slates. Sp:C ratio can be now quantified precisely by XRD (Moore and Reynolds, 1997). Regularly interstratified Sp–C is called dozyite. Sp–C interstratification is accompanied by interstratification of polytypes.

Chlorite–Smectite (vermiculite) (C–S)

C–S is the second most common mixed-layer mineral in sedimentary rocks, often occurring together with I–S, and is characteristic of hypersaline facies, volcanoclastic rocks and graywackes (Reynolds, 1988). Unknown from Recent sedimentary environments, C–S is a product of smectite

chloritization at elevated temperatures (commonly during burial diagenesis). The process is not fully analogous to illitization of smectite and is not fully understood. Instead of a continuous process, overlapping succession of three phases is observed: C–S with <20 percent C, corrensite (regular interstratification), and C–S > 85 percent C. Diagenetic corrensite appears in sedimentary rocks at 60°C to 160°C. A decrease of Si and interlayer exchangeable cations, and an increase of tetrahedral Al accompanies chloritization.

Weathering of chlorite commonly produces corrensite as an intermediate phase. Distinct from diagenetic corrensite, this mineral is characterized as chlorite-vermiculite, that is, high-charge corrensite. The final product is vermiculite (*q.v.*), which may evolve latter into smectite. The process involves loss of Fe and Mg to such extent that the end member vermiculite is strictly dioctahedral (Proust *et al.*, 1986).

Mica–Chlorite (M–C)

M–C is typically close to regular interlayering and the mica component is almost exclusively biotite. All M–C minerals occur as big crystals producing excellent quality electron microscope images. The majority of described occurrences are from hydrothermally altered rocks or the products of low to medium-grade regional metamorphism of granite, gneiss, basalt, or pelites. M–C may form both by alteration of biotite and chlorite.

Talc–Smectite (T–S)

T–S clays are known from saline lake and hot-spring deposits, weathered ophiolites and dolomites. They are frequently associated with sepiolite. Full range of interstratification was reported (Wiewióra *et al.*, 1982), including regular alietite. The temperature of formation (hot springs) and solution chemistry are probably the factors responsible for the variation in expandability. It remains unclear whether the reaction proceeds from smectite to talc, or *vice versa*, or in both directions.

Mica–Vermiculite (M–V)

M–V is a common product of K-removal during weathering of biotite. The reaction is easily reproducible in laboratory. The complete compositional range is known (Pozzuoli *et al.*, 1992), including a regular variety (hydrobiotite). Little is known about the behavior of M–V at the subsequent stages of the rock cycle.

MIXING MODELS

In general, sediments are not faithful recordings of the history of sedimentary input at a given location because they are subject to a variety of postdepositional processes that can alter their composition, structure, and therefore the apparent record. Foremost amongst these processes is widespread mixing of sediments by biological or physical agents. Geologists, geochemists, biologists, and engineers often find it necessary to quantify the effects of mixing on the distribution of *solid* sedimentary components. For example, the fate of a buried contaminant can be controlled by its unanticipated release from the sediments by mixing. In addition, isotopic distributions can be significantly affected by mixing, such that estimates of sediment accumulation rates become highly skewed to unreasonably large values if the influence of mixing is not taken into account.

Correct prediction of the effects of mixing can be obtained through mathematical models; these models are based on the

principle of mass/chemical species conservation, and their mathematical forms depend on the particular assumptions made about the nature of the mixing. For example, mixing due to the random movement of small infauna, the feeding of head-down (conveyor belt) species, the infilling of vacated burrows, and the resuspension of sediment by clams or waves all generate different types of sediment motions and, in principle, these differences are reflected in different mathematical forms for the appropriate mixing model (Boudreau, 1997). However, in practice, workers in this field tend to use a simple array of models, that is, *well-mixed* models, *diffusive* models, and *nonlocal* models. In addition, these models can be distinguished further on the basis of the nature of the inputs they require and outputs they produce. Thus, models can be either of *forward type*, where the user inputs all parameter values and expects a prediction of the distribution of a sediment component with space and/or time, or they can be of *backward type*, where parameters or the input history are calculated from the observed depth profile of a sediment property.

Well-Mixed Models. Mixing can be so intense that the sediment component has uniform distribution (concentration, C) in the mixed layer. For example, the distribution of ^{14}C often exhibits a surficial zone some 4 cm to 10 cm thick of constant “age”, which reflects relatively fast mixing compared to the half-life of this isotope. This type of mixing will cause homogenization of input signals to the sediment and add long tails of the signals when they enter the sediment record. An example is schematically illustrated in Figure M19.

When mixing is so intense, the concentration of the homogenized component, C (mass or numbers per unit volume), in the mixed layer is given by

$$\frac{dC}{dt} = \frac{F_{in}(t) - wC}{L} - R \quad (\text{Eq. 1})$$

where t is time, $F_{in}(t)$ is the input (flux) at the sediment–water interface (mass or numbers per unit area and time), w is the burial velocity relative to the sediment–water interface (length per unit time), L is the depth of the surficial layer that is mixed, and R represents any sources or sinks for the component within the mixed layer, for example, radioactive decay of an isotopic tracer (mass or numbers per unit volume and time). Equation 1 balances the temporal change in concentration in the mixed layer (left-hand side) with the sum of the input at the

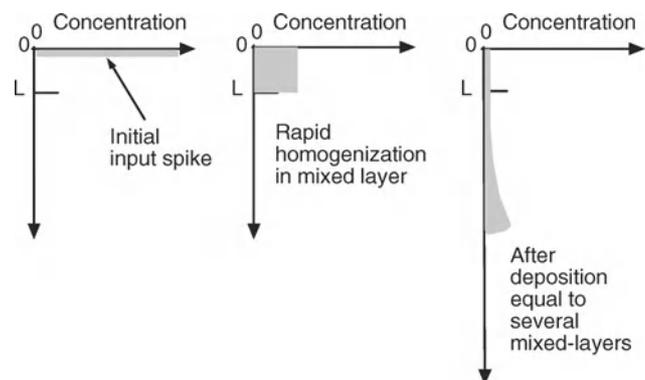

Figure M19 Schematic evolution of a concentration spike deposited at the interface of a sediment with a well-mixed layer of thickness.

interface, the output (burial) at the base of the mixed layer, and the net production (consumption) by sources and sinks on the right-hand side.

Diffusion Models. Mixing is often not strong enough to homogenize the active layer, and in this case the concentration of the sediment component will also be a function of space, as well as time. The most popular model in this case likens the effects of mixing to those of diffusion (see *Chemical Diffusion*), whereby mixing imparts small random motions to the sediment particles. The mathematical form of this model is, at constant porosity,

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} \left(D_B \frac{\partial C}{\partial x} \right) - w \frac{\partial C}{\partial x} - R \quad (\text{Eq. 2})$$

where, x is depth in the sediment, D_B is the mixing coefficient, analogous to the molecular/ionic diffusion coefficient (length squared per unit time), and the other terms are as in equation (1). Here the temporal change at a given depth (left) is the result of a balance (right) between the effects of mixing, burial and reaction.

Equation 2 is typically applied to isotopic data in the mixed zone to obtain D_B , as the accumulation rate w generally cannot be extracted unambiguously from such data. Assuming steady state ($\partial C/\partial t = 0$), constant parameters, $R = \lambda C$ ($\lambda =$ decay constant), and $w^2 \ll 4\lambda D_B$, the solution to equation (2) is

$$\ln[C(x)] = -(\lambda/D_B)^{1/2}x + \ln[C(0)] \quad (\text{Eq. 3})$$

where $C(0)$ is the concentration/activity at the sediment–water interface. An example fit of equation 3 to $^{210}\text{Pb}_{\text{ex}}$ data to get D_B is illustrated in Figure M20.

A large marine data base of D_B values, calculated as above, is available; this data indicates that D_B is correlated to the sediment accumulation velocity w , i.e.,

$$D_B = 15.7w^{0.6} \quad (\text{Eq. 4})$$

so that this equation may be used in situations where D_B cannot be calculated from data.

Nonlocal Models. Biological organisms commonly displace sediment in ways that can hardly be thought of as diffusive, i.e., small scale and/or random. In such cases another type of

model must be employed, wherein the biological mixing acts like related sources and sinks of material (see Boudreau, 1997, for mathematical details). This allows sedimentary components to be transported large distances through the alimentary canal of large infauna and by directed (non-random) motions. For example, with these models it is possible to describe situations dominated by head-down deposit feeder, a.k.a. conveyor-belt feeders, where the organisms ingest sediment at depth and defecate it at the sediment–water interface; the resulting feeding voids are filled-in by compaction. A similar model can account for effects of burrowing fiddler crabs in marshes, and a nonlocal model can explain persistent subsurface maxima in radioactive isotopes in some sediments as a result of subsurface defecation.

Nonlocal models differ fundamentally from the other two models in how they operate on abrupt temporal change in the composition or structure (e.g., laminations) of sediments. In both the well-mixed and diffusion models, such discontinuities are very rapidly lost, which begs the question how any such changes can be preserved in biotic sediments. Nonlocal models, in contrast, are not as effective in dissipating these structures, and their chances of survival are much higher. As the geologic record abounds with many such changes, this fact argues that real mixing is probably nonlocal in character. In addition, nonlocal mixing can actually act to segregate sediment components.

Forward and Backward Models. The two groups do not constitute alternatives to the above models, but reclassifies them in terms of what the model produces. In forward models, we solve the equations given above for C , and to do so we must input values of the parameters, that is, w , D_B , etc., and the flux at the interface, $F(t)$. This type of model describes the sensitivity studies common in the geochemical literature. With inverse models, we start with observed values of C , and then run the equations “backwards” to solve for either the value of a chosen parameter or the input function. Least-squares regression analysis of isotope data to obtain values of w or D_B in sediments is an example of a simple inverse model as in Figure M20. Other more impressive applications have included objective proof of gasoline-based lead reduction in sediments and the need for the use of nonlocal models (see the examples reviewed in Boudreau, 2000).

MUDROCKS

Introduction

Mudrocks are one of the several names for fine-grained, argillaceous sedimentary rocks, also broadly called shales and mudstones, all of which consist mostly of terrigenous clay and

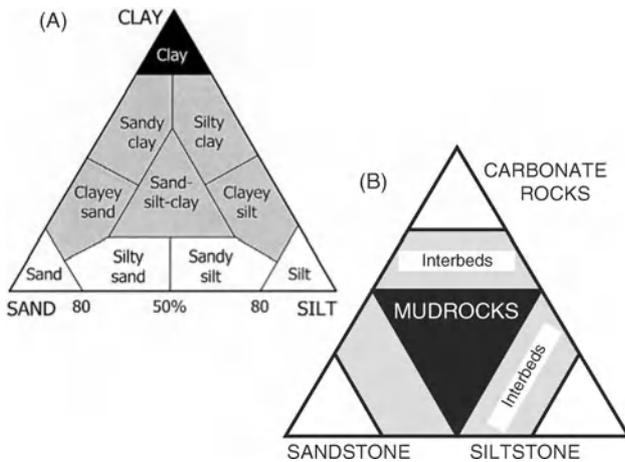

Figure M21 (A) Terminology for muddy unconsolidated mixtures (Shepard, 1954, figure 7); and (B) the three most common lithologic transitions of mudrocks.

silt along with some carbonate and organic matter. Mudrocks occur either as thin beds or in thick sections, but some siltstones, sandstone, or carbonate beds are nearly always present and rare is the section of mudrocks that does not pass laterally into interbedded carbonates or sandstones somewhere along its limits (Figure M21). Mudrocks thus may form but a small part of a deposit or almost all of it with names such as London Clay Formation, Rhinestreet Shale, Quamby Mudstone Group, Cambridge Argillite, etc.

Mudrocks deserve attention for many reasons. They are the most abundant of all the sedimentary rocks, they occur throughout the geologic column in all the major sedimentary environments, and are less studied and understood than either carbonates or sandstones. Thus there is much to learn about and from them. Unlike carbonates and sandstones, whose modern deposits have received much attention and play an important role in interpreting ancient analogs, much more of our understanding of mudrocks is based on studies of the ancient.

From a scientific viewpoint, understanding the origin of mudrocks has the potential to tell us much about ancient environments of deposition and how they may have changed throughout geologic time. Thought of in this manner, mudrocks, and sandstones nicely complement one another in the study of earth history—sandstones provide information about source rocks and their plate tectonic setting and the paleo-hydraulics of sand transport into a basin, whereas mudrocks are keys to the paleo oxygen levels of the basin, and through their microfauna and body fossils, insights to its paleo-circulation system, environment of deposition and possible paleoclimates. Exceptionally, they are also rich *Lagerstätten* for fossils such as the famous Cambrian Burgess Shale Formation of the Canadian Rockies, because in a muddy basins fossils may be quickly buried by a slurry, may die and fall into toxic bottom waters free of scavengers and, because the low permeability of mud minimizes dissolution by migrating acid solutions, escape much diagenesis. Add to this information from the study of interbedded carbonates and

sandstones and a truly comprehensive and integrated view of earth history can be obtained.

Practical uses abound as well. Mudrocks serve as the source of nearly all oil and gas, have many uses ranging from barriers to fluid flow (confinement of toxic waste, caps for aquifers, and seals for petroleum traps) to bricks, china, tooth paste, cosmetics, catalysts to decoloring agents and hundreds more. It is fair to say that without mud and mudrocks, modern life as we know it could not exist—all this having started from sun dried bricks some 6,000 years ago. And, mudrocks, because of their propensity to compact, expand, or fail, also demand special attention in modern construction.

The literature of mudrocks is vast and widely scattered, because so many researchers have different interests in them—basin analysis (petroleum and stratiform ore deposits), biology and paleontology, construction, their role in environmental protection, organic, and inorganic geochemistry, industrial minerals and products, sedimentology, and many more. Four recent texts include those by Chamley (1989), Weaver (1989), O'Brian and Slatt (1990) and the two volumes of Schieber *et al.* (1998), which contain 30 research and review articles and many references. Much of the earlier literature is found in Potter *et al.* (1980).

Texture and nomenclature

By convention, the fine-grained sediments include both silts and clays and it is, in fact, their relative proportions that are used to classify them texturally (Table M3). There are several competing systems of nomenclature for mudrocks, the board general genetic term for fine-grained argillaceous rocks, but all depend on the relative proportions of clay and silt. Once this is understood, it becomes easy to use the different systems. When the clay fraction (less than 4 microns) forms more than 67 percent of the rock, the terms *claystone* or *clayshale* are used; when the clay fraction forms 33–66 percent, the terms *mudstone* or *mudshale* are used; but when silt (>4 microns) forms 67 or more percent, the term *siltstone* is used. This important “purity” distinction is easily carried out in the field as a first approximation by putting a small piece between the teeth and determining its grittiness. Fine carbonate is also common in many mudrocks associated with limestones or dolomites and locally mudrocks may also be siliceous or phosphatic. Color is exceptionally variable ranging from black to brownish black through many shades of gray (the most common) to red and purple and even whitish gray and thus far more variable than other sedimentary rocks. And, unlike sandstones and carbonates, the colors of mudrocks have much genetic significance.

Processes

Sources of clay and silt

The immediate source of the clay and silt fractions of mudrocks are soils and preexisting mudrocks. Weathering in soils is favored by high rainfall and good drainage, which together remove cations from complex silicates formed at high temperatures to make progressively simpler clay mineral structures stable at the earth's surface. Where weathering is incomplete because of either insufficient rainfall or high steep slopes, clay and silt compositions closely reflect

Table M3 Describing mudrocks^a after Stow (1981)

Basic Terms				
<i>Unlithified</i>	<i>Lithified/non-fissile</i>	<i>Lithified/fissile</i>	<i>Proportions & grain size</i>	
Silt	Siltstone	Siltshale	> $\frac{2}{3}$ silt-sized ^b	
Mud	Mudstone	Mudshale	silt & clay mixture	
Clay	Claystone	Clay-shale	> $\frac{2}{3}$ clay-sized ^c	
<i>Texture</i>	<i>Composition</i>			
Silty	Calcareous, siliceous, carbonaceous (all >10%), pyritiferous (1 to 5%)			
Sandy >10%	and ferruginous, micaceous, and fossiliferous			
Pebbly				
<i>Stratification</i> (bedding, if >1 cm & lamination, if less)				
May be parallel, wavy (rippled), cross-laminated, graded, continuous-discontinuous, bioturbated, or deformed (use appropriate combinations)				
<i>Metamorphic equivalents</i>				
Argillite	Slightly	metamorphosed/non-fissile	silt and	
Slate	Metamorphosed/fissile		clay	
Pelite	Either argillite or slate		mixture	

^a More than 50% terrigenous of which more than 50% must be smaller than 63 microns; ^b 4–63 μm ; ^c <4 μm

source rocks, but where rainfall is abundant, soil drainage good, and slopes low, the resulting fine debris mostly consists of kaolinite and quartz (silica, aluminum, and iron oxides) and only poorly reflects source rock composition. Thus, *residence time* in the source area is all important for mudrock composition and is ultimately linked to tectonic stability. The volume of fines depends on relief and rainfall—a combination of high relief and rainfall (monsoons against a high Himalayas) produces large volumes of debris whereas low rainfall and low relief (Sahara craton), high rainfall and low relief (Amazon craton) or wide carbonate landscapes produce but little.

But source rocks also need some consideration too when fines are considered. Advanced weathering of granite and gneiss yields a kaolinite-rich clay fraction plus coarse and fine quartz silt, whereas volcanic rocks yield fines rich in unstable glass, feldspar, and amphiboles that transform rapidly into zeolites and smectites. Low grade metamorphic rocks, on the other hand, especially the greenschist facies, tend to yield micas, illites, chlorites, and silt and fine sand-sized quartz and feldspar. It also appears that most fines travel in jumps as streams rework their alluvium; that is, most of their time is spent in storage on the floodplain. This implies that headwater mineralogy may alter down stream, especially on warm, wet stable cratons. Another major source of the silt fraction of mudrocks is wind erosion of deserts (Sahara, central Asia, and north China) to deposit loess, which may have been far more important in pre-Devonian times before extensive plant cover. And finally, some clay minerals in mudrocks are authigenic such as the illites and chlorites formed in deep burial whereas palygorskite (saline lakes and seas) and glauconite (shallow shelves) are formed on sea bottoms. In addition, some quartz silt may be born in place at temperatures well below 90°C from the diagenetic alteration of opaline quartz of biogenic origin. Although deciphering the proportions of detrital to authigenic components of a mudrock can at times be difficult, it seems safe to say that most of the clay and silt fraction of mudrocks is detrital and that much comes from the erosion of

preexisting mudrocks and siltstones. Ultimately, however, most is derived from the weathering of granites, gneisses, volcanics, and low-rank metamorphic rocks.

Transport

Differential transport is responsible for the segregation of the large volumes of clay and silt that form the world's mudrocks and, on a much smaller scale, it is differential transport that also segregates by particle size and shape the clay minerals of one clay bed from another—an all important distinction in the mining and utilization of clays for their many diverse industrial uses.

In all of these, virtually all the clay fraction is transported in suspension by either wind or water as is much of the fine silt fraction, whereas coarser silt and sand, are transported intermittently by saltation. Fifteen microns seems to be an important size for the hydraulic behavior of silt—experimentally it has been found that below 15 microns most silt is deposited as planar lamination whereas above 15 microns small scale bedforms develop.

In both wind and water it is the upward component of turbulence, v_u that prevents a suspended particle from settling to the bottom. The magnitude of this component is roughly proportional to the average velocity of the flow so the stronger the flow, the greater v_u and the larger the size of the particle that can be suspended. In detail, the criteria for suspension is $v_u > w_s$ where w_s is settling or fall velocity which is given to a good approximation by Stokes Law for small particles as

$$w_s = \frac{1}{18} \frac{d^2 g}{\mu} \Delta\rho \quad (\text{Eq. 1})$$

where d is particle diameter, $\Delta\rho$ is the density difference between particle and fluid, μ is dynamic viscosity, and g is gravity.

As particle size decreases, so too does the downward driving force acting on it. Consequently, particles a few microns in diameter have exceedingly small fall velocities, remain suspended by the weak upward components of turbulence in gentle currents for weeks and are thus carried great distances. It is this small fall velocity of clay and fine silt that is responsible for the great lateral continuity of many mudrocks, be they thick or thin. Stokes law is also the key control on the concentration of organic matter that occurs commonly in mudrocks, bottom oxygen levels permitting. The low density of most organic matter permits it to preferentially settle to the bottom in quiet water along with the clay fraction to produce organic rich shales—the source beds for petroleum. Because clays and organic material settle together in quiet water, the mudrocks of a topographic low—those deposited in a protected paleo sinkhole, in a gentle sag on the seafloor, or abandoned channel or canyon—are nearly always thicker, darker colored and more clay- and organic rich than lateral equivalents outside the low.

Several observations are needed about Stokes law. First, it only applies to single spherical particles smaller than about 180 micrometers settling in quiet, isothermal, nonturbulent water—hardly the conditions of clay flakes in nearly always turbulent natural flows. Thus predicted fall velocities are conservative ones. Still another complicating factor is that many, perhaps most, clays, and fine silts are transported not as single particles, but as loose, large, aggregates called *floccules*, *flocs* for short, which settle differently than single particles. Floccules are composed of networks of clay flakes, silt, fine skeletal debris and organic material all held together by organic slimes or, for the clay minerals, by ionic bonding. Floccules occur in streams, but are most common where fresh water mixes with saline. Saline water favors flocculation, because its positively charged sodium and negatively charged chlorine ions promote the attraction of clay particles. The large planar face surfaces of clay particles are negatively charged and thus brought together by sodium ions. Edge to edge bonding also occurs but, because the edges have both positive and negative charges, the process differs. Depending on the charge, there will be either an edge to face or face to face contact. In low pH environments, say the acid waters of a swamp, hydrogen ions are bonding agents for clay flakes. Finally and exceptionally, in semiarid climates expandable clays can aggregate to form sand-sized particles (peds) which locally form clay dunes and a few, rare alluvial sands. Biological aggregation also occurs in seas and lakes, is far more important, and is called *pelletization*—the product of infauna feeding on delicious organic-rich mud.

In sum, while both weak and strong currents can transport clay in suspension long distances, weak ones are necessary for it to finally settle to the bottom flocculated or not. This means quiet water, either shallow or deep is needed for deposition—a small lagoon fed by a muddy river, a temporary lake on a flood plain during spring floods, a deep lake in a rift, a deep shelf whose bottom is rarely stirred by storm waves, or an oceanic trench only reached by distal, slow moving turbidity currents that deposit thin graded muddy laminations.

It appears that much, perhaps most, transport of clay and silt is episodic. On land this equates to floods—maximum sheet wash erosion of slopes, gullies, and stream banks provides high suspended concentrations and volumes in streams while in lakes and seas, episodic storms and turbidity currents play a comparable role.

Sedimentary structures

Mudrocks and sandstones share the same types of sedimentary structures—hydraulic, chemical, and biologic. These differ only in abundance and scale, all the hydraulic ones in mudrocks being much smaller, because of weaker currents. Thus mudrocks mostly have lamination rather than beds (By convention all stratification thinner than 10.0 mm is called *lamination* and that thicker, *bedding*).

Lamination in mudrocks is mostly seen by variations in proportions of silt and clay, but is also defined by thin carbonates (pelagic rain or algal mats?), by minor textural variations within muddy layers and exceptionally by variations of organic matter (kerogen). Lamination takes many different forms from rare, silty planar streaks only a few grains thick in almost completely muddy sections to almost all siltstone, where each siltstone is separated by a thin clay parting—with all possibilities in between. Individual laminations may be continuous or discontinuous, wavy, or planar, massive, or graded, inclined (cross laminated) or convoluted, random, or rhythmic. Rhythmic lamination is typically defined by alterations of clay and silt and less commonly by carbonate. The presence or absence of lamination in mudrocks is used to divide them into two broad classes—those that have lamination (classically called *shales*) and those that lack lamination and are massive (often called *mudstones*). In several black shale basins individual laminations as well as packets of them have been convincingly correlated more than 100 km after cores were X-radiographed, thus demonstrating a virtual total lack of bottom currents.

Several different processes are responsible for absence of lamination in mudrocks. The principal control is the amount of bottom oxygen that inhibits benthonic organisms from scavenging on or in muddy bottoms and thus destroying primary stratification. In ancient basins paleo oxygen levels are approximated by noting the degree of bioturbation and how it varies with the color, pyrite, and organic content of the mudrock. Lighter mudrock colors, less pyrite and less organic material typically are found as bioturbation increases and lamination decreases. A few massive mudrocks also are the product of muddy slurries that flowed along the bottom, and exceptionally, some are formed by deposition from denser than normal suspensions.

The term *blocky* is used to describe the weathering of a massive, poorly, or non-laminated mudrock. Two other terms are often used in the description of mudrocks, *fissility* and *parting*. Fissility refers to the fanlike separation of one lamination from another during weathering. Thus, while fissility is not a primary sedimentary structure it reflects one. For example, well, and uniformly laminated mudrocks may become paper like (*Blätterton*) upon weathering as their individual laminations separate one another by swelling of expandable clays. An argillite, on the other hand, is usually so well indurated that its laminations do not separate one from the other upon weathering. The term *parting* is used for a single lamination separating more massive lithologies above and below. X-radiography is needed to see the full details of the physical, chemical, and biological structures of many muds, although careful observation of weathered outcrops captures most details.

Present on the bottoms of some thin silty laminations are small flutes and load casts plus borings, traces, and impressions made by bottom dwellers. The orientation of flutes and

cross-lamination provides useful insights to the paleocurrent pattern of ancient shaly basins, which can also be estimated from oriented wood, graptolites, ostracodes, and some elongate foraminifers. It is always good to remember that bottom currents exist in both oxygenated and poorly oxygenated basins, although in mudrocks, thin sections, and polished sections may be needed to see micro cross-lamination and flutes best. Current systems in ancient muddy basins have also, in a few instances, been inferred from their pattern of silt deposition (Jones and Blatt, 1984).

In sum, little is more important in the study of mudrocks than their sedimentary structures, especially when combined with examination of body and trace fossils. Sedimentary structures help us identify types of bottom currents such as distal turbidity currents, contour currents or hemipelagic rains of fine terrigenous debris. Relating abrupt vertical changes in the sequence of structures in a mudrock with the presence of weak discontinuities, changes in fossil assemblages, pyrite, or phosphate, clay content and color is the basis for recognizing the basin-center equivalents of major stratigraphic breaks that are common along basin margins.

Oxygen

The presence or absence of dissolved oxygen in bottom waters and in the first few decimeters of muddy bottoms is all important for the color, degree of bioturbation and abundance of oxygen sensitive minerals such as pyrite and siderite and organic matter (kerogen). The concept of stratification of the water column is needed here. The water of a lake or sea is described as *stratified*, when not uniformly mixed. This may be the result of temperature, density, or oxygen differences. Mudrocks are the best indicators of stratification of the water column in ancient basins.

Three states of oxygen are recognized: *oxic* (fully oxygenated) bottom waters (more than 1.0 ml O₂/l, Eh ≫ 0), *dys-oxic* water (1.0–0.1 ml O₂/l, Eh ≅ 0) and *anoxic* water (less than 0.1 ml O₂/l, Eh ≤ 0). The corresponding sediments are described as *aerobic*, *dysaerobic*, and *anaerobic*. The contact between these oxygen levels is called a *redox front* and is identified in sediments by changes in color or mineralogy (Figure M22).

Three possibilities exist at the sediment–water interface: the base of oxygenated water can be well above the bottom so the bottom is either dysaerobic or anaerobic, the contact may be at the bottom (dysaerobic) or oxygenated pore water can be below the interface. In addition, there may be small, separate, isolated redox fronts around isolated masses of buried organic matter such as a dead fish, in, and near burrows where animals introduced oxygenated water (as do fractures both early and late) and around roots. These locally discolor the sediment as iron is either oxidized or reduced.

The limits of 1.0, 0.1, and 0.0 ml O₂/l were established by observation of organisms, color, bioturbation, and lamination in modern sediments and serve well as *approximations* to the paleo oxygen levels of ancient muddy basins. As oxygen supply decreases—diversity of benthic fauna decreases, fossils become smaller and may be encrusted by pyrite or phosphate, bioturbation is less abundant and burrows become shorter and have smaller diameters (so lamination is better preserved), colors become darker (more preserved organic matter) and pyrite increases in abundance—all variations that can be easily seen and mapped either laterally or vertically in mud-rich

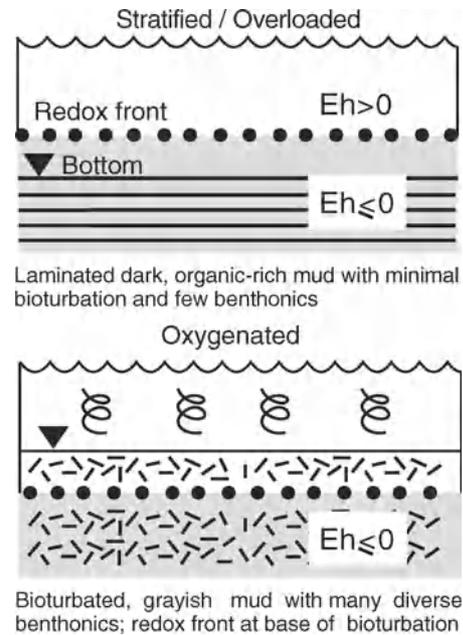

Figure M22 Two end members of a continuous bottom oxygen spectrum—*anoxic* (above) versus *oxic* bottom waters (below). Anoxic bottom waters may result from either a stratified water column or from organic overloading whereas oxic waters require ample turbulence and mixing.

sections. Collectively, these observations are fundamental to the paleo environments of mudrocks and their now vanished paleo-oxygen levels.

The above three principal outcomes depend on the current system of the basin and the local supply of organic matter. Where tidal currents and wind generated waves or an impinging oceanic current reach the bottom, there is turbulence and dissolved oxygen *unless* organic matter generated by dead pelagic organisms near the surface or woody debris transported into the basin overwhelms oxygen supply, a condition called *overloading*. Overloading is perhaps most familiar to us when we read about a fish kill in a stream with excess sewage. Exceptionally, major storms on a shelf oxygenate its water to deeper depths and intruding turbidity currents carry dissolved oxygen from the shelf into bottom waters far beyond its edge and temporally supply enough to support benthic organisms termed “doomed pioneers”. In addition to these dynamic factors, basin geometry, paleogeography, and climate also need consideration. Steep-sided, deep, narrow basins, a deep canyon cutting a shelf, or even a shallow sinkhole flooded by a rise in sea level are all protected from currents and thus poorly ventilated with oxygen-deficient waters. Paleogeography plays a role too (Figure M23). For example, faulting, or volcanism may isolate a gulf from an ocean or a coastal barrier may grow across a bay and create a stratified lagoon. All of the above possibilities for creating anoxia are favored by warm tropical, climates—warm water enhances metabolic rates so productivity will be greater than in cold water, given equal nutrients, which explains why most of the world’s major petroleum source beds were deposited within ±45° of the equator. Dense saline cold water at the bottom also inhibits mixing with surface waters.

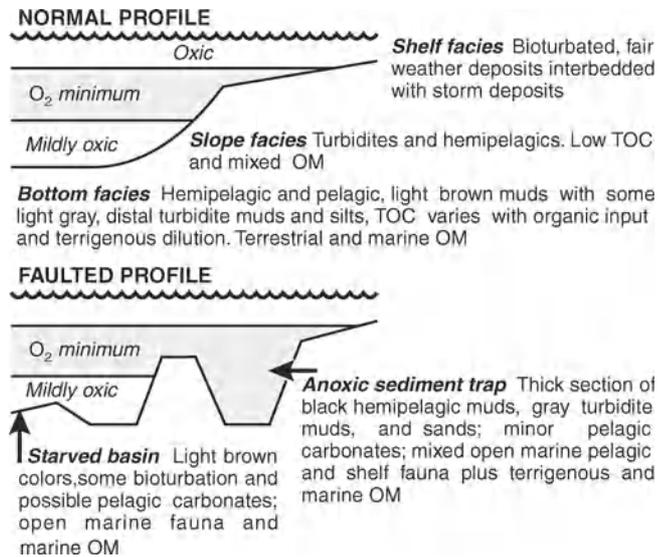

Figure M23 Some common conditions for anoxia (Adopted from Garrison, 1990, figure 3). If more subdued, the bottom topography of the faulted profile also applies to shelves.

Burial

There are both physical and mineralogical aspects to burial and understanding the physical compaction processes and its consequences is necessary before we can properly examine mineralogical changes during burial. What makes the compaction burial process of mudrocks so different from that of sandstones and carbonates is that its starting point is mostly water, clay minerals, fine silt and nearly always some organic debris—a very reactive mixture subject to much change as it is buried, compacted, and heated.

Mud compacts more than any other sediment, because it has the largest initial porosity, as much as 80–90 percent for soupy mud. This porosity initially decreases rapidly and exponentially with depth of burial after which decline is approximately linear. Simultaneously, pore water is expelled, and where siltstone and sandstone carrier beds are interbedded, they and early microfractures serve as conduits for its escape. Consequently, throughout such a subsiding section total pressure equals lithostatic pressure plus hydrostatic pressure. But where pore water cannot readily escape (lack of conduits, rapid sedimentation, or extra water released *in situ* from the transformation of smectite to illite), pore water pressure exceeds hydrostatic and *overpressure* results. When hydrostatic pressure exceeds lithostatic, a mud or mudrock will deform, flow, and perhaps even rise to the surface as a *mud lump* or *shale diapir*. Water expelled by compaction is a medium for petroleum migration and, because it is also rich in ions and dissolved organic acids, the framework grains of distant sandstone reservoirs may be altered by it and their cements dissolved to create secondary porosity or new cements may be precipitated. In this changing system, water is dominant in the first few meters, but as it is expelled with depth and porosity becomes less, both density and sonic velocity increase (except where mudrocks are overpressured or unusually organic rich) as does temperature (Figure M24).

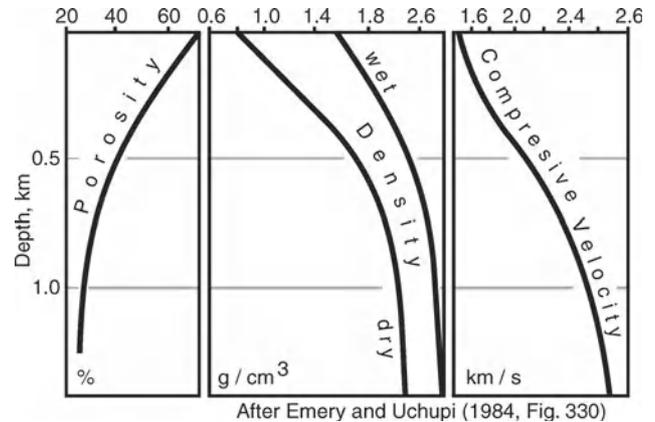

Figure M24 Interdependence of changes in porosity, density, and sonic velocity in the first 1,500 m of deep ocean, fine-grained sediments (After Emery and Uchupi, 1984, figure 330).

In the first few tens of centimeters of burial (beyond the reach of reworking by waves, currents and burrowing organisms), the pore water of mud rapidly becomes anoxic and becomes the principal driving force in early diagenesis. Important early diagenetic minerals are pyrite, siderite, and calcite.

Pyrite commonly develops very early in the burial of mud by the reaction of iron minerals with H_2S . This is produced by anaerobic bacteria using organic material as a feedstock or energy source to reduce dissolved sulfate in anoxic pore waters. In marine waters dissolved sulfate is widely available and, where organic matter is also, pyrite will form abundantly. On the other hand, if pore waters are initially fresh, dissolved sulfate has low abundance and is rapidly consumed by anaerobic bacteria so little pyrite forms—even when organic matter is present. It is this initial difference in availability of dissolved sulfate that explains why pyrite is much more abundant in marine rather than freshwater mudstones, why the C/S ratio helps distinguish them, and why low sulfur coals are common in alluvial deposits, whereas high sulfur coals are closely associated with marine mudrocks and limestones. When pyrite forms early, it is thought to be small and disseminated, but when formed later, say around a dead organism buried under anoxic or dysoxic bottom waters, it is larger and less concentrated.

Decaying organic matter also generates HCO_3^- , which may precipitate siderite or calcite at or a short distance below the interface to form early concretions (commonly with a core fossil). Careful study of the carbonate chemistry and morphology of such concretions combined with mudrock color, fossils, types, and abundances of organics and pyrite seems essential for understanding the paleoenvironments of muds. Phosphatic nodules and ferruginous encrustments also occur early and are indications of slow sedimentation.

At depth, the driving force is temperature which causes a random mixture of detrital minerals and kerogen to move to a new mineralogical equilibrium in the presence of now concentrated pore water. Some key mineral transformations include smectite and mixed lattice clay minerals into illite and chlorite, volcanic glass into smectite clays, zeolites, and others, amorphous (opaline) silica into first opal CT followed by low quartz, diverse feldspars into albite, and the progressive

evolution of kerogen to yield first gas, then oil and finally dry gas. Crystallinity of the clay minerals also improves as temperatures rise. In a broad way, many of these transformations can serve as guides to burial history keeping in mind, however, that important variations will result from different geothermal gradients and how long the mixture remained at a given temperature range (its subsidence history).

The final result of the above processes is the transformation of a mud into a low permeability, low porosity, compact, tightly interconnected and inter grown, felt-like fabric of both neoformed and detrital clay minerals and quartz, commonly with some pyrite and even some supermature kerogen into a well indurated, lower Paleozoic or Precambrian mudrock.

Mudrock stratigraphy, environments, and basin fill

Although mudrocks occur in all the major depositional environments, they are most abundant by far in the marine and lacustrine realms, because they provide the best accommodation, the best traps, for fines—their wide areas of quiet water below wave base are the end of the line, so to speak, for the suspension transport of clay and fine silt from far distant headwaters. In seas and lakes, mud accumulates readily in bordering low-energy deltas and on shelves, slopes, and basin floors (notable is how closely the facies of deep rift lakes mimic deep marine facies). And, although far less abundant, mud also occurs in shallow lakes, alluvial deposits, on protected coasts, and in estuaries.

Mudrocks play an important role in understanding sedimentary basins and developing their resources. First of all, in marine and lacustrine basins they are likely to be the most widespread and continuous lithologies and thus are of great value for correlation; secondly, they are the very best lithology to study to infer paleo-oxygen levels (which are likely to be more regional than local even though many anoxic events are short lived) and thus are useful for correlation; thirdly, their silt content and gamma ray intensity provide rough proxies for distance from the shoreline (silty mudrock is more proximal, whereas more clay-rich is more distant); fourthly, mudrocks nearly always are the repository for rich assemblages of pelagic microfauna and spores; and finally, the study of their vitrinite reflectance gives a good indication of their thermal history after deposition. So to ignore mudrocks is to miss much in the study of sedimentary basins.

Shifting shorelines and changes in relative water depth in a lacustrine or marine basin best explain the origin, distribution, and kinds of their mudrocks. For example, pro delta mud, possibly even including some deposited by distal turbidity currents, occurs far inshore at highstands, but as shorelines retreat, perhaps even beyond the shelf edge, a low stand delta will develop far downdip intercalating near shore mudrocks with deepwater ones (Figure M24). Or, as relative sea level uses, thin transgressive organic-rich mudrocks (black shales) are likely to occur above a low-relief scour surface as mud is temporarily trapped inshore and in estuaries.

Today, the methodology of *sequence stratigraphy* is standard to identify the migration of relative water depths in lacustrine or marine basins (Bohacs, 1998). Recognition of two surfaces is essential to apply it—*flooding surfaces and sequence boundaries*. Flooding surfaces represent an increase in *accommodation* (space for deposition), whereas sequence boundaries represent a decrease. Flooding surfaces are identified by abrupt increases in water depths (more clay, less silt, more

open marine fauna and marine organic matter, etc.) as a result of either greater distance from the shoreline or an abrupt cessation of terrigenous supply. Consequently, deeper water deposits overlie shallower ones. Successive flooding surfaces define *parasequences*, which range from a few to many meters in thickness and it is always their mudrocks that record the *maximum flooding surface*. During such a highstand, far down dip, there is little or no sedimentation and a *time-rich condensed section* develops; where the bottom is well oxygenated, a hardground forms, but where it is not, organic-rich muds are deposited (toe of a cyclothem). Sequence boundaries, on the other hand, represent the converse—abrupt shallowing as evidenced by a disconformity (coarser silts and sand with cross lamination and scours and lags underlying above finer-grained deposits plus regional truncation below and onlap above). Both surfaces typically cover 100s to 1,000s of square kilometers and provide time lines for correlation. In proximal coastal deposits paleosoils and peats and coals help identify changes in relative sea level. Paleosoils, like their modern equivalents, need good drainage (low water tables, low stands), whereas coastal mires and peats require rising sea levels and water tables.

Gamma ray logging and organic content help identify flooding surfaces and sequence boundaries. More clay produces high gamma ray readings and less clay lower ones. In addition, both the abundance and kind of kerogen systematically vary as well; because a flooding surface marks deeper water and less detritus, the fines above it will have more total organic carbon and more marine kerogen (types I and II) above the boundary whereas the reverse is true for a sequence boundary (Creaney and Passey, 1993). The sedimentology of particulate organic matter (its size, sorting, and abrasion) also helps identify both surfaces (Tyson, 1995, table 25-2).

Combined use of sequence stratigraphy along with the identification and mapping of mudrock facies is needed to efficiently identify the depositional environment of mudrocks, the one nicely complementing the other. Sequence stratigraphy relates the local section to the big picture—where the section is in relation to basin center or edge and at the same time incorporates information about transitions from prior to subsequent environments (with or without stratigraphic breaks). Mudrock facies, on the other hand, are the key to the local interpretation of the section, because they provide information about current regimes, oxygenation, and water depths based on sedimentary structures plus the kinds, abundance, distribution (patchy or uniform), and preservation of body and trace fossils (Brett and Allison, 1998; Wetzel and Uchmann, 1998). Combine all of the above with the possible presence of early authigenic minerals—pyrite, siderite, calcite, glauconite, and phosphate plus total organic carbon and kerogen types—and rare is the mudrock section that cannot be interpreted (Figure M25).

Provenance

There are five mineralogical and chemical ways to determine the provenance of mudrocks—study their inter bedded sandstones and siltstones with thin sections, use heavy minerals from the sandstones and siltstones (and even possibly the mudrocks), identify, and systematically map their clay mineral composition, and study both their inorganic and organic chemistry. As with sandstones, the broad objective here is insight to their kinds of source rocks and their location,

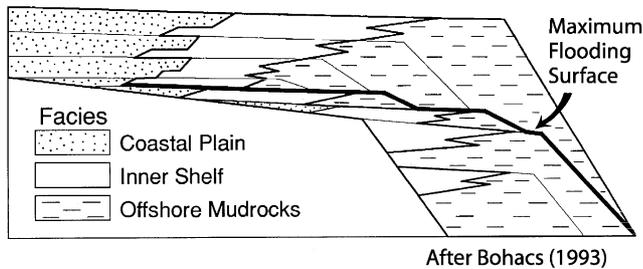

Figure M25 Idealized down-dip cross section of mudrocks in a basin with a well defined shelf break; note maximum flooding surface. Lightest lines indicate stacking patterns in mudrocks (After Bohacs, 1993).

relief, and weathering regimen. Commonly, this reduces to magmatic arcs, continent-to-continent collisions, or stable cratons, although, more specific targets are possible (Morton *et al.*, 1991). Where available, paleocurrent information should always be combined with such studies.

The most direct, simplest, and nearly always the most informative, is to apply the standard methods of thin section petrography to inter bedded sandstones and siltstones, which are commonly present. But thin section study of mudrocks has also been made with profit for provenance, especially to identify fine-grained volcanic debris (Zimmerle, 1998). Heavy minerals in mudrocks and siltstones, although rarely studied today, deserve more attention, especially to constrain geochemical investigations.

Identification and regional or basin wide mapping of clay mineral composition works well in modern muddy basins, where the relative abundance of two end members is the most telling—the kaolinite-rich facies (coarse-grained, and indicative of good drainage, ample rainfall and tectonic stability) and the smectite-rich facies (fine grained, volcanism, or frequent wetting and drying in the source region). The mapping of clay mineral distributions across a muddy basin largely depends on their differential settling by size (kaolinite is coarser and proximal, smectite finer and distal). Many applications to ancient basins show similar relations, although with deep burial and time, both kaolinite and smectite are replaced by illite and chlorite; hence burial diagenesis can blur original compositional variations across a basin.

Chemical study of mudrocks to determine their provenance is truly vast and includes bulk composition and selected ratios based on it, trace elements, the rare earths and the types of organic matter. Chemical study seems most appropriate where interbedded terrigenous siltstones and sandstones are absent. Below only several of the most common techniques, mostly based on the 10 standard oxides, are reported (but see Provenance for more techniques).

The CAI index, $100 [Al_2O_3 / (Al_2O_3 + CaO^* + Na_2O + K_2O)]$, where CaO^* is only the calcium in the silicates, was introduced by Nesbitt and Young (1982) to assess the mineralogical maturity of a mudrock or sandstone—the more CaO , Na_2O and K_2O , the less weathered. Low values of 45–55 equate to little weathering, whereas high values of 80 or more indicate advanced weathering so the higher the index the more weathered the detritus. There have also been several attempts to use the entire bulk composition to assign a tectonic setting (Roser and Korsch, 1988; Zhang *et al.*, 1998). The Ti/Al ratio

has received much attention, because both elements vary widely in igneous rocks, but are relatively stable in weathering (Young and Nesbitt, 1998). For example, it has been used to distinguish cratonic muds (high Al) from those derived from oceanic basalts (high Ti). Another useful pair of ratios are SiO_2/Al_2O_3 and K_2O/Na_2O , which have been used to discriminate accretionary from passive margins (Roser and Korsch, 1988). The study of REE elements is very popular and one of the most informative elements is europium, Eu; when high relative to the chondrite standard, derivation from mafic rocks is inferred, but when low, acid felsic rocks are inferred. In part related to bulk composition is gamma ray logging of outcrops and cores (Bohacs, 1998), which measures the concentration of potassium (illite and feldspar), uranium (phosphate and organic matter), and thorium (volcanic ash and heavy minerals). This is rapid and easy and, while not totally a provenance tool, has the advantage of direct correlation to subsurface logs.

The three types of organic matter based on bulk hydrogen, oxygen, and carbon ratios (Tyson, 1995, pp. 367–382) are useful in separating woody plant organic matter of continental, Type III, from marine or lacustrine, Types I and II. When this separation can be made and mapped, proximity to land can be identified keeping in mind that land-derived organic matter can be transported far seaward. On the other hand, the direct study of pollen (polymorphs), which hydrodynamically are deposited with silt and mud, directly identifies shorelines and, to some degree, paleoclimates (Tyson, 1995, pp. 1–6, 261–284).

NEOMORPHISM AND RECRYSTALLIZATION

Recrystallization and neomorphism are processes that transform minerals *in situ* into different forms of themselves, or a polymorph. Confusion exists with the term recrystallization because it is sometimes restricted to strain induced transformation (Bathurst, 1958) but at other times it is used in a general way for any change in form without a change of mineral species. The term replacement is sometimes used for any mineral transformation, including recrystallization and neomorphism. Replacement, however, is often restricted to transformations that involve changes in bulk composition (synonymous with metasomatism) such as dolomitization or silicification of limestone. Neomorphism and recrystallization are thought to occur by simultaneous transformation across a thin fluid film and are to be distinguished from cementation (mineral crystallization in fluid filled cavities). Neomorphism, recrystallization and cementation all involve dissolution and precipitation, but cement crystallizes in visible (scale of light microscope) cavities and does not involve simultaneous dissolution and precipitation at sites separated by a few microns or less.

Folk introduced the term neomorphism in 1965 to include all transformations of older crystals that are gradually consumed, and their place simultaneously occupied by new crystals of the same mineral or a polymorph. Folk pointed out that recrystallization, used loosely, is synonymous with neomorphism but that recrystallization *sensu stricto* excludes inversion. As such, considerable overlap exists between neomorphism and recrystallization, and to avoid confusion it must be clear whether recrystallization is being used in a strict or loose sense. Folk added textural riders to the term neomorphism to indicate an increase (aggrading) or decrease (degrading) in crystal size and whether an increase in size occurred by growth from a few isolated crystals (porphyroid) or every adjacent crystal (coalescive).

The transformation of aragonite to calcite, with or without interstitial liquid films (Folk, 1965, p.21) has been called

inversion but Bathurst (1975, p.234) specifically excluded water from the process and defined inversion as a dry, solid-state reaction. Folk (1965) considered dry inversion of aragonite to calcite as a special type of neomorphism. The dry inversion of aragonite to calcite, however, does occur naturally in blueschist metamorphic facies (Carlson and Rosenfeld, 1981). The reaction path and textures produced in this reaction are different from those found in water-saturated sediments. Consequently inversion and neomorphism are both polymorphic transformation process, the former is dry and the latter is wet and their reaction products are readily distinguishable.

Since 1965 neomorphism has been applied most commonly to the aragonite to calcite transformation. Investigation has concentrated on mollusc shells (Sandberg and Hudson, 1983; Hendry *et al.*, 1995; and Maliva, 1998), scleractinian corals (Pingitore, 1976; Martin *et al.*, 1986), ooids (Wilkinson, *et al.*, 1984) and botryoidal cements (Sandberg, 1985).

The overlap between recrystallization and neomorphism and the variable number of transformation processes encompassed by these terms has caused confusion. This led Machel (1997) to recommend the abandonment of the term neomorphism. The term can, however, be usefully applied to the wet aragonite to calcite transformation for which it has been used overwhelmingly since 1965. Neomorphism would then become restricted to a common and important type of polymorphic transformation. Recrystallization, on the other hand, applies to transformation without change in mineral species. Folk (1965) used neomorphism for transformations where the mineralogy of the precursor mineral is unknown but recrystallization would be just as apt and the general term transformation is recommended here to avoid confusion.

Calcitization is the transformation of any mineral to calcite and as such can be a type of recrystallization (calcite to calcite), replacement (e.g., anhydrite to calcite) or neomorphism (aragonite to calcite).

Neomorphism

Neomorphic transformation of a mass of aragonite crystals usually starts from many points within and at the margin of

that mass. The fluid that exists at each initiation point moves centrifugally away from that point as a thin film until it stops against a seam of organic matter; meets another fluid film, or the transformation stops (Wardlaw *et al.*, 1978; Martin *et al.*, 1986). The number of initiation points and the manner in which these films move controls the resulting mosaic of comparatively few neomorphic (sometimes a single) calcite crystals. These are optically and texturally largely unrelated to the precursor aragonite (Figure N1). Mineralogical transformation across such a film is often incomplete, with aragonite relics being found encased in the neomorphic calcite. These relics retain their original orientation and indicate the structure of the transformed grain. Palimpsest structures can also be preserved in neomorphic calcite by trapped original organic matter that can give rise to a pale to dark brown pseudopleochroism that is distinctive of some neomorphic calcites (Hudson, 1962; Sandberg and Hudson, 1983). In some cases neomorphism occurs in two stages separated by a long (10^6 year) time interval (Hendry *et al.*, 1995).

Transformation within the confines of a thin film (although one has never been directly observed; Wardlaw *et al.*, 1978) allows chemical information to be transferred from aragonite to neomorphic calcite. Many neomorphic calcites contain $\sim 1,000$ ppm Sr (tabulated in Maliva, 1998, p.181) a concentration above that recorded for most calcite cements (~ 300 ppm Sr) and often used to diagnose transformed aragonite (Sandberg and Hudson, 1983). Some neomorphic calcites, however, have Sr concentrations that are similar to adjacent cements (Maliva and Dickson, 1992) and the Sr content of neomorphic calcite is often overestimated due to analytical problems (see discussion Pingitore, 1994 and reply Moshier and Kirkland, 1994).

Work in the 1960s and 1970s concentrated on neomorphic calcite that formed in meteoric waters; some neomorphic calcites described from vadose and phreatic environments have different properties (Pingitore, 1976). Neomorphic calcite can also form in modified marine waters (Maliva, 1995) and from evolved isolated connate waters (Kendall, 1975; Bathurst, 1983). In all these cases the neomorphic products are similar and are undiagnostic of the transformation fluid.

Recrystallization

The case for recrystallization is often made for the matrix of ancient carbonate rocks that are composed of calcite microspar. Modern marine, tropical lime mud—the likely precursor to calcite microspar—is composed predominantly of metastable aragonite and Mg calcite. Lasemi and Sandberg (1984) have differentiated calcitic microspar into that originally dominated by aragonite (that has neomorphosed) and that originally dominated by Mg calcite (that has recrystallized). Some workers (Steinen, 1982; Munnecke *et al.*, 1997), however, doubt that the aragonite mud neomorphosed but some aragonite was trapped in calcite cement that filled the mud's pore system. Microspar commonly has an irregular crystal size distribution, is composed of turbid crystals and contains impurities concentrated along crystal boundaries (Figure N2). Such calcite microspar is thought to arise by recrystallization (Folk, 1965) caused by the metastability of original Mg calcite but physical processes such as Ostwald Ripening may also provide the driving force for finely crystalline calcite (Kile *et al.*, 2000).

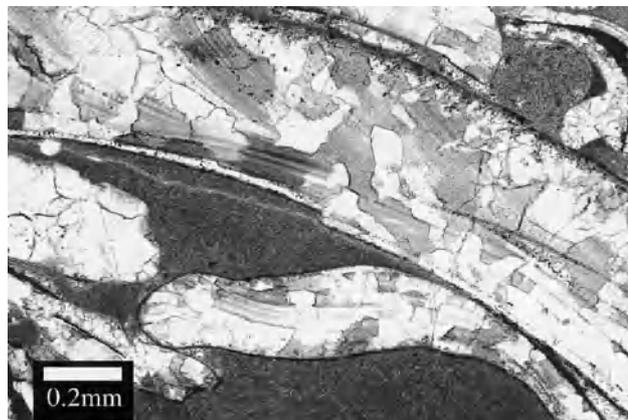

Figure N1 Photomicrograph (plane polarized light) of thin section of Unio Bed, Purbeck Beds, Lulworth Cove, Dorset, England. *Unio* valves are set in a micritic matrix. The original shell structure is preserved in coarsely crystalline calcite that neomorphosed the original aragonite shell. The mottled appearance of the neomorphic calcite is caused by pseudopleochroism, an effect that causes a color change from colorless to brown as the microscope stage is rotated.

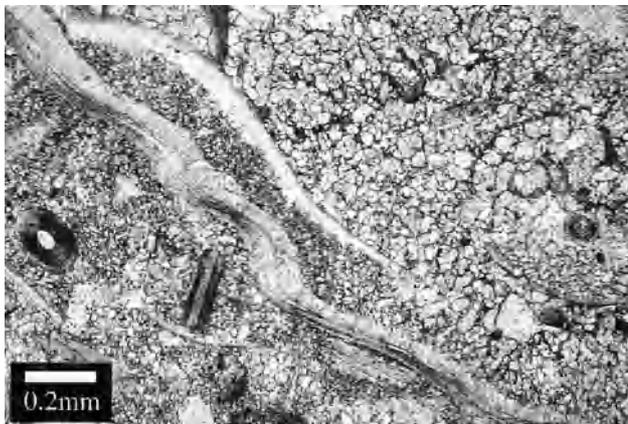

Figure N2 Photomicrograph (plane polarized light) of thin section of the Purbeck Beds, Durlston Bay, Dorset, England. Skeletal grains are separated by recrystallized lime mud. This sample shows an erratic crystal size variation and impurities along the intercrystalline boundaries of the calcite crystals. Original mineralogy unknown.

Conclusions

Recrystallization is a change in mineral form (crystal size and/or shape) without a change in mineral species or bulk composition. The term neomorphism as coined in 1965 is confusing due to overlap in meaning with recrystallization, but if restricted to wet polymorphic transformation serves a useful purpose. Inversion is a dry, solid-state polymorphic transformation that is unlikely to occur in water-saturated sediments. No specific term is available for a mineral that is interpreted to have changed form from an unidentified precursor, as is thought to occur when some lime muds are transformed to calcite microspar; here the general term transformation can be used.

NEPHELOID LAYER, SEDIMENT

Introduction

The lower water column in most parts of the ocean, both shelf waters and the deep sea, shows a large increase in light scattering and attenuation conferred by the presence of increased amounts of fine-grained particulate material. This has been confirmed by size measurements and filtration of seawater with gravimetric analysis. This part of the water column is termed the bottom nepheloid layer (BNL) (Figure N3). Optical work shows that the BNL is up to

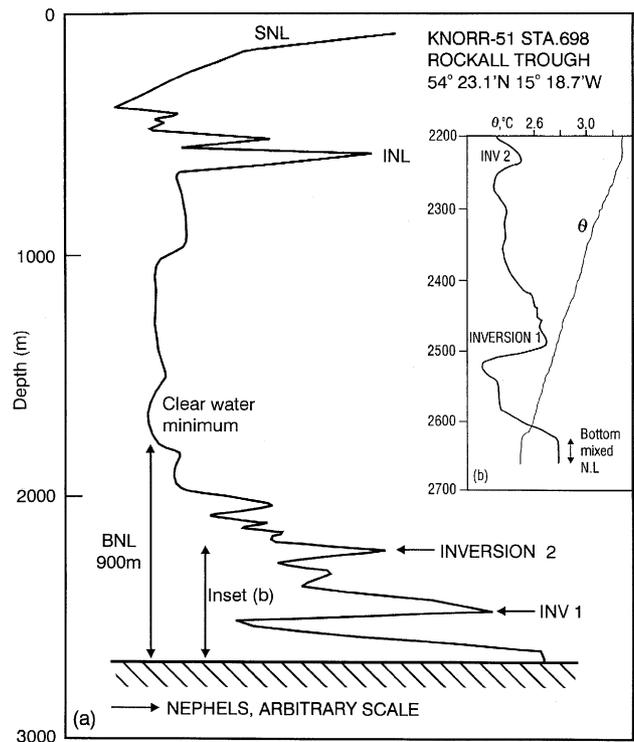

Figure N3 Full depth nephelometer profile in the Rockall Trough. Bottom, intermediate and surface nepheloid layers and the clear water minimum are apparent as well as two large inversions (after McCave, 1986). The instrument is uncalibrated but in this area the maximum concentration is probably of order 500 mg m^{-3}

2000 m thick and generally has a basal uniform region, the bottom mixed nepheloid layer, corresponding quite closely to the bottom mixed layer defined by constant potential temperature. Above this light scattering falls off more or less exponentially to the clear-water minimum marking the top of the BNL.

Another class of nepheloid layer found especially at continental margins is the intermediate nepheloid layer (INL) occurring frequently at high levels off the upper continental slope and at the depth of the shelf-edge (Figure N3). These INLs are similar to the inversions observed in the BNL on some profiles (Figure N3).

Nepheloid layers of both types are principally produced by resuspension of the bottom sediments. Their distribution thus indicates the dispersal of resuspended sediment in the oceans and coastal seas. Most concentrated nepheloid layers occur on the continental shelf, upper slope or deep continental margin. They indicate the locus of active suspension and deposition by strong bottom currents. Nepheloid layers off the shelf almost always have concentrations $<1 \text{ g m}^{-3}$.

A surface nepheloid layer (SNL) occurs almost everywhere but varies in strength seasonally. In the open ocean it is mainly due to phytoplankton, whereas in shelf seas it is often the seaward extension of river outflow plumes.

Optics: what instruments “see”

Most detection of deep ocean nepheloid layers has been through measurement of light scattering or nephelometry. Because most nephelometers do not measure a defined optical parameter their outputs cannot be quantitatively compared, save via calibration with some standard such as Formazin. Nowadays transmissometry is more commonly used for precise work. Most of the light scattering recorded by nephelometers is caused by fine particles. Although larger particles are present, they are rare and are not important contributors to the signal. For a transmissometer, the transmission T is related to beam attenuation coefficient c over pathlength l as $T = e^{-cl}$. Attenuation is due to absorption a and scattering b , thus $c = a + b$. The value of c for pure seawater is $0.360 \pm 0.005 \text{ m}^{-1}$ for an instrument operating at $\lambda = 660 \text{ nm}$, and any excess is due to particulate effects. Because large particles scatter more at angles very close to the beam axis, the transmissometer is more sensitive to larger particles.

Bottom nepheloid layer features and origin

The principal features of BNLs are that the concentration is generally highest close to the bed and decreases upward, but with important increases or inversions. The thickness of the BNL is generally in the region of 500 m to 1500 m, and exceptionally up to 2000 m. This is clearly greater than the thickness of the bottom mixed layer, a fact which precludes the possibility of simple mixing by boundary turbulence being a sufficient mechanism for BNL generation. Inversions, upward increases of concentration, become less common in the upper part of the bottom nepheloid layer. Pronounced inversions (INLs) are seen over slopes and on margins with canyons. These are produced by internal wave and tide resuspension (Dickson and McCave, 1986). Thus some canyons act as point sources for supply of turbid layers which mix out into the ocean interior (Gardner, 1989). These features are accounted

for in the “separated mixed-layer model” in which vertical transport by turbulent mixing in bottom boundary layers of 10 m to 100 m thickness, is followed by their detachment and lateral advection along density (isopycnal) surfaces. The detachment occurs where isopycnals intersect the bottom and this is likely to occur both in areas of steep topography with relief of hundreds of meters, and also in areas of lower gradient at benthic fronts where sloping isopycnals intersect the bottom (Armi and D’Asaro, 1980; McCave, 1983). With time these layers thin by mixing at their boundaries and lateral spreading to yield, eventually, a uniform stratification.

Particles comprising the nepheloid layer are modified by aggregation with similar sized particles, scavenging by larger rapidly settling ones, and by biological activity. Particles tend to settle and be deposited from the bottom mixed layer. The larger particles should be deposited in a few weeks to months, $10 \mu\text{m}$ to $20 \mu\text{m}$ particles taking 50 days to 20 days to settle from a 60 m thick layer. This affects the transmissometer signal but has little effect on the nephelometer record because the timescale of fine particle removal involves Brownian aggregation with a “half-life” of several months to years giving fine material in dilute nepheloid layers a residence time of years (McCave, 1984). The dilute nepheloid layers in tranquil parts of the oceans could thus contain material originally resuspended very far away. The contribution of this material to the net sedimentation rate of these tranquil regions may not be negligible. The rate of deposition in the Pacific of only 0.5 mm ka^{-1} to 2 mm ka^{-1} could include up to 1 mm ka^{-1} of fine material from the nepheloid layer.

The turbidity minimum

Over the depths separating the BNL from the SNL (and from shelf edge and upper slope INLs) stratification is weak, primary production of organic matter is absent and the ocean is often under-saturated with respect to calcite, aragonite and opal. Supply of particles from the side is thus scarce and decreasing downward transport due to dissolution and bacterial consumption of particles leads to a nepheloid minimum where (in the Atlantic) concentrations are 5 mg to 20 mg m^{-3} . Concentrations given by nephelometers at the minimum differ by a factor of about three between areas under high surface productivity (high) and mid gyre regions (low). Thus, the flux of large particles from the surface in these areas appears to provide a seasonal supply of smaller particles to mid-depth rather than their removal by scavenging. Temporal variability also occurs seasonally with higher mid-water turbidity under higher summer productivity.

Regional distribution

In general, deep western boundary currents and regions of recirculation carry high particulate loads. However, the highest turbidity is also found beneath regions of high surface eddy kinetic energy (variance of current speed). The broad picture of high speed inflows on the western sides of ocean basins with a distributed return flow, demonstrated by hydrographic and current measurements, is reflected in the distribution of BNL concentration for the Atlantic and Indian Oceans. Nevertheless several areas of very high concentration or load are not obviously related to likely increases in mean bottom flow velocity, for example the center of the Argentine

Basin (Biscaye and Eittrheim, 1977). These turbidity highs may be caused by intermittently high velocities.

The fact that there is more suspended material at ocean depths greater than about 4000 m partly reflects the fact that waters at those depths are in contact with a much greater potential source area of seabed in proportion to their volume than the shallower parts of the oceans. For 4 km to 5 km depth the value is $0.83 \text{ km}^2/\text{km}^3$, whereas for 2 km to 3 km it is $0.11 \text{ km}^2/\text{km}^3$. Deeper waters feel more bed.

NERITIC CARBONATE DEPOSITIONAL ENVIRONMENTS

Introduction

Marine carbonate sedimentation (Bathurst, 1975; Scholle *et al.*, 1983; Tucker and Wright, 1990; James and Kendall, 1992; Wright and Burchette, 1996) takes place in two environments, the benthic, neritic realm and the pelagic deep-sea realm (see *Oceanic Sediments*). Neritic carbonate sediments are “born” as precipitates or skeletons within the depositional environment. This attribute has profound consequences: (1) large structures such as platforms are produced entirely by sediments formed in place, they are self-generating and self-sustaining; (2) the temporal and spatial style of accumulation depends upon the nature of the sediments themselves; (3) sediment production can fill accommodation space and thus create shallowing-upward, autostratigraphic patterns; (4) grain size variations need not signal changes in hydraulic regime; and (5) sediment composition is fundamental in characterizing the depositional environment.

A *carbonate platform* (Figure N4) is a large edifice formed by the accumulation of sediment in an area of subsidence. Such structures can be several kilometers thick, extend over many

CARBONATE PLATFORMS

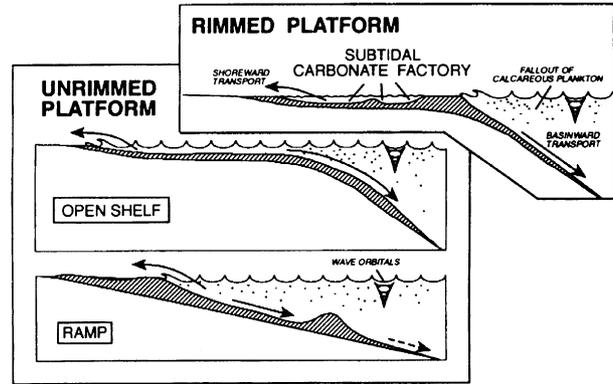

Figure N4 A sketch illustrating the different types of carbonate platforms (after James and Kendall, 1992).

hundreds of square kilometers, and be constructed by stacked carbonate ramps and/or flat-topped platforms. A *carbonate shelf* is a platform tied to an adjacent continental landmass. This hinterland is a potential source of terrigenous clastic sediment, fresh water, terrigenous organic matter and nutrients. A craton many hundreds to thousands of kilometers across is called an *epeiric platform* when covered by shallow seawater. A *carbonate bank* is an isolated platform surrounded by deep ocean water and cut off from terrigenous clastic sediment. A *carbonate atoll* is a specific type of bank developed on a subsiding volcano. Similar banks, unrelated to volcanoes, are termed *faros*. Atolls and banks can be so dominated by reefs that their geological expressions are termed *reef complexes* or *carbonate buildups*.

These morphological structures are generally either a *flat-topped platform* with narrow rim and relatively steep basin-facing margin, or a *ramp*, a structure that slopes gently basinward from the shoreline at angles of less than one degree.

Ramps

A *ramp* (Figures N4, N5) is an unrimmed edifice in which nearshore, wave-agitated facies grade into deeper water, low-energy deposits and there is no discernable break in slope (Read, 1985; Burchette and Wright, 1992; Wright and Burchette, 1998). Modern examples are found in areas where coral reefs are absent because of elevated salinity (Persian Gulf, Shark Bay), cool seawater (southern Australia—New Zealand, western Florida) or high nearshore terrigenous sedimentation (Papua New Guinea). They are “distally steepened” (with a subtle shelf break), or “homoclinal” (uniform low slope gradient with no slope break). Most are storm-dominated.

Ramps are hydrodynamically partitioned into depth-related, shore-parallel facies belts. The *Inner Ramp* lies within fairweather wave base (FWWB), is subject to high-energy agitated conditions, onshore currents push coarse material shoreward and muds into lagoons, offshore-directed storm-surge currents transport finer-grained material basinward. Facies are dominated by carbonate sand shoals, shoreface deposits, tidal deltas, seagrass banks and barrier islands backed by lagoonal and peritidal flats. The *Mid Ramp* lies

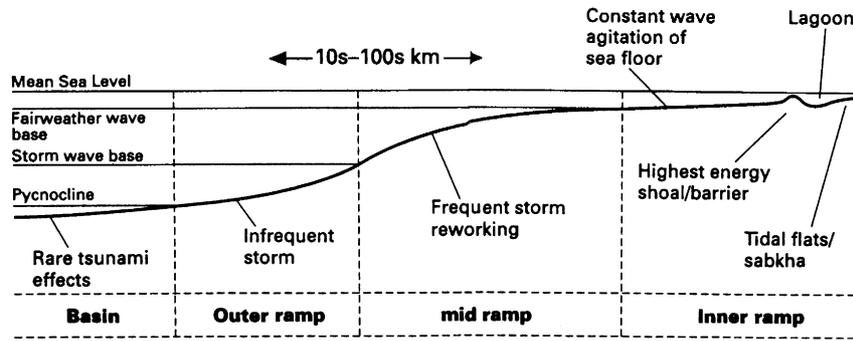

Figure N5 The main environmental subdivisions on a homoclinal carbonate ramp (from Burchette and Wright, 1992).

between FFWB and storm wavebase (SWB), is a generally quiet environment disturbed by episodic high-energy storm events and is characterized by decreased organic productivity offshore. Fair-weather muds are deposited from suspension while storm events transport coarser-grained material from shallow-water areas (storm surge currents) producing deposits that change progressively offshore from swaley-cross-stratification to amalgamated HCS to HCS to graded “tempestite” couplets. The *Deep Ramp* lies below SWB, is an area of quiet water suspension deposition of carbonate and terrigenous muds and rare storm events. Sediments there have few sedimentary structures, are typically laminated with some silty rippled beds floored by skeletal lags, and contain a sparse *in situ* macro-biota. The wackestones and packstones are locally interbedded with anoxic shales, if there is a strong pycnocline, and can have rhythmic alternations resulting from climatically, and/or oceanographically driven fluctuations.

Flat-topped platforms

A flat-topped platform, generally with a steep basinward margin, can be rimmed or unrimmed. An *unrimmed* or *open flat-topped platform* (Figure N4), is one in which there is no basin-facing barrier. Unrimmed platforms occur today on the leeward side of large tropical banks and are the norm in all cool water settings. Because oceanic waves and swells can sweep directly onto and across the shallow seafloor of open shelves and ramps, (1) the energy level of most shallow water environments is high; (2) nearshore facies are complex; (3) sediment can easily be transported into deep water; (4) only the nearshore zone can keep pace with sea level rise; and (5) subtidal accumulation space will be controlled as much by the depth of wave abrasion as by sea level. Since the same physical processes as those on terrigenous clastic shelves affect unrimmed platforms and ramps, they have similar facies. What sets them apart is the continual in place production of carbonate sediment and early cementation, which constantly alters the nature of the seafloor.

A *rimmed flat-topped platform* (Figure N4) has a segmented to continuous rampart of reefs and/or lime sand shoals along the seaward margin that absorbs ocean waves. Modern warm water platforms, typified by the Great Barrier Reef, the Belize Reef Complex, the Bahama Banks and oceanic atolls and fringing reefs worldwide, are generally rimmed because corals are prolific today and construct large reefs along the edges of shelves and banks. By absorbing waves and swells and dissipating storm energy, the rim protects a variety of lower

energy environments. It also confines the movement of coarse-grained sediment to the lagoon/shallow platform and can potentially restrict water circulation, increasing the possibility of lagoonal evaporites. Accumulation space is limited by sea level and carbonate facies are strongly differentiated.

The margin is typified by extensive growth of *barrier reefs*, with associated islands and passes, resulting in rapidly accumulating carbonate reef limestones and coarse skeletal grainstones and rudstones that are periodically swept lagoonward and basinward. Some platform margins are occupied by ooid-peloid *sandshoal complexes* that are either storm- or tide-dominated. The leeward *lagoon*, 10s to many 100s of kilometers wide, ranging from less than 10 m to many 10s of meters in depth, is the site of widespread, muddy, biotically diverse, extensively bioturbated seafloor carbonate sediment in environments that range from shallow grass banks to deep, poorly illuminated burrowed muds. The area may be dotted with patch reefs and/or small islands resulting from hurricane (cyclone) resedimentation. The strandline can be the site of beaches but more commonly, is an area of muddy *tidal flat* sedimentation. The muds on the tidal flats are driven onshore during cyclonic storms.

The rapid accretion rates of reefs and ooid shoals generally leads to steep basin-facing *carbonate slopes*, typified by a mixture of pelagic and resedimented carbonate deposits. While many have the attributes of outer ramp facies, they also contain numerous sediment gravity flows and debrites. These materials pass rapidly into basinal sediments.

The sediment factory

The whole carbonate deposition system is depended upon the productivity of the carbonate factory (Figure N4), that region of the seafloor where sediment is generated by biotic growth and inorganic/microbial particle production (see *Algal and Bacterial Carbonate Sediments*). Particles of all grain sizes are formed here, either crystallizing as skeletons or precipitating directly, to generate muddy “subtidal” deposits, ooid sands or reefs and mounds. Much of the abundant fine fraction is resuspended periodically and piles up as muddy peritidal flats against highs on the platform and along the shoreline. Fine sediment is also swept seaward where, together with sediment gravity flows originating at the margin, it accumulates on the slope and on adjacent basin margin. Regardless of facies, it is the factory that is at the core of carbonate deposition. All carbonate facies and carbonate stratigraphy depend on the “health” of this production unit.

For carbonate production and sediment accumulation to be at a maximum, the environment must be just right; not too deep, not too shallow; not too warm, nor too cold; not too fresh, but not too saline either; not too much terrigenous clastic sediment; not too many nutrients but neither too few (the *Goldilocks Window* of Goldhammer *et al.*, 1990). The warm-water, tropical factory is dominated by the *photozoan assemblage* (James and Clarke, 1997) which comprises calcareous phototrophic/mixotrophic organisms with photosymbionts, calcareous algae, ooids and mud-producing algae and microbes. These thrive in the euphotic zone (generally <120 m deep in the modern ocean) and produce most sediment in waters less than 20 m deep (Schlager, 1981). This factory is highly sensitive to oceanic perturbation and is best developed in clear oligotrophic, open ocean settings, with elevated nutrients, terrigenous clays, saline and fresh water all being deleterious to optimum accumulation. The slower-growing *heterozoan assemblage* is there in the background of tropical environments but dominates cool-water settings. It can extend to depths of ~300 m, beyond which it becomes insignificant, but maximum production is generally <150 m.

Accumulation rates

The Holocene warm-water carbonate factory (excluding reefs) produces sediment that accumulates at rates of ~10 cm/1,000 years to 60 cm/1,000 years. Cenozoic cool-water platform sediment accumulates at ~1 cm/1,000 years to 10 cm/1,000 years. It is difficult to assess rates of sediment accumulation in ancient platforms because of post-depositional diagenesis, that is, physical and chemical compaction, but most are in the range of 2 cm/1,000 years to 10 cm/1,000 years (Schlager, 1981; James and Bone, 1991).

Subtidal environments

Shallow inner to mid ramp and lagoonal seafloor settings are euphemistically called "subtidal environments", as separate from reefs, sand shoals, strandline and slope settings, and constitute the bulk of the carbonate factory. They comprise that part of the seafloor that is relatively uniform in composition and biota. Conditions are normal open marine, the biota is diverse and sediment is typically muddy.

Sediment forms through biogenic or biogenically mediated processes and if not buried quickly is altered by early, seafloor diagenesis (see *Diagenesis*). Little material is generated by physical abrasion. Mud is produced by water-column precipitation, by disintegration of calcareous algae and delicate invertebrate skeletons or by bioerosion. Sands are biofragmental, oolitic, peloidal and intraclastic. Granule and boulder-size material is formed by invertebrate skeletons and sediment lithified in the environment of deposition and eroded by physical processes. Because so much sediment is biogenic, grain-size is as much a function of organism skeletal architecture as it is hydrodynamic energy. The nature of the sediment is principally controlled by water temperature although elevated salinity dramatically reduces benthic and thus particle diversity.

Sediments, once produced, are typically burrowed and/or ingested by a host of infaunal organisms. Dwelling burrows are particularly conspicuous, creating both a labyrinth of tunnels and reworking vast amounts of sediment. Ingestion of sediment in turn passes sediment through the guts of

invertebrates many times before final deposition, and these organisms produce fecal pellets, which, if lithified early, are preserved.

Storms are particularly effective in carbonate environments because they are so shallow. Warm-water, tropical environments are especially susceptible to hurricanes and cyclones. Cool-water environments are affected by winter storms where, in open ocean situations, wave-base may reach 200 m or more. On rimmed platforms storms erode and transport sediment on the shelf, sweep sediment into islands and transport fines onto tidal flats or across the shelf edge as mud plumes. On open shelves and ramps there is transport from shallow to deeper water. Thus, storm beds are a common feature of "subtidal" environments, usually typified by shell lags in Phanerozoic carbonates and storm lags of rounded intraclasts in Precambrian and early Phanerozoic rocks.

Modern, shallow, euphotic environments in all realms are characterized by prolific growth of plants, especially seagrasses. Plant leaves act as renewable substrates for delicate calcareous encrusters that eventually produce mud-size particles. The roots bind sediment together and thus impede erosion. The leaves also act as a baffle slowing water movement and as a protective canopy for the growth of a variety of other algae and invertebrates. Modern grasses are angiosperms and so this environment is Cretaceous and younger. While microbes doubtless played a similar role in the older rock record, the nature of this niche is uncertain. In cold-water, high-energy, neritic environments soft green and brown algae (kelp) are prolific, and act in the same way as renewable substrates for carbonate epibionts.

In general, sediment in warm-water, inner ramp or lagoonal environments is typically biotically diverse floatstone, wackestone and packstone that is burrowed and punctuated by storm deposits in the form of biofragmental tempestites and/or shell-intraclast lags. On cool-water shelves and ramps, muddy sediments are rare and the sediment is typically high-energy biofragmental rudstone and grainstone. Mud only accumulates below storm wave base.

Sand shoal complexes

Sand bodies occur at the strandline, on the inner ramp or along the flat-topped platform margin. Ooids are common throughout, pelmatozoans are ubiquitous in the Paleozoic and benthic foraminifers are typical of the Mesozoic and Cenozoic. Inner platform and inner ramp carbonate sand bodies (Figure N6) have the same textural attributes as siliciclastic sediments in similar settings except for common early cementation which produces beachrock that can be fragmented into clasts forming rudstones. A striking terrestrial facies adjacent to carbonate beaches is thick accumulations of *eolianites* (carbonate eolian dunes), particularly in the Cenozoic, in both warm- and cool-water realms.

Ooid and biofragmental sand complexes are common at platform margins of all ages and the best studied in the modern ocean are from the Bahamas. Their location and style is controlled by seafloor relief (presence of islands or reefs), whether they are located on the windward or leeward side of the platform and the local tidal range. Islands at the platform edge may have flood-tidal deltas between them. Alternatively, the rimmed margin may develop marine or tidal bar belts (Harris, 1984) (Figure N6). A *Marine Sand Belt* is a strike-oriented shoal on either the windward (typically ooid-rich with

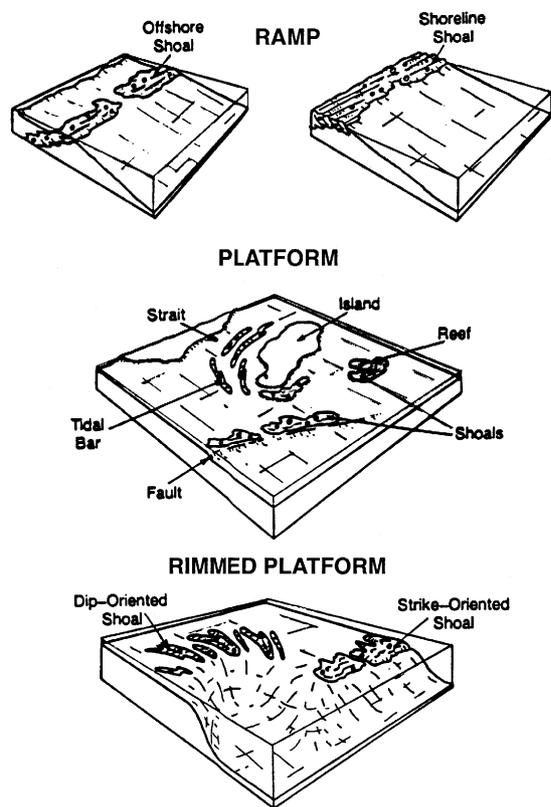

Figure N6 The style and location of carbonate sand shoals.

on-shelf directed transport) or the leeward (typically ooid-peloid-biofragmental and offshore directed transport) margin. Such shoals are a few km wide and up to 100 km in length and comprise a “shield” of subaqueous dunes covered in asymmetrical, m-scale, flood-directed smaller dunes and broken periodically by spillover lobes. Sands grade outboard into more biofragmental deposits and inboard into muddy subtidal facies. The shoals are capped locally by islands and eolianites. In contrast, a *Tidal Bar Belt* comprises dip-oriented bars of elongate subaqueous dunes normal to the platform margin. They develop where strong tidal flow exceeds 1 m/second, with flood or ebb flow dominating different sides of the bar.

Work on high-energy cool-water platforms indicates that much of the shelf is covered with widespread subaqueous dunes composed of biofragments.

Peritidal environment

Calcareous sediments deposited in shallow seawater on and adjacent to muddy tidal flats (*peritidal* sediments and facies) are some of the most conspicuous in the rock record (Ginsburg, 1975). Such facies are typically arranged vertically in a m-scale, a *shallowing-upward sequence*, or *shallowing-upward succession*, (Pratt *et al.*, 1992) in which marine sediments are overlain successively by muddy carbonates deposited in paleoenvironments subject to varying periods of exposure (Figure N8).

Three bathymetric zones are recognized: subtidal, intertidal and supratidal (Figure N7). The *subtidal zone* is permanently submerged and ranges from low-energy, lagoonal environments to higher energy shoals. Semimonthly neap tides may briefly expose the shallowest portions. The *intertidal*, or *littoral*, zone lies between normal low- and high-tide levels and is therefore submerged on a diurnal or semidiurnal basis. It is generally dissected by subtidal creeks and can be dotted with brackish or saline ponds. The *supratidal zone* is above normal

MUDDY CARBONATE TIDAL FLAT ENVIRONMENTS

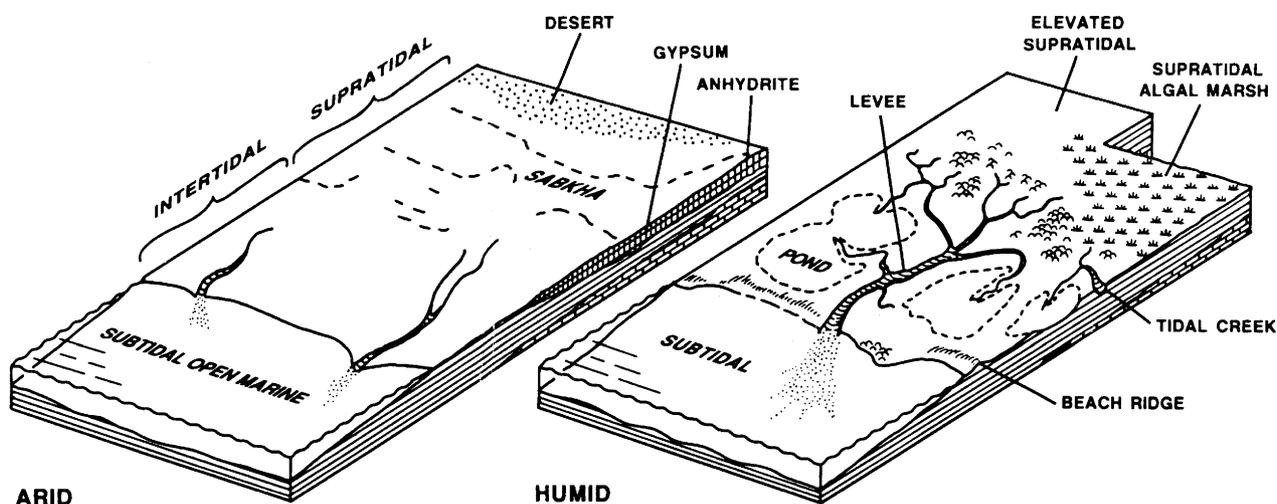

Figure N7 Block diagrams showing the main morphological elements of a muddy tidal flat under humid and arid climates (from Pratt *et al.*, 1992).

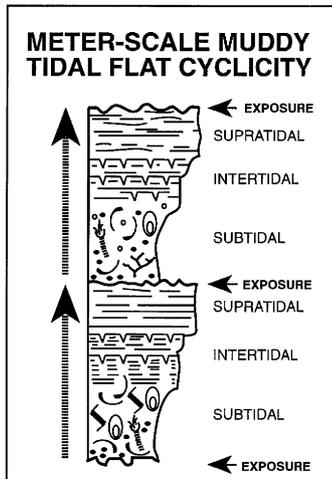

Figure N8 A diagram illustrating the nature of stacked m-scale peritidal cycles (from Pratt *et al.*, 1992).

high tide, and is flooded only during storms and semimonthly spring tides. It can become evaporitic in semiarid and arid climates (*sabkha*).

Tidal flats are geographically complex and tidal range is modified by wind. Deposition is dominated by storms, which stir up the adjacent offshore sediment and drive mud-laden waters up the tidal creeks and onto the flats. Depositional textures and fabrics are generated by daily lunar tides, and contain the distinctive sedimentary features that allow precise location of paleoenvironments. Tidal flats are thus repositories of allochthonous sediment, and prograde as wedges seaward shorelines (e.g., Qatar, Shark Bay, Spencer Gulf), in the lee of rocky islands (e.g., northern Bahamas, Caicos, Belize), spits (e.g., Florida) and reefs and shoals (e.g., Trucial Coast), and as discrete islands and banks in shallow seas (Purser, 1973; Hardie, 1977; Hardie and Shinn, 1986).

Shallow subtidal and lower intertidal environments

In tranquil settings of normal salinity, the lowermost intertidal zone is a thoroughly bioturbated mixture of lime mud, pellets and bioclasts. Sediment is usually covered during low tide with an ephemeral microbial (“algal”) slick that is the source of food for grazing organisms such as gastropods and worms. Crabs, shrimps, worms and fish bioturbate underlying sediment. Many low-energy flats are fronted by beaches of bioclastic sand winnowed from creeks and ponds or the adjacent seafloor during storms. Beach sands can be partially lithified forming gently seaward-dipping layers of beachrock.

Intertidal flat environments

Microbial mat cover here is more permanent, and forms thick, leathery carpets that can be locally shrunken, torn and folded. They exhibit various surface features such as pustules, blisters, wrinkles, crenulations or small, domical stromatolites. Such mats are a variety of filamentous and coccoid cyanobacteria (“blue-green algae”) and bacteria, and are responsible for the millimeter-scale lamination exhibited by most of the sediment beneath them.

Wavy-, lenticular-, and flaser-bedded peloidal lime mudstone or grainstone (calcisiltite) and dolomitized argillaceous lime mudstone (sometimes interbedded with small hemispherical stromatolites), arising from the alternation between slack water and sediment transport by both unidirectional currents and waves under lower flow regime, are particularly distinctive of Precambrian and lower Paleozoic facies. These carbonates typically contain intraclastic horizons which are absent in siliciclastic counterparts. Phanerozoic intertidal facies frequently have bioclastic layers. Well-sorted coquinas were likely washed in from the subtidal zone by storms, whereas poorly sorted shelly deposits containing a low-diversity assemblage of gastropods or bivalves probably represent the *in situ* intertidal fauna. Laminae that appear laterally continuous, undulating and uniform in thickness, are typically intercalated in this facies, and record periods of stabilization or binding of the substrate by a microbial mat. Post-Paleozoic intertidal sediments are generally thoroughly churned, bioturbated, poorly fossiliferous lime mudstone units that can be interpreted as intertidal if other criteria, such as vertically juxtaposed beds with desiccation cracks, are not present.

Ponds and creeks

Ponds containing brackish or hypersaline water are common features of the intertidal zone (Figure N7), especially in more humid climates. These contain a restricted biota of microbial mats, foraminifers, gastropods, small bivalves, shrimps, ostracodes, and nematode and polychaete worms that is adapted to fluctuating salinity. This assemblage, living in a stressed environment, is typically one of high numbers of individuals but low species diversity, different from the immediate offshore biota.

Also characteristic of the intertidal zone are permanently submerged tidal creeks or channels that are the conduits for tidal flooding and draining. Such tidal creeks (least common in arid settings) are up to several meters deep and tens of meters wide with a basal lag of semilithified intraclasts eroded from the surrounding flats and flanking levees, and bars of bioclastic sand winnowed from the ponds. Supratidal “levees” protrude above high-tide level and are microbially laminated.

Supratidal flats

Most of the sediment surface here is covered by microbial mats that are typically shrunken into desiccation polygons and commonly dislodged as chips or intraclasts. Laminated sediment beneath these mats is fine grained with occasional coarser intercalations that reflect deposition by exceptional storms and, in some regions, by winds blowing off the adjacent land surface. Beds and nodules of anhydrite precipitate in these sediments in arid settings. In many areas, the supratidal zone is the locus of widespread syndimentary cementation by microcrystalline aragonite, high-Mg calcite, or dolomite. This forms lithified pavements a few centimeters thick that are usually broken into intraclasts by forces exerted during crystal growth, groundwater pore pressure, or the roots of halophytic plants such as grasses and mangroves.

Landward parts of the supratidal zone grade into eolian deposits, soils or freshwater marshes and lakes, or onlap bedrock surfaces, depending on the region’s geography and climate. Marshes and lakes, which exist in the more humid areas and have fluctuating water chemistry, are characterized

by microbial mats and stromatolites; these are partially lithified by high-Mg calcite cement and calcification of organic substrates, and are interbedded with thin-bedded, locally bioturbated lime mud and bioclastic and peloidal carbonate sand deposited during storms. Much of the microbially laminated sediment shows fenestral fabric, millimeter- to centimeter-sized subhorizontal, sheet-like pores formed as voids bridged by microbial mats or as molds of degraded mats. Decimeter-scale tepee structures, consisting of disrupted and overthrust crusts of lithified, tufa-like fenestral sediment giving an inverted V-shaped cross section, form in areas of groundwater discharge (Kendall and Warren, 1987). These also contain complex generations of internal sediment and aragonite and high-Mg calcite cements.

Ancient supratidal facies

Microbially laminated limestone or dolostone, usually with desiccation cracks and coarser rippled layers, is a common peritidal rock type. Intercalated within many microbially laminated rocks are intraclastic horizons, which are analogous to pavements of microbial mat chips or fragments of cemented crusts in modern supratidal environments. Fenestral lime mudstone and peloidal grainstone are common and, by analogy with tidal flats of Florida and the Bahamas, were probably deposited in moist supratidal "algal marshes" or around ponds. This facies sometimes exhibits features, such as pendent fibrous cement, brecciated crusts and tepees, pisolites and pores with geopetal sediment floors, suggestive of flushing by downward-percolating seawater and rainwater and upward-flushing by groundwaters in a subaerial environment.

Reefs

There has for decades been an ongoing debate as to what constitutes an ancient "reef" (Heckel, 1974; James, 1983; Geldsetzer *et al.*, 1988; Wood, 2000). A useful compromise is that reefs are *biologically constructed reliefs* which were, like modern reefs, constructed by large, usually clonal elements (on average >5 cm in size), and capable of thriving in energetic environments; *mounds* are those structures which were built by smaller, commonly delicate and/or solitary elements in tranquil settings (see *Carbonate Mud Mounds*). Two terms, bioherms and biostromes, are commonly used to designate biogenically constructed geological structures. A *bioherm* is a lens-shaped reef or mound; a *biostrome* is a tabular rock body, usually a single bed of similar composition. Another commonly used generic epithet with no compositional, size or shape connotation is *carbonate buildup*.

Depositional facies

Reefs generally comprise three facies (Figure N9): (1) *Core facies*—massive, unbedded carbonate with or without skeletons; (2) *Flank or fore reef facies*—bedded carbonate sand and conglomerate of in place and/or core-derived material, dipping and thinning away from the core; and (3) *Interreef or open platform facies*—subtidal limestone or terrigenous clastic sediment, unrelated to reef growth.

Any living reef or mound is a delicate balance between: (1) upward growth of in place calcareous elements (metazoan and microbial); (2) continuing destruction by a host of raspers, borers and grazers; (3) prolific sediment production by rapidly growing, short-lived, attached calcareous benthos; and (4) concurrent inorganic or organically induced cementation. The

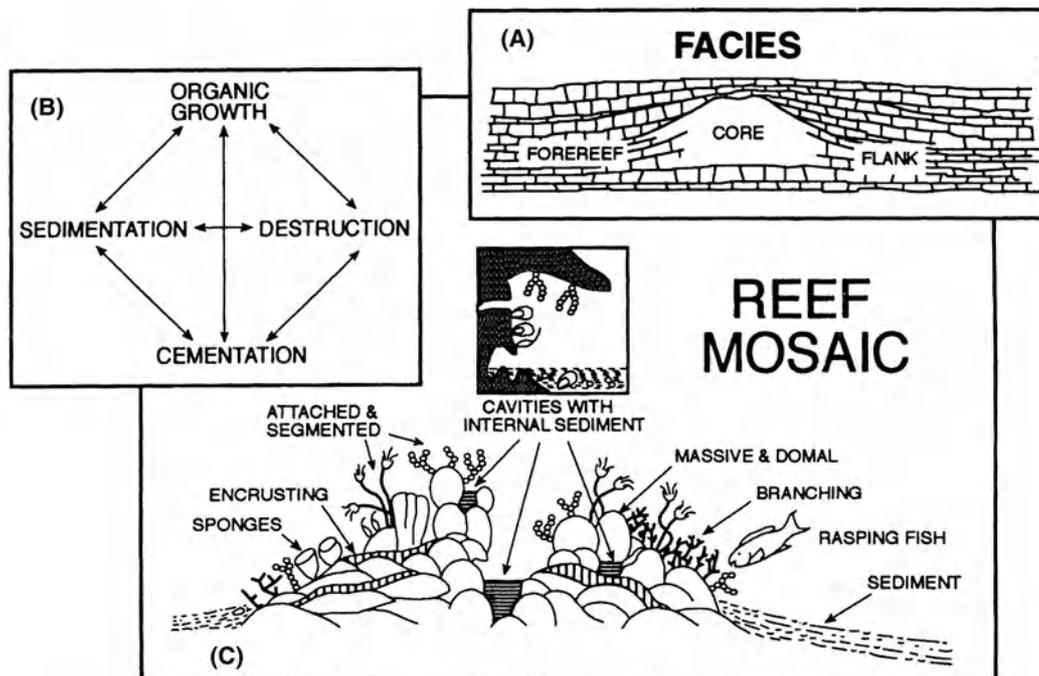

Figure N9 A sketch illustrating the facies (A), processes (B) and general attributes (C) of reefs (after James and Bourque, 1992).

large skeletal metazoans (e.g., corals) generally remain in place after death, except when so weakened by bioeroders that they are toppled by storms. Their irregular shape and growth habit result in roofed-over cavities that can be inhabited by smaller, attached calcareous benthos. Encrusting organisms growing over dead surfaces aid in stabilization. Branching reef-builders can also be preserved in place, but are just as commonly fragmented by storms into sticks and rods, which form skeletal conglomerates.

Most sediment is produced by the postmortem disintegration of segmented (e.g., calcareous green algae) or nonsegmented (e.g., bivalves, brachiopods, foraminifers) organisms. Additional sediment is generated by bioeroders: boring organisms (worms, sponges, bivalves) produce lime mud; rasping organisms, generally herbivores (echinoids, fish), graze the surface creating copious quantities of carbonate sand and silt. The sediment accumulates around the buildups as an apron, lodges between skeletons as a matrix and filters into growth cavities as geopetal internal sediment. Rigidity of many reefs is accomplished by invertebrates and microbes encrusting or growing on top of one another. Many reefs are also preferential sites for syndimentary cement precipitation (see *Diagenesis*), and are hard limestone just below the growing surface.

Results of these processes can be seen in many Phanerozoic reefs and mounds, and especially in Mesozoic and Cenozoic structures, which are decidedly “modern” in composition. Paleozoic buildups do not appear to have been affected much by boring organisms but were typically sites of intense syndimentary cement precipitation; some reefs contain so much cement that they have been called “cementation reefs”. Precambrian buildups, with their limited biological components, were mainly constructive, clearly fractal in character, and contained few growth cavities.

The reef growth window

The modern growth window is determined by the combination of factors that control growth of the major organism, in this case corals. Hermatypic (reef-building) corals grow in waters between 18° and 36 °C, but are best adapted to form reefs in waters between 25 °C and 29 °C. Periodic exposure is not necessarily lethal and some intertidal corals are out of water for many hours daily. The salinity window ranges from 22‰ to 40‰, but most corals grow best in waters between 25‰ and 35‰.

Hermatypic, reef-building corals are cnidarians which contain light-dependent, photosynthetic symbiotic microorganisms (zooxanthellae). Light decreases exponentially with depth and the lower limits of hermatypic coral and calcareous green algal growth are 80 m to 100 m. Because they are mixotrophs corals flourish in nutrient-impoverished oceanic regions. Increased nutrient levels, from upwelling on the outer platform and runoff on the inner platform, lead to dramatic changes in reef structure; at intermediate levels the animal-plant symbionts are replaced by more heterotrophic forms and “fouling organisms” such as filamentous algae, fleshy algae and small suspension-feeding animals (barnacles and bivalves) of the heterozoan assemblage. Reefs still grow in such regions only because herbivores graze back the algae. Fine-grained suspended sediment limits coral growth because it decreases light penetration and covers or clogs the polyps. It is difficult to decouple the effect of fine terrigenous sediment and nutrients on coral reef growth because they usually occur together.

Scleractinian coral reefs

Modern reefs exhibit depth zonation (Figure N10) because of decreasing wave energy, light intensity and to a lesser extent temperature, with increasing bathymetry.

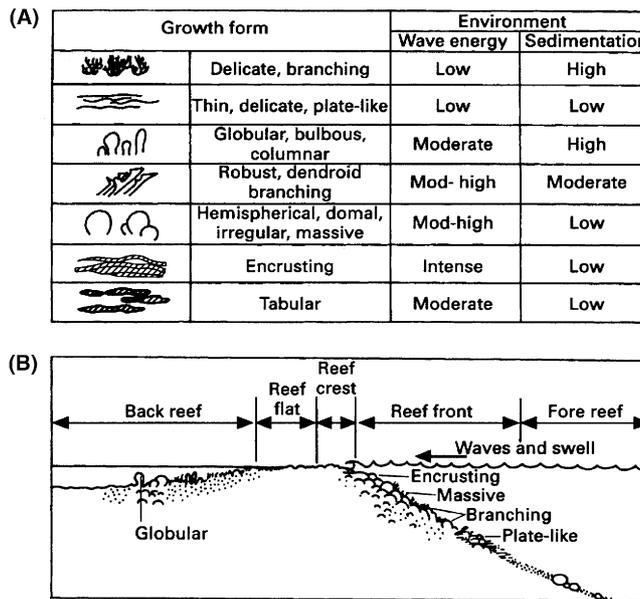

Figure N10 (A) growth forms of reef-building organisms and their general environments, (B) the zonation of a modern, windward coral reef (after James and Bourque, 1992).

Reefs on the leeward side of banks can be strikingly different, either because of reduced wave activity or because of "bad water". The bad water is formed on the platform by fine-grained sediment production, oxygen depletion, heating or evaporation. It is usually driven off the bank downwind, across the leeward margin, inhibiting reef growth to a depth of several 10s of meters. Such shallow leeward margins can, therefore, be bare rock floors covered by soft fleshy algae or hard coralline algae with active reef growth taking place only in deeper water, below this interface.

There is commonly a cross-shelf zonation in reef composition that partly reflects the outboard decrease in fine sediment and nutrients. *Inner shelf reefs* are characterized by (1) quickly growing corals with a high tolerance for fine sediment but unable to withstand turbulent waters; (2) large and abundant heterotrophic sponges; (3) low epifaunal diversity; (4) few soft corals; and (5) abundant soft algae and few calcareous algae. *Outer shelf reefs* (in areas of little upwelling) are distinguished by (1) slow-growing autotrophic corals which cannot withstand suspended sediment but are adapted to high-energy seas; (2) reduced numbers of sponges, most of which contain photosynthetic symbionts; (3) common tridacnid bivalves in the Pacific; (4) high epifaunal diversity; and (5) prolific calcareous algae.

Ancient reefs

The history of Phanerozoic reefs and mounds (Figure N11) is complex (James, 1983; Wood, 2000) Descriptions of

Precambrian buildups can be found in Geldsetzer *et al.* (1988) and Grotzinger (1988).

During geological periods when large calcareous skeletal and microbial structures were common, reefs grew as fringing reefs inboard, as patch reefs across platforms, and as semicontinuous to continuous barrier reefs along platform margins. Coeval mounds developed in quiet water settings across the platform, on ramps or on the slope. During geological periods when there were no large reef builders, mounds were the early buildups and grew leeward of sand shoals on deep water ramps and slopes.

Although we cannot be certain about the physiological tolerances of all fossil reef-builders, some generalities are possible. Scleractinian corals, the modern reef-building corals, evolved in the Triassic and were probably zooxanthallate and reef-building by late Triassic, certainly by Middle Jurassic, time. Tabulate corals are a diverse group of several organisms and it is not clear whether they contained similar symbionts. Rudist bivalves, mound builders of Cretaceous seas, are related to modern, zooxanthallate tridacnid bivalves and their ability to form large skeletons is thought by many to be the result of symbiosis. Fossil sponges, both spiculate and soft bodied, and coralline sponges (hard skeletoned such as stromatoporoids, archaeocyathans) are poorly understood, but modern sponges on outer shelf reefs commonly contain cyanobacterial symbionts. Regardless, for those organisms that did contain phototrophic symbionts, light and nutrients would have been important limiting factors.

Fossil reef facies distribution is generally the same as that of modern coral reefs with the caveat that is not clear whether all stromatoporoid and tabulate coral reefs built structures up into the surf zone. Modern reef facies characteristics are directly applicable to Mesozoic and Cenozoic coral-algal reefs, and, with the above caveat, useful for the interpretation of Paleozoic and Proterozoic structures as well.

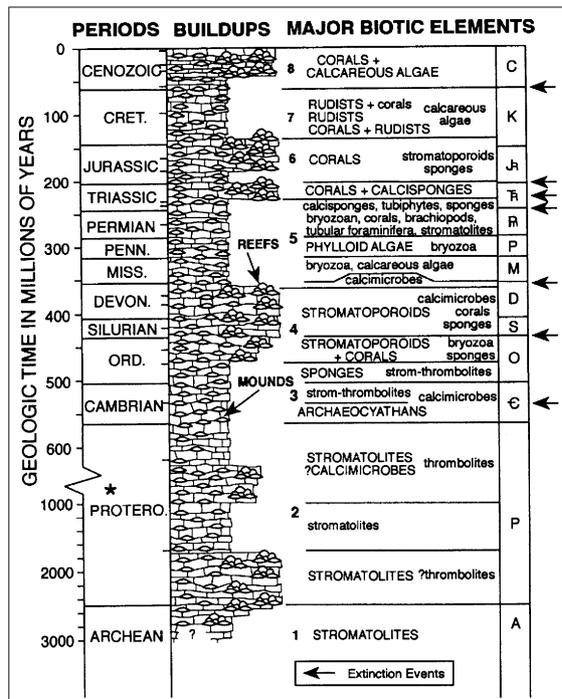

Figure N11 An idealized stratigraphic column illustrating periods when there were only biogenic mounds (see *Carbonate Mud Mounds*) and periods when there were both mounds and reefs. The main reef-building organisms are noted beside each stage (from James and Bourque, 1992).

Autostratigraphy

Ecological succession as exemplified in reefs by an increase in species diversity, biomass, structural complexity, and stability through time is manifest as autostratigraphy. The stages of succession have been called *stabilization*, *colonization*, *diversification* and *domination*. In more general terms the first two stages are really pioneer or developmental phases whereas the last two are climax or mature phases. Such *pioneer communities* are composed of generalists which are small, solitary, generally erect, hardy and fast growing, have high recruitment and reproduction rates, and are of wide geographic distribution. They can readily adapt to new substrates and tolerate abundant suspended matter. Assemblages are of generally low diversity and dominated by one or two elements, poorly zoned and characterized by clumps of fossils with spaces between. A *climax community* is composed of clonal, long-lived, commonly endemic specialists who occupy narrow environmental niches, are slow growing and of large to gigantic size and have a wide variety of shapes. The community is one of high biomass that completely covers the seafloor and in which nutrients are conserved and efficiently recycled, but it is vulnerable to catastrophe.

Allostratigraphy

The allostratigraphy of reefs is a function of: (1) varying conditions in the growth window; (2) ecological succession; (3)

antecedent topography; and (4) the rates of sea level rise and organism growth (Kendall and Schlager, 1981).

Reef *Start-up* can take place: (1) during sea level rise following exposure; (2) during sea level fall when the seafloor comes into the growth window; (3) when the seafloor is raised by mound development into the growth window; (4) when factors inimical to reef growth are turned off.

Keep-up Reefs maintained their crests at or near sea level, tracking sea level rise. *Catch-up Reefs* began as shallow reefs which became deeper as rise rate exceeded accretion rate, only to grow upward and catch up with sea level. Alternatively, they started on a deep substrate and then grew up to sea level. Once reefs of either type reached sea level they maintained a near-surface crest or developed a capping facies of subtidal pavements to storm-ridge deposits. At this point growth was limited to the seaward margin and reefs prograded laterally over their own reef front and fore reef sediments. *Give-up Reefs* initially grew as did the others but then succumbed to changing environmental conditions and died. All studies note that the responses of reef growth to sea level rise varied greatly, even within the same reef.

Reefs can turn off and die in a variety of situations. The most obvious reason, that sea level rise was too rapid for the reefs to keep up, is not the answer. This is because reefs can have extraordinarily high growth rates that potentially exceed any rise in sea level except that related to tectonics. Changes in the growth window are more likely to be the cause of reefs giving up. *Drowning* (Schlager, 1981) is submergence of the platform top below the photic zone by a rise in sea level or shallowing of the photic limit. Alternatively reefs can be killed by some combination of increased turbidity, nutrient excess or hot saline waters which swept off the shelves when sea level flooded the wide shallow platforms (the "bad water" syndrome).

Basin-facing slopes

Introduction

Carbonate slopes (Cook and Enos, 1977; MacIlreath and James, 1984; Mullins and Cook, 1986) encompass a suite of environments which pass seaward from shallow water, sunlit, platform margins and inner ramp environments to the deep, dark, basin settings. They are variably affected with depth by changing seawater chemistry, temperature, pressure and biota. The best studied carbonate slopes in today's oceans are those in the northern Bahamas-Florida region, augmented by more local studies in Belize, Jamaica, Grand Cayman, and several atolls in the Pacific and Indian oceans.

Slope sediment is a variable mixture of autochthonous benthic biofragments, resedimented, allochthonous material from upslope and pelagic fallout. The pelagic component is mostly terrigenous in pre-Jurassic rocks and mostly planktic carbonate in younger strata. *Periplatform ooze* is intermixed platform-derived and pelagic carbonate muds while *hemipelagic sediment* is a mixture of carbonate and terrigenous clastic material.

Autochthonous sediment

This material includes fecal pellets derived from epifauna and infauna, seafloor Mg-calcite cement, peloidal Mg-calcite cement precipitated within foraminifer tests, and skeletal

debris associated with biota indigenous to the slope environment. Siliceous sponge spicules form a locally important supply of noncarbonate sediment.

Allochthonous sediment

Such sediment is transported to and accumulates on the slope by suspension settling, gravity (resedimented) flow, rock fall, and submarine creeping and sliding. Bottom currents, particularly contour currents, can winnow and rework these deposits, or prevent accumulation entirely, resulting sediment starvation, submarine dissolution or lithification.

Fine-grained carbonates composed shallow water-derived particles are transported basinward from shallow water by tides, storms, and currents forming concentrated to dilute sediment-seawater mixtures. These plumes can dissipate, in which case material rains down to the seafloor, or progress downslope as unconfined and confined dilute turbidity currents. Such flows can also move along mid-water density interfaces (e.g., pycnoclines) from which sediment rains down on the basin floor.

This sediment is varying proportions of mud-size algal and inorganically precipitated aragonite needles, blades of Mg-calcite and aragonite, mud- to sand-sized skeletal and nonskeletal debris, lithoclasts, and bioeroded particles (e.g., sponge chips). Jurassic and younger muds are rich in calcareous plankton while older slope carbonates are mostly platform-derived sediment. Locally, coarser periplatform sediments contain gravels and boulder-sized lithoclasts derived from shallow water facies or carbonate bedrock.

A common lithology in many ancient slope sequences is interbedded, finely crystalline, dark grey to black, lime mudstone and shale, forming evenly and continuously rhythmic sequences. In places where the carbonate is finely laminated, suspension deposition may have occurred within an oxygen minimum zone that limited bioturbation. Oxygenated slopes are commonly intensively bioturbated, obliterating primary sedimentary laminations and possibly encouraging the formation of nodular bedding.

Sediment gravity flow deposits are manifest as carbonate turbidites, carbonate grain flow deposits and debrites. Most particles are polygenetic, from the platform, inner to mid ramp and the slope.

A hallmark of many carbonate slopes are massive, thick limestone conglomerates called *debrites*, *debris sheets or avalanches*, *olistostromes*, and *mass breccia flows*. A few decimeters to several tens of meters in thickness, such deposits are generally poorly sorted, lack stratification, and have a random or chaotic clast arrangement. Some have normal and reverse grading, clast alignment near the base, sides or top of the deposits, local clast imbrication, and swirled domains in which clasts display a gradual change in flat clast orientation. Clasts are rounded to angular, and sizes vary from gravel- to house-sized boulders with maximum clast size and bed thickness commonly being correlated.

Paleomargin proximity is commonly indicated by the most abundant and thickest conglomerates containing the largest sizes and varieties of clasts. *Polymict conglomerates* result from the mixing of platform-derived exotic clasts (which may be variable themselves) with slope-derived clasts and matrix. *Oligomict conglomerates* are almost always due to erosion and redeposition of slope limestone in the form of tabular clasts (limestone chips) and interparticle matrix. Rafts of coherently

bedded, slope-derived limestone several tens of meters in size are identical to *in situ* slope limestones. Such rafts become fragmented during progressive downslope transport to yield matrix and tabular clasts. Soft-sediment folding, faulting, fracture cleavage formation and brecciation characterize such rafts.

Intraformational truncation surfaces, shear zones, and detached slide masses are all products of slope failure and form in any of the preceding facies. The first two provide evidence for an ancient slope; the third, like gravity flows, can be preserved either downslope or within an adjacent basin.

Slope styles

Depositional or accretionary slopes, particularly characteristic of ramps, demonstrate net accumulation with the locus of sedimentation along the upper slope or mid ramp and sediment thickness decreasing seaward. A *bypass slope* is one in which there is little sediment accumulation because sediment has largely moved across it, to accumulate at the base of slope as a sediment wedge. *Erosional slopes* illustrate net sediment loss and are characterized by truncated bedding and relatively steep gradients.

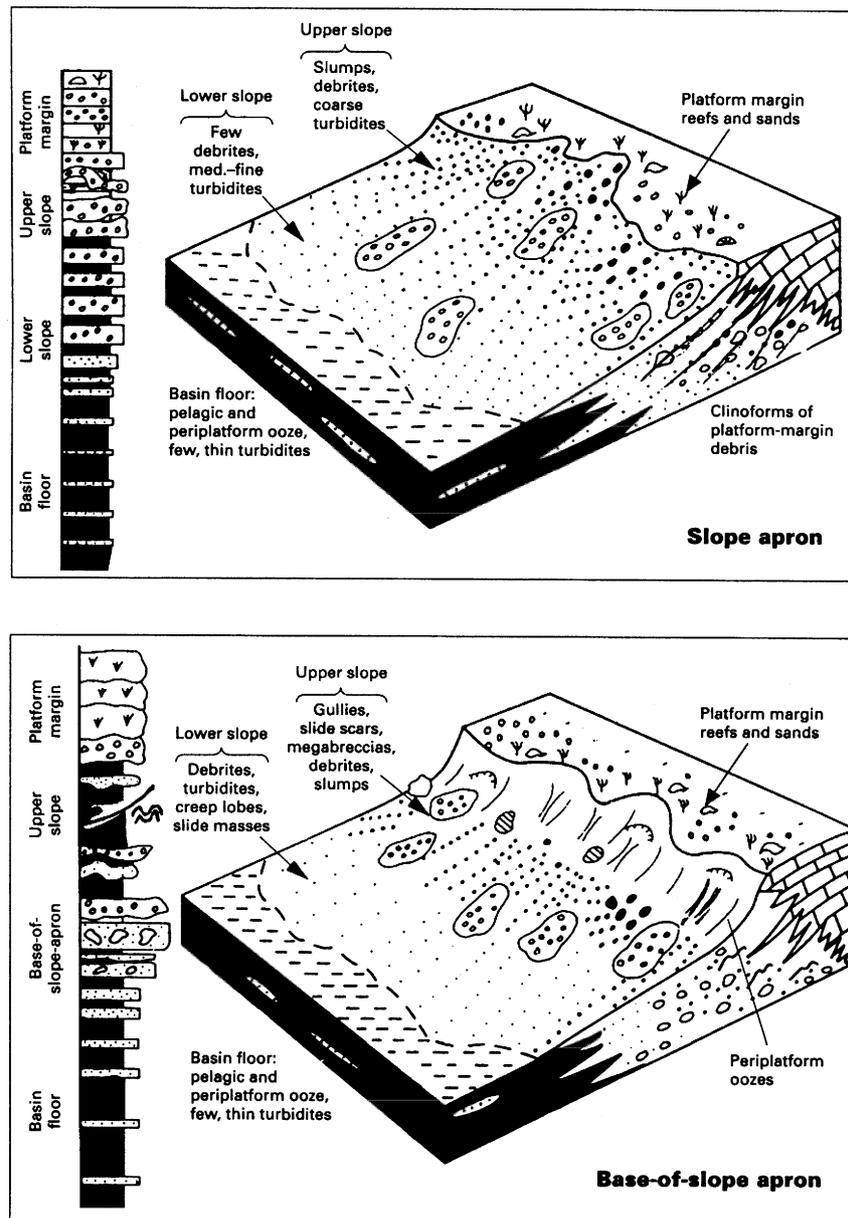

Figure N12 Deep water carbonate slope apron facies (from Mullins and Cook, 1986).

Modern carbonate slopes are generally steeper than their terrigenous counterparts and tend toward concavity with the angle of the upper slope increasing with slope height. Steepening of the carbonate slope, results from: (1) reef-building; (2) submarine cementation; and (3) shallow subsurface lithification. Early lithification may act to delay large-scale failure. Gradients are steeper (30°–40°) for sediments with cohesionless, grain-supported fabrics (with or without mud), than those of paleoslopes dominated by mud-supported, cohesive fabrics (<15°). Pure muds have slope angles of less than 5°.

Many modern carbonate slopes are typified by numerous parallel incised gullies, oriented perpendicular to the margin. Such gullies form a *line source* of sediment supply from the platform and upper slope to the lower slope.

Slope sediment aprons

The ultimate sediment accumulations are wedge-shaped to lenticular bodies that thicken toward the platform margin. Facies belts closely parallel the platform margin.

Carbonate slope aprons (depositional slopes) (Figure N12) extend without break from the basin along gentle (<4°) gradients up to a shallow water platform margin. A line source of platform-derived sediment originates from numerous channels dissecting shoals, reefs and islands along the platform margin. Downslope sediment transport along such carbonate aprons is predominantly via unchannelized sheet flows. These are like the mid- and outer-ramp facies and the two systems seem to merge.

Rimmed platform base-of-slope aprons form downslope from the platform-slope break along a relatively steep (>4°) margin. Sediment is supplied from a line source which typically takes the form of a series of closely spaced gullies transporting shallow water and slope-derived sediment through some portion of the upper to middle (bypass) slope. Sediment emerging from a gullied slope initially follows a dispersal path outlining a series of small, interleaved fan-shaped deposits while broadly defining platform margin-parallel facies belts. As with carbonate slope aprons, systematic vertical sequences are not expected.

Open (unrimmed) platform aprons occur in both warm and cool-water realms. In warm-water settings, because the platform margin is below depths at which the carbonate factory operates, such sediment aprons are likely to be dominantly pelagic in origin. In cool-water settings, however, where the sediment factory is typically deeper, the slopes are in part depositional. Mass-wasting deposits include pelagic turbidites and debrites, the latter of which can contain clasts derived from the platform margin or fragmented beds of early lithified pelagite. The generally finer-grained nature of the deeper platform margin sediment implies that submarine cementation (and therefore production of clasts) may not be as important as along shallower rimmed platform margins. Pre-Mesozoic aprons adjacent to open platform margins are argillaceous.

Carbonate submarine fans appear to be rare in the rock record, but several have been described from the Paleozoic. No modern-day examples have been documented.

Stratigraphy

Since so much of the sediment comes from the platform the stratigraphic style of slope deposits closely reflects conditions

on the platform. Abundant allochthonous carbonate generally signals a healthy, generally prograding platform while starved carbonate or just shale usually means exposure, rapid accretion or subsidence of the platform below the zone of optimum production.

NUMERICAL MODELS AND SIMULATION OF SEDIMENT TRANSPORT AND DEPOSITION

A numerical model simulating sediment transport and deposition is an equation set describing the spatial and temporal evolution of a fluid flow carrying sediment over, and interacting with, an adjacent mobile particulate bed. Although literally scores of such models exist, each starting from quite different assumptions and incorporating quite different sedimentary processes, the most common and the focus of this entry are process-based models constructed with the mutual goals of prediction and understanding. Given water and sediment mass fluxes delivered to a geomorphic system through time, these numerical models are expected to

accurately predict the total mass flux and character of sediment passing each point in the system at time and space scales appropriate for the application. To do so, each model must capture how changes in state variables of the fluid flow, the sediment transport, and the deforming bed influence one another through feedback loops. Each also must embody the physical processes thought to be relevant and consequently each is a conjecture about the dynamical behavior of the geomorphic system. Thus, for example, if the geomorphic system is a river channel reach of a given initial hydraulic geometry and sediment characteristics with a given sediment and water feed at the upstream end, the model in question should predict accurately the temporally evolving flux of water and sediment along the reach and the amount of bed erosion or deposition through time using conservation and rate laws that describe all the processes and their interactions. This entry describes the character, use, and limitations of this general class of sediment transport model. Channelized flows are emphasized, although much of the discussion also applies to sediment transport models of lakes and coastal oceans. Also, the emphasis here is on non-cohesive sediment transport because most models, if they address cohesive sediment at all, are still quite primitive in its treatment. Table N1 list some popular examples.

Model components

There are five components or computation modules in a sediment transport model: (1) a hydrodynamic module to compute the flow field; (2) a shear stress module to calculate the stress effective in transporting sediment as the bed roughness evolves and in some models, to calculate the shear stress distribution arising from turbulent fluctuations; (3) a bed-load transport module; (4) a suspended load transport module; and (5) a bed module that keeps track of bed erosion, deposition, and the evolving bed texture. The computation modules are organized into a solution algorithm, the structure of which depends upon whether the equation set is to be solved simultaneously or in series. Figure N13 gives a typical organization of the computation modules for a series solution of a 1-D, unsteady, nonuniform application. Because continuous solutions to the equation set are not known, the set is always solved by either finite-difference or finite element techniques at discrete nodes in the model space, $x = 1\Delta x, 2\Delta x, \dots, n\Delta x, y = 1\Delta y, \dots, t = 1\Delta t, \dots$, and so on.

Each of the five components is described below. For the purposes of illustration, a right-handed Cartesian coordinate system is assumed in which x defines the primary horizontal flow direction, y the transverse direction, and z is positive upward.

Hydrodynamic module

An accurate description of the fluid flow field is a necessary condition for predicting sediment transport and deposition. Without significant loss of generality most geomorphic hydraulic models assume that the fluid is incompressible, the fluid density is everywhere equal, the pressure distribution in the fluid is hydrostatic, and the eddy viscosity approach can be used to describe the role of turbulence in momentum transfer (see Lane, 1998 for a review). Whether further simplifications are justified depends upon the application. In the most demanding applications the flow field is unsteady and

nonuniform and significant secondary circulation exists. Consequently, the hydraulic module must compute the instantaneous, turbulence-average flow velocities u , v , and w at all nodes in the model space, as well as the water surface elevation, h at all surface nodes. Four dependent variables require four equations for their solution. The equations are the x - and y -directed general laws of motion, the hydrostatic pressure distribution in the vertical, and conservation of mass equation:

$$\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial}{\partial y} uv + \frac{\partial}{\partial z} uw = fv - \frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{\partial}{\partial x} \left(A_H \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(A_H \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left(A_V \frac{\partial u}{\partial z} \right) \quad (\text{Eq. 1})$$

$$\frac{\partial v}{\partial t} + \frac{\partial}{\partial x} uv + \frac{\partial v^2}{\partial y} + \frac{\partial}{\partial z} vw = -fu - \frac{1}{\rho} \frac{\partial p}{\partial y} + \frac{\partial}{\partial x} \left(A_H \frac{\partial v}{\partial x} \right) + \frac{\partial}{\partial y} \left(A_H \frac{\partial v}{\partial y} \right) + \frac{\partial}{\partial z} \left(A_V \frac{\partial v}{\partial z} \right) \quad (\text{Eq. 2})$$

$$\frac{\partial p}{\partial z} = -\rho g \quad (\text{Eq. 3})$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (\text{Eq. 4})$$

where u , v , w = velocity components in the x , y , z -directions; t = time; f = Coriolis parameter; ρ = local fluid density, accounting for temperature, salinity, and sediment concentration; p = pressure; A_H = horizontal turbulent diffusion coefficient; A_V = vertical turbulent diffusion coefficient; and g = gravitational acceleration. Term 1 above accounts for unsteadiness of flow; Term 2 accounts for nonuniformity of flow; Term 3 accounts for Coriolis accelerations; Term 4

accounts for fluid pressure gradients arising from gradients in the water surface elevation; Term 5 accounts for shearing forces per unit mass due to velocity gradients in the horizontal and Term 6 accounts for shearing forces per unit mass due to velocity gradients in the vertical.

Before the equation set can be solved for the dependent variables, the turbulent diffusion coefficients must be specified. Numerous approaches exist (*cf.* Nezu and Nakagawa, 1993) ranging from “zero-equation” turbulence models that specify

constant coefficients to “two-equation” models that equate A_V to the square of the turbulence energy per unit mass and to the inverse of its rate of dissipation. Turbulence production and dissipation in turn are computed at all nodes using transport equations for the turbulence.

In selected applications the above equation set can be considerably simplified. For example, if only a cross-sectional average description of the flow in a rectangular channel is

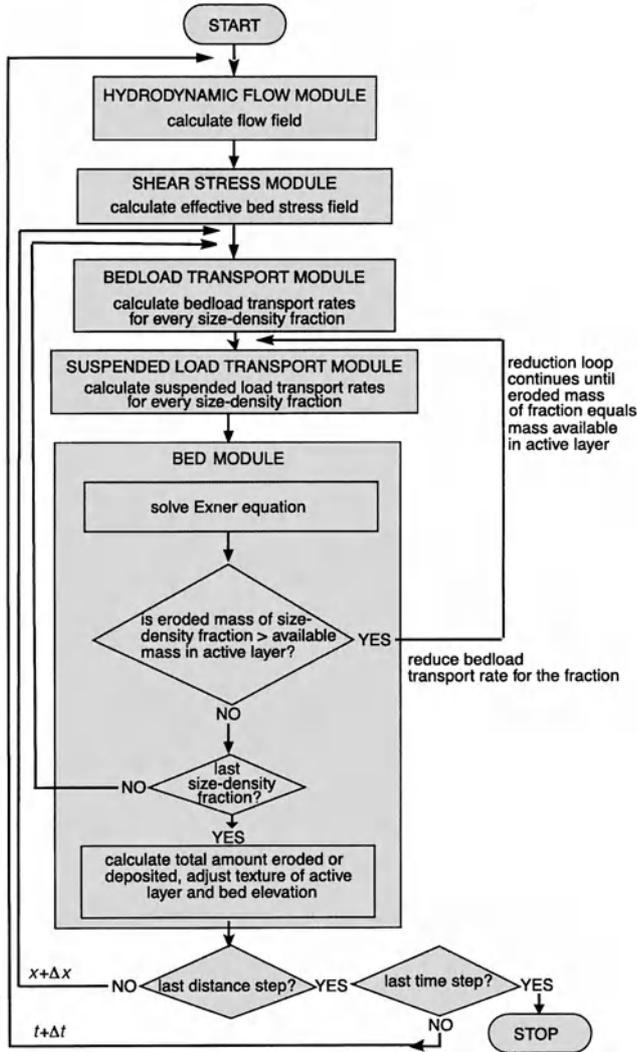

Figure N13 Flow Chart of a typical sediment transport model.

needed, the Coriolis term may be dropped and equations 1–4 integrated to yield:

$$\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x} QV + gA \frac{\partial h}{\partial x} + \frac{fWV^2}{8} + gA \frac{\partial b}{\partial x} = 0 \quad (\text{Eq. 5})$$

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} - q_l = 0 \quad (\text{Eq. 6})$$

where Q = water discharge; V = cross-section average velocity; A = cross-section area; h = water depth; f = friction factor; W = channel width; b = bed elevation; and q_l = lateral inflow per unit length of channel. Equations 5 and 6 can be simplified further by assuming the flow is steady and uniform provided that the ratios V/gST and h/SL are much less than 1 (Paola, 1996), where S is the bed slope, T is a timescale over which the unsteadiness occurs, and L is a length scale over which the channel nonuniformity occurs. It should be noted however, that if the application requires dynamical adjustments in channel width, a 2D formulation is necessary at minimum.

Shear stress module

The suspended load is determined by the sediment concentration and velocity distributions over the vertical, both of which depend upon the total turbulence-averaged bed shear stress τ_0 , exerted by a flow on its bed and banks. The bed-load on the other hand, should be computed using only the skin friction component of the bed shear stress, τ_0' , and should not include the bedform shear stress, τ_0'' , that is, that portion of the fluid drag expended exciting roller vortices on the lee sides of dunes. The skin friction component is called the *effective bed shear stress* and various schemes are available to compute it (e.g., Einstein and Barbarossa, 1952; Kazemipour and Apelt, 1983). For example, in the case of equation 5 where the mean properties of the flow are of interest, the effective bed shear stress law may be computed from the quadratic shear stress law as:

$$\tau_0' = \frac{f}{8} \rho V^2 \quad (\text{Eq. 7})$$

where f , the Darcy–Weisbach friction factor for turbulent flows, is calculated using the Colebrook–White formula. Alternatively, if the flow is steady and uniform, the total turbulence-averaged bed shear stress, given by:

$$\tau_0 = \rho g RS \quad (\text{Eq. 8})$$

where R = hydraulic radius and S = bed slope, may be reduced by subtracting the bedform shear stress, the latter equal to:

$$\tau_0'' = \frac{1}{8} \rho V^2 \frac{s^2}{lh} \quad (\text{Eq. 9})$$

where s = dune height and l = dune length.

Although most sediment transport models use the temporal mean fluid shear stress to represent the fluid forces on grains, in reality the local instantaneous bed shear stress fluctuates dramatically due to flow turbulence. Some sediment transport models incorporate this variation (e.g., van Niekerk *et al.*, 1992; Bridge and Bennett, 1992) by computing a Gaussian distribution of instantaneous effective shear stresses.

Bedload transport module

The bed material load consists of all those grains in transport that are directly supplied by, and interchange with, the alluvial bed, whether traveling as bed-load or suspended load. Its opposite is wash load. For a given flow strength and bed material it is assumed that each size fraction will be transported at a fixed rate, the sum of which is called the sediment transport capacity of the flow. Prediction of the bed material load at capacity usually proceeds by computing the bed-load and suspended load independently.

As discussed elsewhere (see entries in this volume on *Sediment Transport*), bed-load refers to all those sliding, rolling, and saltating grains supported at least in part by collisions with other grains or contact with the bed. In water, the grains travel within a few grain diameters of the bed as a low-concentration, dispersed, grain flow.

Grains are considered to be in motion when:

$$\Theta' > \Theta_{ci} \quad (\text{Eq. 10})$$

in which Θ' = the dimensionless effective bed shear stress of the local flow and Θ_{ci} = the critical shields parameter for the i th grain size and density in question. Accurate prediction of

bed-load fluxes depends strongly upon knowing these critical shear stresses.

Research over the last two decades (*cf.* Komar, 1996) shows that:

$$\Theta_{ci} = \Theta_{c50} \left(\frac{D_i}{D_{50}} \right)^{-m} \quad (\text{Eq. 11})$$

where Θ_{c50} = the critical shields parameter of D_{50} , the median size in the bed size distribution, D_i = the grain size in question, and $m \approx 0.65$ for beds coarser than sand.

Once grains are entrained, they may pass directly into the suspended load. Grains are moving as bed-load when:

$$w \geq Bu_*' \quad (\text{Eq. 12})$$

where w = the grain fall velocity (see entry in this volume on grain fall velocity), $B = 0.8$, and u_*' = the local effective shear velocity.

The weight or volume transport rate of bed fractions meeting the criteria of equations 11 and 12 may be calculated using one of many formulas (see reviews by Gomez and Church, 1989; Yang and Wan, 1991). Most can be shown to reduce to a function of the form:

$$i_{bi} = aP_i(\Theta' - \Theta_{ci})^b \quad (\text{Eq. 13})$$

where i_{bi} = bed-load transport rate per unit width of the i th fraction at capacity; a is roughly a constant, P_i = volumetric proportion of the i th fraction in the bed, and $1 \leq b \leq 2$. Note that as the various size fractions are differentially entrained, the bed size distribution evolves, thereby modifying the bed-load transport rates through the coefficient P_i .

Suspended load transport module

The suspended load consists of all those grains borne aloft in the flow by an upward-directed turbulence momentum flux. Operationally, the suspended load consists of all moving grains for which equation 12 is untrue. Here too, the researcher can choose among numerous formula (see entries in this volume on sediment transport). The most basic conception assumes that if the vertical profiles of both sediment concentration $C(z)$, and forward velocity $u(z)$, are known, the volumetric discharge of suspended grains passing through a cross section of unit area at height z is given by $C(z)u(z)$. Integration of this quantity over the depth yields the suspended load transport rate:

$$i_{si} = \int_a^h C_i(z)u(z) dz \quad (\text{Eq. 14})$$

where i_{si} = volumetric suspended load transport rate per unit width of the i th fraction moving in the x -direction, and a = the height off the bed at which a reference concentration is known.

The concentration function is defined by the *Rouse equation*:

$$\frac{C_i(z)}{C_i(a)} = \left[\frac{(a)(h-z)}{(z)(h-a)} \right]^R \quad (\text{Eq. 15})$$

or more recently, by the van Rijn equation (van Rijn, 1984), where R = the Rouse Number. In either case, a reference concentration $C_i(a)$, is needed for the integration. Some researchers (e.g., van Niekerk *et al.*, 1992) take the reference height as the top of the moving bed layer and the reference concentration as the concentration of the i th fraction in the

subjacent bed-load as defined by a function of the form given by equation 13. Others, such as van Rijn, point out that in the presence of bedforms another approach is needed. Van Rijn takes the reference height as one-half the dune height or the equivalent roughness height if bedform dimensions are not known and computes the concentration at that height as a function of excess effective shear stress.

The velocity profile traditionally is defined by the law of the wall for hydraulic rough flow conditions:

$$\frac{u(z)}{u_*} = \frac{1}{\kappa} \ln \left(\frac{z}{z_0} \right) \quad (\text{Eq. 16})$$

where: u_* = flow shear velocity; κ = von Karman's constant; and $z_0 = 33$ percent of the equivalent roughness height of Nikuradse.

Predictions of suspended load flux by equation 14 are suitably accurate provided the concentrations do not increase to values that dampen turbulence.

Bed module

The core of a sediment transport model is its bed module. The bed is both a source and sink of the various size fractions in transport and it dynamically responds to and modifies the overlying flow field by changing its elevation and roughness. These roles can be described by an equation accounting for the mass fluxes of grains to and from the bed. It is a simple statement of conservation of mass of the bed, often called the *Exner equation*:

$$\frac{\partial}{\partial t} T b_i = - \frac{1}{(1-p)\gamma'} \left(\frac{\partial}{\partial x} T(i_{bi} + i_{si}) \right) + q_b \quad (\text{Eq. 17})$$

where: T = width of the active bed, usually assumed to be channel width; b_i = bed elevation attributable to the i th size-density fraction; p = bed porosity; γ' = immersed specific gravity of grains; $(i_{bi} + i_{si})$ = the immersed weight transport rates per unit width of the bed-load and suspended loads; q_b = volumetric lateral sediment inflow per unit along-stream distance; and it is assumed for simplicity that the application is 1D. Equation 17 expresses how spatial gradients in transport rates of the various size fractions give rise to temporal changes in bed elevation. If the changes in bed elevation are nonuniform, bed slopes and cross sectional areas evolve, thereby changing the flow field. Note that per unit area, the relative proportions of the b_i represent the proportions of the various size fractions in the static bed, thereby allowing computation of a new bed grain size distribution and hydraulic roughness.

In practice, equation 17 is applied to an upper layer of the alluvium called the *active layer*, in recognition of the fact that over timescales of minutes to hours there is a finite thickness of alluvium exposed to the flow. The active layer may be conceived as a layer of mixing between the traction carpet and the static bed. The thickness of the active layer has been taken variously as the height of dunes present on the bed, the thickness of the armor layer (and hence some multiple of a characteristic grain size of the bed), or a function of excess shear stress. As grains are removed from the active layer on its upper surface, grains are added from below in proportion to their concentrations in the subjacent layer. During deposition,

grains pass out of the bottom of the active layer in proportion their concentrations in the layer.

Solution of equation set

The computational modules described above require initial and boundary conditions to form a closed set of equations. In addition, if the application involves channelized flow, either the alongstream channel widths must be specified or an additional function added to relate width to the state variables. Initial conditions include the geometry and bed textures of the geomorphic domain of interest and flow velocities and sediment transport rates everywhere in the domain (both usually taken to be zero for lack of better information). To avoid errors arising from bogus initial conditions, it is common practice to “spin-up” a model before interpreting the results. Boundary conditions include temporally evolving water and sediment hydrographs along upstream open boundaries and (typically) water surface elevations along downstream open boundaries. Lateral inflows of sediment and water along closed boundaries also must be specified.

Because the equation set is analytically unsolvable, the time-space domain is subdivided into a finite number of nodes or elements, and solutions are obtained at discrete points in space and discrete times. The flow chart of MIDAS (van Niekerk *et al.*, 1992), provides a typical example of computational flow for a 1D case (Figure N13). After the user has specified the initial and boundary information, the flow field at time $t + \delta t$ is computed across the whole domain by some combination of equations 1 through 6. The effective shear stresses are calculated next from equations 7 through 9. Starting at the upstream end of the domain, the bed-load transport rates are computed from equations 10 through 13, thereby providing the reference concentrations for the suspended load computation using equations 14 through 16. After the bed material load at node 1 has been computed, equation 17 is solved for changes in bed elevation at that node arising from erosion or deposition of each size fraction. If the mass of any size fraction to be eroded is greater than is available in the active layer, then that fraction’s bed-load transport rate (and consequently its suspended load transport rate) are incrementally reduced until mass is conserved. Computation proceeds through the domain, after which the time step is incremented, the flow field is recomputed taking into account the updated water depths and hydraulic roughnesses, and the sediment transports are recomputed in light of the new flow field.

This algorithm is not the only possible computation method. Although this uncoupled approach is the most common, a few models such as CH3D-SED (Gessler *et al.*, 1999) simultaneously solve for all dependent variables in a fully coupled solution. The advantage of a coupled solution is that uncoupled models are restricted to short time steps so that the hydrodynamic solution scheme adjusts to small changes in the bed.

An example

To gain an appreciation of model capabilities, consider a comparison of predictions from the sediment-routing model MIDAS (Table N1) with flume data collected by Little and Mayer (1972). Little and Mayer investigated the effects of sediment gradation on channel armoring. A nonuniform bed of sand and gravel was placed in a flume 12.2 m long, 0.6 m

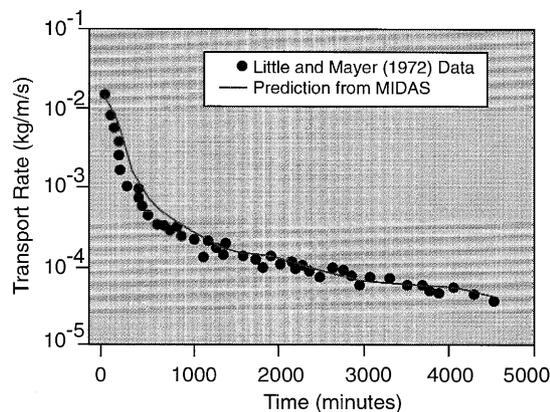

Figure N14 Comparison of observed sediment transport rates from a flume study of bed armoring by Little and Mayer (1972) with predictions from the sediment transport model MIDAS (van Niekerk *et al.*, 1992).

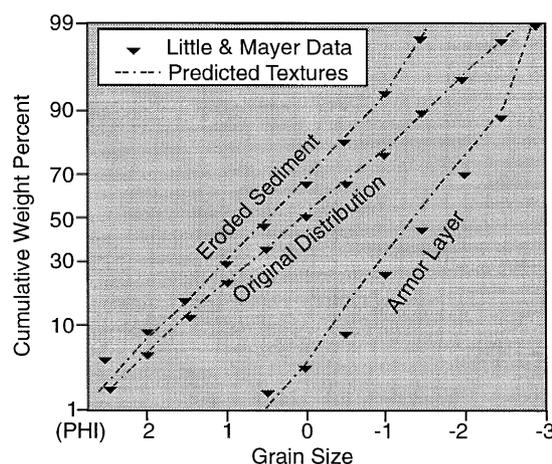

Figure N15 Comparison of observed textures from a flume study of bed armoring by Little and Mayer (1972) with predictions from the sediment transport model MIDAS (van Niekerk *et al.*, 1992).

wide, and 0.1 m high. Clear water was passed over the bed to produce bed degradation and armoring. The eroded sediment was caught by screen separators at the downstream end of the flume, and at regular intervals was dried, weighed, and stored for later sieving. When the total transport rate was 1 percent of the initial transport rate and the armoring was thought complete, the flume was drained and the armor layer was sampled using molten beeswax as described by the authors. For numerical modeling, the flume was divided into eight sections and solutions of the MIDAS equation set were computed for every section every minute.

The computed and the measured total transport rates (Figure N14) show good agreement, the computed values being within a factor of 2 of the measured values at all times. Temporary divergence of the two curves arises because turbulence produces random and intermittent movement of the bed particles. After 75.5 hours of flow, the size distributions of the original sediment, the bed-armor sediment, and the total eroded sediment (Figure N15) show that the numerically

simulated armor layer is slightly finer than observed, although the difference in mean grain sizes is only 2.7 mm versus 3 mm. The numerically simulated and physically observed grain-size distributions of the transported sediment almost coincide.

Unresolved problems

Although much progress has been made in sediment transport models, the accuracy of predictions in many applications is still regrettable. Bedload functions are still prone to order of magnitude errors (*cf.* Gomez and Church, 1989; Yang and Wan, 1991), and present formulations need to be tested in extreme events when much of the sediment transport occurs in many geomorphic systems. These errors are compounded when computing sediment flux divergences in equation 17. Also, suspended load formulations break down at hyper-concentrations such as seen in many rivers draining loess provinces and do not yet account for the wash load. There is also a pressing need to treat channel pattern changes and dynamic adjustments in channel hydraulic geometries. Secondary flows are commonly assumed to be negligible, yet in natural channels, and particularly during overbank flows, lateral gradients of flow depth and friction factor induce significant lateral velocity gradients. Although not much has been said about coastal ocean sediment transport models, a better understanding of the basic physics of combined oscillatory and unidirectional flows is needed and the processes of sediment aggregation, flocculation, and disaggregation in marine waters must be better understood.

A final thought

Given the work yet to be done, it is sobering to realize that the most severe test yet of numerical sediment transport modeling is being carried out right now on the Yangtze River in China. Construction of the Three Gorges Dam began in 1994 and is scheduled to take 20 years. It will be the largest hydroelectric dam in the world, stretching nearly a mile across and towering 575 feet above the world's third longest river. Its reservoir will stretch over 350 miles upstream and force the displacement of 1.2 million people. The role that numerical sediment transport modeling has played in the dam's conception, feasibility studies, and design is unprecedented and the predictions are controversial. Physical and in particular, mathematical modeling of sedimentation was conducted by the Yangtze Valley Planning Office (China) and reviewed by the Yangtze Joint Venture (Canadian International Development Agency). Dr Luna Leopold, a respected elder statesman of fluvial engineering in the United States has written, "The sedimentation conditions at various times during the first 100 years of operation have been forecast by use of mathematical models and physical analogues that involve many assumptions of

unverified reliability". Let us hope our faith in numerical models of sediment transport and deposition is justified.

O

OCEANIC SEDIMENTS

Introduction

Oceanic sediments are found on the deep ocean floor (generally below 3 km depth) hundreds of kilometers seaward of the continental margins and cover more of the earth's surface (55 percent) than the continents (29 percent). Within this vast realm there is an array of distinctive sediments, *Globigerina* ooze, red clay, hemipelagic muds, manganese nodules that occur nowhere else on earth. These sediments are largely generated within the ocean although detritus from the continents can also be important, especially at the margins of the ocean basins. Ocean drilling reveals that the oldest deep-sea sediments are Jurassic (*ca.* 140 Ma) and that the type and distribution of oceanic sediments has changed with time. Ocean waters filling the ocean basins today are cold and well oxygenated but 50 million years ago were warmer and less well oxygenated. Pelagic clays are accumulating where once calcareous-rich sediments were deposited. As climate and the ocean environment have evolved, the suites of sediments that cover the modern seafloor have changed.

Oceanic sediments and deep-sea sediments are used herein interchangeably although some authors use "deep-sea sediments" as encompassing the sediments of both the deep ocean and the continental margin (shelf, slope, rise). The "deep ocean", "deep ocean basins", "oceanic floor" and "deep seafloor" refer to portions of the ocean basins that generally lie below 3 km, although some texts define the deep ocean as greater than 4 km. The emphasis in this article is on the type, distribution and sedimentation of modern oceanic sediments that occur beyond the continental rise with the exception of abyssal fans (cones). The latter are really features that originate on the slope-rise and extend into deep ocean basins. For readers interested in a more comprehensive discussion of deep-sea sediments, I suggest reviews by Berger (1976), Davies and Gorsline (1976), Barron and Whitman (1982) and texts by Kennett (1982), Lisitzin (1996), the Open University, Volume 5, *Ocean chemistry and Deep-sea sediments* (1989 and later editions) and Seibold and Berger (1996).

Historical development

Marine sediments are mentioned in writings as far back as Greek and Roman times (e.g., Strabo and Posidonius in the first century BC) but it was not until the 19th century with the advancement of microscopes and the introduction of cable and sampling devices that the systematic collection and description of deep ocean sediments really began.

The *Challenger* Expedition (1872–76) revolutionized knowledge about the deep ocean and, among many firsts, made the first systematic sampling of oceanic sediments (see *Sedimentologists*). At the urging of the Royal Society of London, the British government commissioned the corvette, *H.M.S. Challenger*, under the direction of Charles Wyville Thomson, professor of natural history at the University of Edinburgh to determine the "conditions of the deep-sea through all the great ocean basins". It was the first major scientific exploration of the ocean. The introduction of steam winches and steel cable made deep sampling practical and in four years, the expedition carried out nearly 500 deep soundings with a mechanical grab and 133 dredging. Sediment samples were collected in all of the major ocean basins and near Antarctica, even in the Mariana trench at a depth of 8,185 m. Over the next two decades, Sir John Murray, in collaboration with A. F. Renard, (Murray and Renard, 1891), described and classified the samples, introduced many of the terms still in use today and laid the foundation for the study of deep-sea sediments. Murray, the naturalist on board the *Challenger*, also collected samples of shell-bearing plankton and correctly related their distribution in the surface ocean to the calcareous and siliceous sediments on the seafloor (Murray, 1897).

The *Challenger* Expedition generated a major interest in the scientific investigation of the oceans and was followed by an era of national oceanographic expeditions spanning nearly 70 years although interrupted by two world wars. Expeditions were conducted by many nations, including England, the United States, Germany, Japan, Russia, Holland, Sweden, and France and led to the establishment of the first oceanographic institutions, Woods Hole Oceanographic Institution (United States) and Plymouth Marine Laboratory (England). While most expeditions were devoted to the biology, chemistry, and

physics of the oceans, some important advances occurred in the study of ocean sediments. It was during the German Southern Polar Expedition (1901–03) that the gravity corer was invented and the first sediment cores were recovered.

By the 1930s, electronic depth sounders replaced wire soundings to measure ocean depths and reveal the complex bathymetry of the deep ocean. This technology was first used during the German *Meteor* Expeditions in the Atlantic. In 1935, Schott (1935) in a pioneering study based on gravity cores collected by the *Meteor*, devised a means for correlating between cores, calculating reliable rates of sedimentation and studied the effects of the Ice Ages in the Atlantic Ocean.

One of the last major national expeditions was the Swedish Deep Sea Expedition (1947–49) to the equatorial Pacific Ocean. It employed the newly developed Kullenberg piston corer that could recover sediment cores tens of meters in length and made possible the study of Pleistocene ocean history. In these cores, Arrhenius (1952) discovered distinct Pleistocene cycles in calcium carbonate content which he related to glacial to interglacial variations in productivity and preservation. He proposed that the higher carbonate content was due to increased surface productivity during glacial times, initiating a debate about the processes which control biogenic sedimentation, a debate that continues today (see Berger, 1992).

In 1968, the Deep Sea Drilling Project (DSDP) was launched to test the theory of continental drift by determining the age and evolution of the ocean basins. Prior to ocean drilling, information about deep-sea sediments was limited to the surface layer penetrated by a piston corer, a few tens of meters. The entire inventory of pre-Quaternary deep-sea sediments was fewer than 100 cores. In the past 34 years, DSDP (and its successors, the Ocean Drilling Project (ODP) and International Decade of Ocean Drilling (IDOP)) have collected a vast array of information from all of the ocean basins except the Arctic Ocean, including long cores of sediments extending back to the early Jurassic. These data have significantly expanded our understanding of the ocean basins, their origins, the sediments that fill them, life that existed in the past and the dynamics of the interplay between tectonics, climate and the oceans.

Classification and major types

Sediments of the deep ocean basins are termed *pelagic* (*pelagios* = of the sea) if they originate in the ocean or *hemipelagic* when mixed with terrigenous material derived from the continent. Pelagic sedimentation involves two processes: the packaging of biologically produced debris in the water column and dust that falls into the ocean and its transfer to the seafloor. Pelagic particles “rain” down from the surface. These processes occur everywhere within the ocean.

Sedimentation of the terrigenous component in hemipelagic sediments involves resuspension and turbidite and suspension flows. These processes move mud (silt and clay) that was originally deposited on the continental slope into the deep ocean where it becomes mixed with pelagic debris. While the distinction between pelagic and hemipelagic seems obvious, in practice it can be difficult to determine the origins of sediment particles because the terrigenous component in both types of deposits is derived from the continents and the mineralogy and grain size may be very similar. Determining the relative proportion of particles that are pelagic in hemipelagic sediments can be difficult.

There is no single widely agreed upon classification of oceanic sediments and different authors even use some of the common terms differently. Two broad approaches have been used to classify marine sediments: descriptive, based on grain size and composition or genetic, based on origins, or a combination of the two. Murray and Renard (1891), for example, used a descriptive-genetic approach when they coined the terms “red clay” and “*Globigerina* ooze” for common deep-sea deposits and this approach is followed here in a scheme modified from Berger (1974) (Table O1). A useful discussion on the philosophy of sediment classifications is given in Davies and Gorsline (1976).

There are three kinds of sediments in the deep-sea: *Terrigenous* (or Lithogenous): detrital or clastic particles produced by the weathering, erosion and transport of pre-existing rocks, primarily from the continents and volcanic eruptions; *Biogenous*: biologically produced shells or skeletons of calcium carbonate, siliceous or calcium phosphate, either in the water column or on the seafloor; and, *Chemogenic* (or hydrogenous): primary (authigenetic) or diagenetic chemical precipitates from seawater or interstitial waters, sometimes mediated by bacteria.

Aerially and volumetrically two types of sediments dominate in the deep ocean: biogenic oozes, especially calcareous oozes and pelagic clay (abyssal “red” clay). Ooze is the loose, unconsolidated accumulation of biogenic debris (shells of foraminifera, diatoms, radiolaria or coccoliths) usually mixed with some clay. In the modern ocean, roughly 50 percent of the seafloor is covered by foraminiferal-rich calcareous ooze, 37 percent by pelagic clay and 12 percent by siliceous-rich sediments (Berger, 1976). All other sediment types equal < 1 percent (Figure O1).

Volcanogenic materials are common in the deep sea but the coarser-grained materials are limited to the source area. Volcanic ash can be transported hundreds of kilometers from its source and is widely distributed in the ocean. Within the sediments it is an important source of silica in the formation of zeolite and clay minerals. There are several rare but distinct deposits that occur in modern and ancient sediments. One of them is cosmic dust (microtektites) particles that survive the trip through the atmosphere and fall into the ocean. They are found in pelagic red clay, mostly in the southern hemisphere. Another is laminated, diatom-rich mud that occurs in Pliocene and Miocene deposits in the eastern equatorial Pacific (Pearce *et al.*, 1996). Typically such deposits are associated with organic carbon-rich hemipelagic sediments beneath upwelling areas in continental margins and not the deep ocean.

Data from the ocean drilling indicate that the relative abundance and distribution of major sediment types has changed with time under the influence of different climate and oceanic environments and that biogenic sediments were even more widely distributed in the early Tertiary and Cretaceous. The record of deep-sea sediments provides one of the most important sources of information about the history of global wind patterns, ocean fertility, ocean geochemistry and biotic evolution.

The distribution of major sediment types in the deep ocean can be related to three factors: (1) distance from the continents; (2) water depth, which influences the preservation of biogenic sediments; and (3) ocean fertility, which controls surface productivity. There are two major sediment boundaries in the deep ocean: (1) The Calcium Carbonate Compensation Depth (calcite compensation depth) that separates carbonate-rich

Table O1 Classification of Oceanic Sediments**I. Pelagic deposits (oozes and clays)**

< 25 percent of fraction > 5 μm fraction is terrigenous or volcanogenic
 medium grain-size > 5 μm (except for authigenic minerals and pelagic fossils)

A. Pelagic clay

1. Calcareous clay: 1–30 percent calcareous fossils (foraminifera, coccoliths)
2. Siliceous clay: 1–30 percent siliceous fossils (diatoms, radiolaria, sponge spicules)
3. Zeolitic clay: > 30 percent zeolitic minerals

B. Oozes (loose, unconsolidated accumulation of pelagic skeletal debris)

1. Calcareous ooze: < 30 percent < 2/3 calcareous fossils (foraminifera, pteropods, coccoliths)
2. Siliceous ooze: > 30 percent opal silica fossils (diatoms, radiolaria)

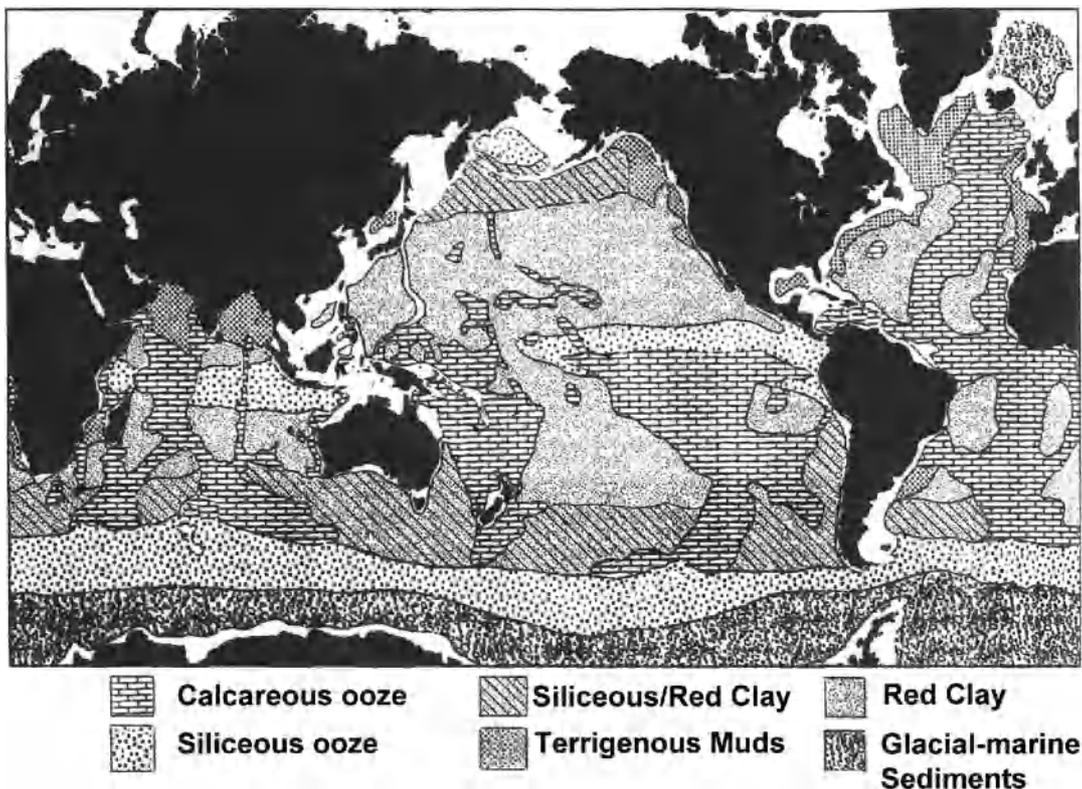

II. Hemipelagic deposits (muds, mostly silt and clay)

> 25 percent of fraction > 5 μm is terrigenous or volcanogenic
 median grain-size > 5 μm (except for authigenic minerals and pelagic fossils)

A. Calcareous muds: > 30 CaCO_3 **B. Terrigenous muds: < 30 CaCO_3 > 50 percent quartz, feldspar, micas, lithic fragments****C. Volcanogenic muds: < 30 percent CaCO_3 > 50 percent ash, palagonite, etc.****III. Chemogenic deposits (authigenetic and diagenetic precipitates from seawater)**

- A. silicate minerals-smectitic clay, zeolites (phillipsite, palagonite, palygoskite, sepiolite)
- B. Ferromanganese minerals-oxyhydroxides of Fe and Mn; amorphous, fine-grained crystals, coating, nodules
- C. Sulfate minerals-barite

(after Berger, 1974, with modifications).

**Figure O1** Distribution of the major types of oceanic sediments (after Davies and Gorsline, 1976, with modifications based on many sources).

oozes and carbonate-poor pelagic clay (see *Calcite Compensation Depth*). The depth and distribution of this boundary varies within and between ocean basins; and (2) the transition from hemipelagic to pelagic sediments at the margins of the deep ocean, which is gradual and often difficult to, delineate, exactly.

Sedimentation rates and thickness of oceanic sediments

While John Murray and other 19th century workers suspected that sediments in the deep ocean accumulate slowly, they had

no means by which to access rates of sedimentation and it remained for Schott (1935) to provide the first quantitative estimates by using the occurrence of a distinctive tropical foraminifer, *Globorotalia menardii*. During glacial periods, this species is absent in cores in the central Atlantic Ocean and its first appearance coincides with the base of the Holocene. Using the age of the base of the Holocene (determined on land) as a datum, he calculated that the calcareous oozes in the Atlantic had accumulated at rates of several centimeters per thousand years. Today a variety of dating techniques (radiocarbon, Uranium series, etc.) are available to determine the rates of sedimentation. While rates vary considerably, in general, they fall in the range of millimeters to tens of centimeters per thousand years with the lowest rates occurring in abyssal pelagic clays (1 mm/kyear) and highest rates in hemipelagic muds (meters/kyear) (Table O2).

Prior to deep ocean drilling, the ocean basins were believed to be permanent, unchanging features of the earth and therefore to contain a thick sediment record extending back to earliest Earth history. In the 1950s, marine geophysical surveys revealed that the sediment cover in the ocean basin was in fact remarkably thin (Ewing *et al.*, 1964; Raitt, 1956) but it remained for the Deep Sea Drilling Project to confirm the age and thickness of deep-sea sediments. In the central Pacific Ocean the sedimentary layer resting on basaltic crust varies from 100 m to 300 m thick, except along the equator and a few plateaus, where it exceeds 500 m (Winterer, 1989; see Figure O2). Near the continental margins it may exceed one kilometer. The pattern is similar in the deep Atlantic although the average sediment thickness is thicker, closer to 500 m thick.

Terrigenous sediments

Terrigenous sediments are composed of particles that are characterized by grain size (gravel, sand, silt, clay), composition and origin.

Terrigenous material in the ocean comes from three sources, rivers, glaciers in polar latitudes and eolian dust. Between 14 billion tons/year to 19 billion tons/year of particulate matter and another 3.9 billion tons of dissolved substances are delivered annually to the ocean, largely by rivers (Garrels and Mackenzie, 1971; Lisitzin, 1996). Most of this is trapped in estuaries, deltas or offshore basins and except for the muds transferred by turbidity and suspension flows, little of the total travels beyond the continental margin and into the deep ocean. The bulk of terrigenous sediments (nearly 90 percent) are

contained in the continental margin (shelf, slope and rise), and the fine-grained hemipelagic muds of the continental slope and rise are the most abundant by volume of all marine sediments (about 70 percent).

Today glaciers in polar regions erode and transport 1.5–2 billion tons/year of sediment to the oceans (Garrels and Mackenzie, 1971; Lisitzin, 1996), and the input must have been greater during periods of glaciation. While much of the material is dumped on the shelf and slope near the ice margin, ice-rafted debris and the fine grained suspended fraction reach the deep seafloor. When icebergs melt in the open sea they dump their load so that ice-rafted lithic fragments in deep-sea sediments trace the drift and extent of icebergs. During glacial times, drop-stones occurred in all high latitude sediments and ice-rafted debris was transported south to about 40°N in the North Atlantic and north to about 40°S around Antarctica. The suspended load of glaciers transports large volumes of sand, silt and clay, including the clay minerals chlorite and illite. Lisitzin (1996) believes that most of this material reaches the pelagic realm and is a more important source of pelagic clay than river-derived suspended sediments.

Dust storms generated in arid regions transport 1.6 billion tons/year of fine-grained materials over the ocean where it settles-out and eventually reaches the deep-seafloor. Most of this is silt and clay and contributes over half of the mineral component in pelagic clay (Windom, 1975).

Three important sedimentary deposits in the deep ocean are primarily terrigenous, the hemipelagic muds of abyssal cones and abyssal plains and the pelagic red clay of the deep basins.

Abyssal cones and plains

Off major river deltas, where the supply rate of terrigenous material is high, large submarine fans (*q.v.*) or abyssal cones form at the base of the continental slope (Bouma *et al.*, 1985). These features may be very large, extending to depths > 4,000 m and covering 1,000s km² of the seafloor. The largest of them is the Bengal debris cone of the Ganges and Brahmaputra Rivers, occupying all of the Bay of Bengal and extending south to Sri Lanka. This feature covers more than 2 million km² and contains 5 million km³ of sediments (Curry and Moore, 1971). Similar large abyssal cones are found off the Amazon, Congo and Mississippi Rivers. Abyssal cones are formed by turbidite flows, fan-shaped in plan view and have channels, levees and interchannel areas typical of all submarine fans (Normark and Piper, 1991). At their distal end, cones merge gradually into abyssal deep-sea plains.

Abyssal plains are large features (1,000s km³) formed by the accumulation of distal turbidites and suspension flows in the deep, peripheral parts of the ocean basins between the margins and the oceanic ridges. Sediment trap data show they are the result of hemipelagic processes involving fine-grained muds (silt and clay), winnowed off the shelf and slope and transported offshore at depths of 2–3 km as a plume (nepheloid flow: see *Nepheloid Layer*) that extends 100s of km seaward. Abyssal plains are the flattest surfaces on earth, with less than a few meters of relief over thousands of kilometers. While they are present in all the basins, they are most common in the Atlantic Ocean. In the Pacific Ocean, abyssal plains are relatively rare because trenches intercept the flow of sediments from the continents. An interesting case is the Alaskan abyssal plain found in the Gulf of Alaska. It is essentially a “fossil” feature that began in the Eocene off the

Table O2 Typical Rates of sedimentation in oceanic sediments

Sediment Type	Rate (meters/million years = mm/thousand years)
Hemipelagic muds	10s–100s
Abyssal plains and cones	10s–100s
Ice-rafted material	> 10
Pelagic red clay	1–5
Chemogenic sediments	< 0.2
Manganese nodules	0.2–5 mm/myr
Calcareous ooze	3–50
Siliceous ooze	2–10

(based on many sources).

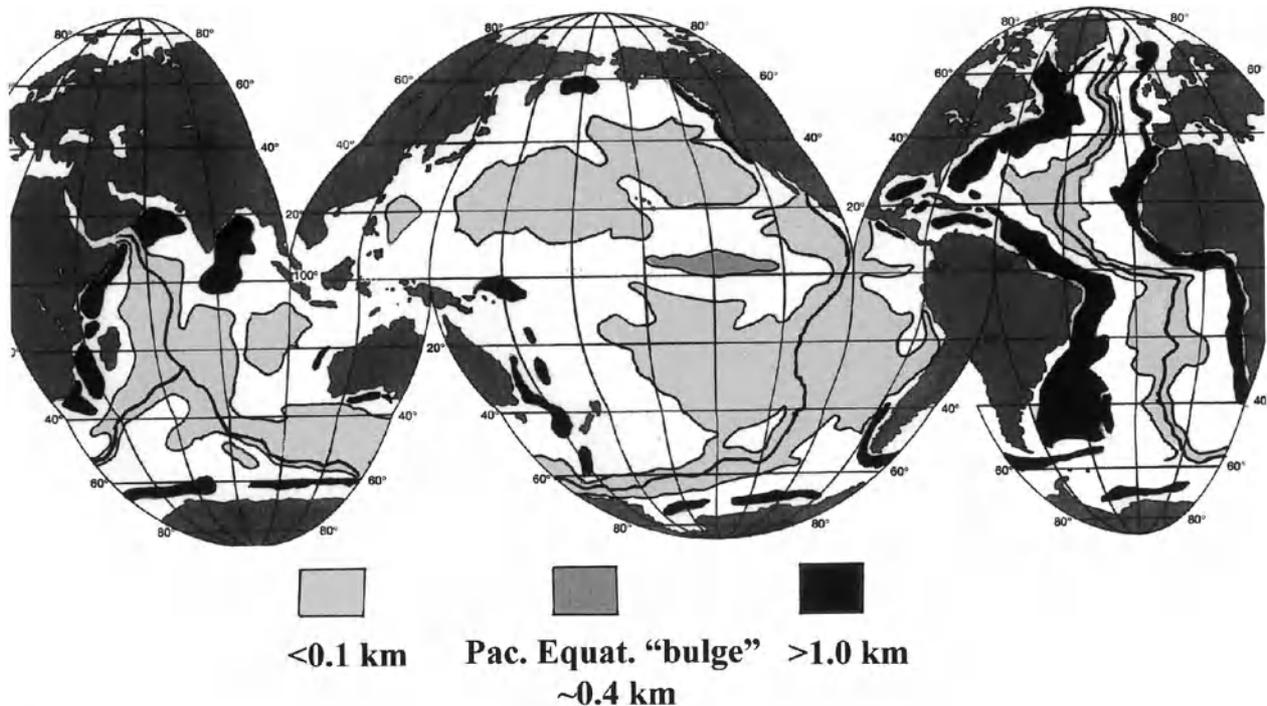

Figure O2 Thickness of the sedimentary cover overlying oceanic basalt. Note that except for the continental margin and the narrow belt along the equator, the sediment cover is less than 200 m thick on crust upto 60 million years old (after Berger, 1974 with modifications from several sources, including Heezen and Hollister, 1971; Winterer, 1989 and results of the Ocean Drilling Project).

coast of Washington but with the northward motion of the Pacific plate, is now isolated from a major sediment source.

Pelagic red clay

Pelagic clay, also commonly known as deep-sea clay or abyssal red clay, is a fine-grained lithogenous deposit, the bulk of which is clay and silt with minor amounts of sand that is unique to the deep ocean (generally below 4,000 m). The deposit is widespread, especially in the Pacific, South Atlantic and southern Indian Oceans (Figure O1). Murray and Renard (1891) named it red clay and concluded that it is the *in situ* alteration of volcanic ash or clayey material from land. The actual color is dark reddish brown or chocolate caused by amorphous or poorly crystalline iron-oxide coatings and minerals and is indicative of an oxidizing environment.

Pelagic red clay is limited to areas of the seafloor shielded from more rapidly accumulating turbidites and biogenic sediments. In the North Pacific, for example, deep trenches along the western and northern sides of the basin and oceanic ridges (Juan de Fuca and Gorda) along the eastern side prevent terrigenous materials from the continents from reaching the central region. Also, because of the great depth, generally below 4,000 m, calcareous biogenic materials are dissolved and never reach the bottom except for insoluble debris like shark teeth. The situation is similar in the South Pacific. In the Atlantic, where terrigenous input is higher and trenches are rare, areas of pelagic red clay are more limited and lie at the distal margins of abyssal plains.

One of the basic features of pelagic red clay is that it accumulates very slowly. Typical sedimentation rates are $< 1\text{--}2\text{ mm}/1,000$ years, which explains why the thickness of post-Cretaceous sediments in the central North Pacific is less than 200 m (Winterer, 1989). Leinen (1989) and others have shown that the rates of accumulation have varied with time, increasing significantly in the past 20 million years and since the Quaternary, apparently in response to increase atmospheric transport of dust (Rea, 1994).

While the bulk of "red clay" is very fine-grained clay and silt, it also contains coarse silt and sand size particles of authigenetic chemogenic minerals, volcanic debris and fish teeth. In high latitudes, it may contain ice-rafted debris and dropstones. The chemogenic minerals are mostly zeolites (phillipsite), Fe-Mn oxides and amorphous hydroxides (Griffin *et al.*, 1968; Piper and Heath, 1989; Leinen and Pisias, 1984). Manganese and iron oxides occur as grain coatings, nodules and encrustations. Much of the sediment (up to 50 percent) is X-ray amorphous which chemical analysis indicates is rich in amorphous iron and manganese oxyhydroxides (Piper and Heath, 1989). Typically pelagic clay deposits are 75 percent to 90 percent clay minerals less than 3 microns in size but it was not until the introduction of x-ray diffraction techniques in the 1930s that it was possible to determine their composition. In the last three decades much has been learned about the source of the clays in the ocean, where they originate and how they are transported.

Oceanic clays contain many minerals but are dominated by four: smectite (montmorillonite), illite, chlorite and kaolinite (see articles on each of these clay groups). Illite, the most

pervasive clay in the ocean, is a general term for clays belonging to the mica group. It is largely land derived and transported as suspended particulates by rivers and glaciers and as dust (Kennett, 1982). Smectite is also widespread, especially in the Pacific and mostly originates in the ocean from the low temperature alteration of volcanic ash and hydrothermal activity although it is also formed by weathering on land and transported to the oceans. Kaolinite, a product of intense weathering in humid, tropical climates, and chlorite, a mineral from low-grade metamorphic rocks common in the glaciated shield areas of North America, also are land-derived.

The distribution and relative abundance of the clay minerals in pelagic clay deposits indicate that except for the South Pacific and parts of the Indian Ocean, the primary source of the clays in the deep ocean is the continents. Illite dominates in the central North Pacific, the North Atlantic and is abundant off major rivers in the South Atlantic. Koalinite is concentrated near the continents in tropical areas in the Atlantic and Indian ocean and abundant chlorite is limited to the margin near Antarctica and in the Alaskan Bight (Windom, 1976; Berger, 1974; Lisitzin, 1996). Only the smectite clays of the South Pacific and Indian Ocean that reflect volcanism and hydrothermal activity are mainly of oceanic origin. Murray's conclusions of a century ago regarding the origin of abyssal red clay are basically correct.

While rivers are important suppliers of fine-grained materials to the ocean, it is now recognized that most of the clay and fine silt fraction in pelagic clay is delivered by wind transport (Rex and Goldberg, 1968; Windom, 1976; Duce *et al.*, 1991; Rea, 1994) (Figure O3). Major sources of eolian (windblown) sediments are seasonal dust storms in arid and semiarid regions that are moved by zonal winds (Trades, Westerlies)

over the ocean. Rea (1994) notes that essentially all of the dust transport in the North Pacific and North Atlantic occurs in the spring, rather than winter when the trade winds and westerlies are much stronger and reflects the frequency of major storms. Dust from eastern Asia dominates the entire Pacific north of the Intertropical Convergence Zone (ITCZ). In the subtropical Atlantic north of the equator dust is dominantly from the sub-Saharan Africa. Accumulation rates of eolian sediments in the deep ocean match the pattern of global flux of dust into the ocean, with the highest rates (up to 1,000 mg/cm²/ka) occurring in the northwestern Pacific downwind of east central Asia, in the subtropical North Atlantic off the Sahara and Sahel and in the Arabian gulf southeast of the Arabian peninsula (Rea, 1994). In the southern hemisphere, moderate amounts enter the ocean from the deserts of the Horn of Africa and southwest of Australia.

The composition of windblown dust is related to the source area and in general is similar to the mineralogy of red clay. Comparison of the mineral aerosol collected at sea demonstrates that the clays, quartz and feldspar are virtually identical with those in surface sediments (Leinen, 1989; Rea, 1994). The silt-size quartz common in pelagic clay has long been recognized as eolian in origin (Murray and Renard, 1891) and used as an indicator of the wind-blown dust contribution in deep sea sediments. In the North Pacific, a broad band of high quartz content between 20°N and 40°N, which closely matches the distribution of illite, has been used to infer the extent of quartz-rich Asian dust by the westerlies (Rex and Goldberg, 1968; Moore and Heath, 1978; see Figure O3). Rare earth geochemistry and Sr and Nd isotopes can now be used to pinpoint the provenance of the eolian materials in pelagic clays.

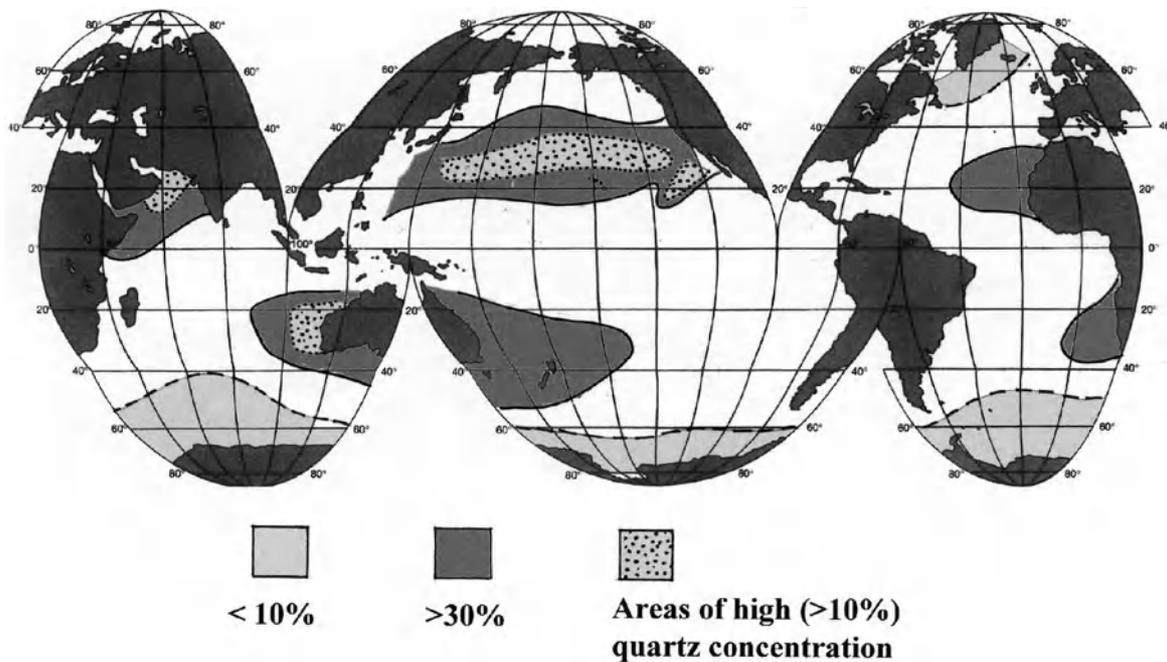

Figure O3 Contribution of eolian (windblown dust) debris to terrigenous sediments in the deep ocean. Areas of high, silt-size quartz content indicated in the central Pacific, NW Indian Ocean and SW of Australia (after Lisitzin, 1996 with modifications based on Moore and Heath, 1978; Rea, 1994).

Table O3 Common Minerals in Deep Ocean Sediments

Biogenous	Terrigenous	Chemogenous	Other
Aragonite	Quartz	Ferromanganese	cosmic spherules
Calcite	Feldspar	Minerals	
Opal	Clay minerals	Barite	
Apatite	Mica	Phillipsite	
Organic matter	Volcanic glass	Clinoptilolite	
		Smectite	
		Palygorskite	
		Sepiolite	

(modified after Goldberg, 1963).

As noted by Rea (1994) the eolian component of pelagic clay can be confused with hemipelagic sediments because both are similar in composition and grain size and it is unclear how far offshore the influence of hemipelagic processes extend. He restricts studies of the eolian component of pelagic sediments to deposits more than 1,000 km offshore.

Chemogenic sediments

In addition to the materials introduced into the ocean, a number of minerals are precipitated from seawater, either as primary authigenic minerals or during burial and diagenesis, as diagenetic alterations of precursor minerals. They are referred to as chemogenic, authigenic or hydrogenous sediments.

Common minerals formed in the pelagic realm include metal-rich deposits, oxides and oxyhydroxides of iron and manganese, silicates, mostly zeolites and clay minerals and barite (Table O3). Normally chemogenic minerals are a minor fraction of the total sediment and masked by the terrigenous or biogenous component. The exceptions are the metal-rich sediments formed by hydrothermal activity on the flanks and at the crest of oceanic ridges and in the slowly accumulating pelagic clays of the abyssal seafloor. An excellent review of seafloor mineralization associated with mid-ocean ridges is given in Humphris *et al.* (1995).

Within pelagic clays, the chemogenic component can represent a significant or even major fraction of the bulk sediment. Zeolites, hydrous aluminosilicate minerals, especially the mineral Phillipsite, can account for up to 50 percent of the bulk sediment in pelagic clay. It is believed to be an alteration product of basaltic glass or possibly from the reaction of biogenic silica and aluminum dissolved in seawater (Piper and Heath, 1989). Its decreasing abundance below the surface suggests that the mineral is metastable. Smectite, which is widespread in the ocean, commonly occurs with zeolites in surface sediments and the co-occurrence suggest it is also an alteration product of volcanic glass.

The best-known chemogenic deposits in the deep ocean are iron-manganese minerals that occur as coating, micronodules, macronodules and, when the nodules join, pavement (see *Iron-Manganese Nodules*). Manganese nodules are found in all ocean basins but are most extensive in the Pacific Ocean, covering vast areas (Cronan, 1977: see Figure O4). Similar but much smaller deposits are present in the Atlantic and Indian Oceans because the higher accumulation rates of terrigenous sediments tend to bury the nodules. Manganese nodules have been extensively studied because of the economic potential of

the trace metals (Ni, Co, Cu, and Ti) contained within the principal nodule minerals, birnessite and todorokite.

Nodules usually begin as coatings around some object like a shark tooth or rock fragment, and grow outward as thin layers of manganese oxide precipitated from seawater and from within the sediments. The coatings vary from a few millimeters to tens of centimeters thick and the nodules can be from millimeters to tens of centimeters in diameters. Their formation is a complex chemical interaction between seawater, sediments, pore waters and decomposition of the tiny amount of organic carbon that survives from biogenic rain. The composition of nodules varies, apparently in relation to distance from geochemical processes at the oceanic ridges and nodules in the eastern-most Pacific are rich in Ni, Cu, and Co poor while those in the western Pacific are rich in Co and Pb and poor in Ni and Cu (Cronan, 1977). Nodules grow very slowly, at the rates of millimeters in thousands of years.

Biogeneous sediments

Biogenous sediments in the deep ocean are the accumulations of organic debris, shells and skeletal parts produced mostly by pelagic organisms, single celled phytoplankton (diatoms, silicoflagellates and coccolithophores) and zooplankton (foraminifera, radiolaria) (Table O4). The main types in the deep ocean are calcareous and siliceous oozes (Table O1) produced by plankton while biogenous sediments in shallow-water (shelf, banks, islands) are produced by benthic organisms (algae and molluscs, echinoderms and corals). Following Murray, who introduced the term, oozes are named for their dominant component, such as foraminiferal ooze or *Globigerina* ooze (a foraminifer), diatom ooze or various combinations, e.g., foraminiferal-radiolarian ooze.

Biogenic deposits are the most widespread and abundant deposits in the modern deep ocean (Berger, 1976) and ocean drilling results indicate they were even more so in the geologic past. The type and distribution of biogenous materials reflects ocean-climate interactions that control primary productivity at the surface and ocean geochemistry at depth. Unlike terrigenous sediments, whose particles are the product of weathering, erosion and transport, biogenic particles are grown "in place" and generally come to the seafloor as a pelagic "rain". As a result, the distribution of biogenic sediments tends to closely resemble the biotic distributions of the organisms that produced them (Murray and Renard, 1891).

Processes that govern the delivery and accumulation of biogenous sediments in the deep ocean are understood in general but not in detail. They include primary productivity and recycling in the euphotic zone, export of material from this zone and its regeneration in the water column and seafloor. The net accumulation on the seafloor is a balance between production, the supply of organic matter and shells and preservation, the loss from chemical (dissolution) and biological destruction in the water column and seafloor. Influencing the net outcome is the rate, type and quantity of material produced, its transport to the seafloor, temperature, pressure and ocean geochemistry at depth and the rate of burial in the sediments.

Rates of primary production are controlled by nutrient supply and mixing in the ocean and regions of highest productivity are divergence zones along the equator and upwelling at the ocean's margins. Recent estimates of primary

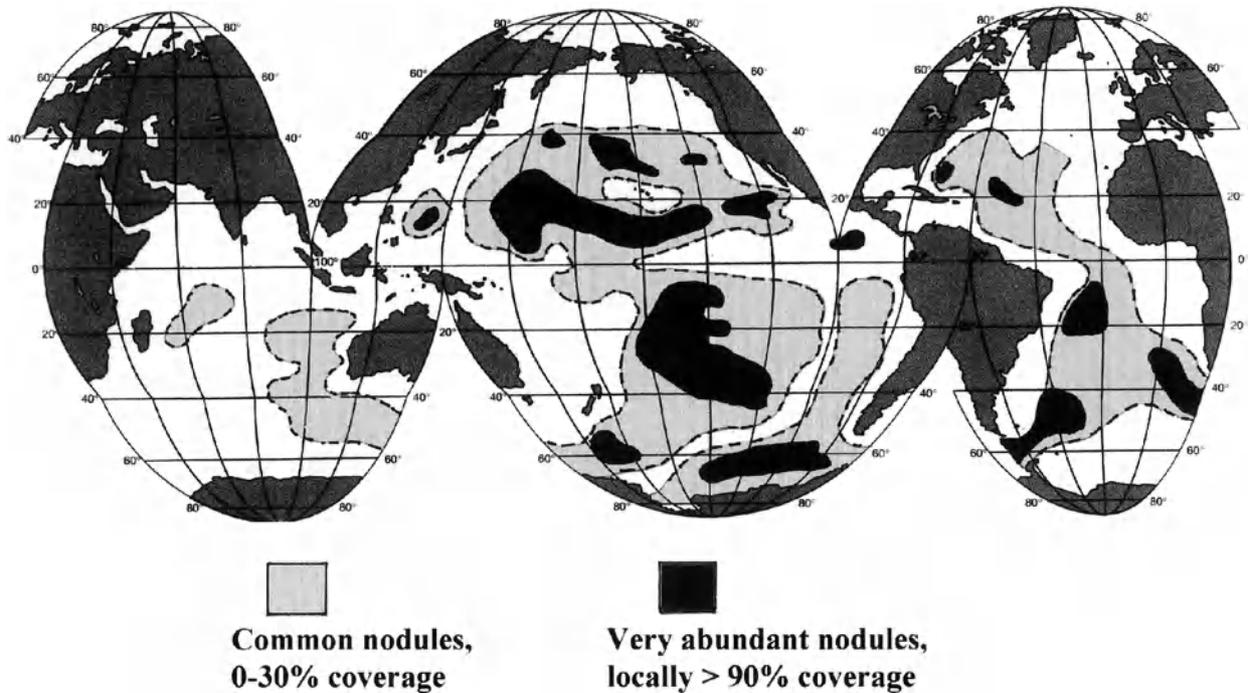

Figure O4 Distribution of Manganese nodules (after Berger, 1976, based on data from Cronan, 1977, with modifications from Piper and Heath, 1989, Lisitzin, 1996 and others.).

Table O4 Common minerals, type of plankton and potential preservation of common biogenic sediments

Type	Plankton	Shell Mineral	Preservation Potential
Calcareous oozes	Foraminifera	CaCO ₃	good/fair
	Coccolithophores	Calcite (low Mg)	very good
	Pteropods	Calcite (Very low Mg)	poor
		Aragonite	
Siliceous oozes	Diatoms	Opal (hydrated)	moderate/poor
	Radiolaria	Opal (hydrated)	good/excellent
	Silicoflagellates	Opal	fair

productivity make use of satellite observations and global databases but still have difficulty in assessing the contribution of cyanobacteria (picoplankton), the largest group of photosynthesizers in the ocean, and nanoplankton (Azam, 1998; Falkowski *et al.*, 1998). Useful “best-guess” maps of global productivity are given in Berger *et al.* (1989).

Most of the organic matter and skeletal debris produced in the euphotic zone is consumed and a fraction is exported as particulate organic matter (POM). The particles range in size from less than one to several hundreds of microns in size. The smaller material is bacteria, algal cells and fine organic detritus while the larger particles are clumps of organic matter, diatoms, plankton shells and inorganic particles such as clay. Transport to the bottom occurs in a complex process of packaging and repackaging of particulate matter into

fecal pellets and clumps or aggregates of detritus that because of greater size and density than individual shells provide a fast track to the bottom (Honjo *et al.*, 1995). The larger pellets and aggregates fall as a pelagic “rain” called “marine snow”.

The preservation of biogenic materials follows two pathways: organic carbon-rich debris is nearly all recycled (remineralized) by microbial consumption and only a tiny trace (< 0.5 percent) reaches the deep ocean floor (Gardner, 1997). Mineralized skeletal debris is dissolved in the water column or, once buried, in the sediments. Surface waters are saturated with respect to carbonate [CO₃²⁻] but undersaturated at depth. Silica is the inverse; surface waters are greatly undersaturated while deep waters are more silica-rich. The ocean is generally undersaturated for silica at all depths and especially in the euphotic zone because of high biological demand (Figure O5). An excellent discussion of the geochemical and physical factors which control the preservation of calcium carbonate and opal silica in the ocean is given in Broecker and Peng (1982).

Calcareous oozes

Calcareous oozes (> 30 percent calcareous materials) are the remains of pteropods, foraminifera, and coccolithophorids. Pteropods are pelagic gastropods common in warm water latitudes that grow small (200–1,000 microns) aragonitic shells. As ocean waters become undersaturated for carbonate [CO₃²⁻], aragonite is unstable and dissolves in deep water. Pteropod-rich deposits are limited to depths of less than 2500 m in the Atlantic and 1,500 m in the Pacific Ocean. Foraminifera, rhizopodan protists, live both on the bottom

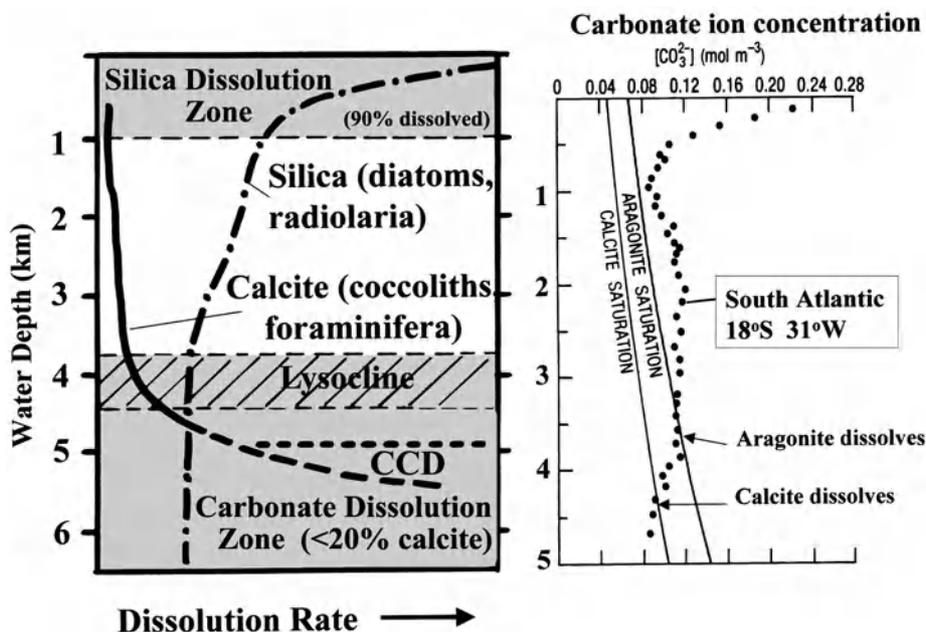

Figure O5 Generalized dissolution profiles of calcite and silica. The depth of the Lysocline, taken as the level of rapid increase in calcite dissolution and Calcium Carbonate Compensation Depth (CD), where the rate of supply equals the rate of dissolution, varies within and between ocean basins. Typical carbonate ion profile for the Atlantic Ocean with the saturation profiles for calcite and aragonite indicated (after many sources, including, Berger, 1974, Broecker and Peng, 1982, Lisitzin, 1996).

and in the plankton and secrete tiny (50–500 microns) shells of CaCO_3 that incorporate minor amounts of Mg and Sr. Modern species show distinct latitudinal patterns related to water temperature. *Globigerina* ooze is one of the most common deposits in the ocean. Coccoliths are very tiny (1–50 micron) calcareous plates secreted by coccolithophodidae, a member of the golden-brown algae. Because of their size, they are referred to as nannoplankton. Coccoliths are single calcite crystals and more resistant to dissolution than the shells of foraminifera or pteropods.

Murray (1897) recognized that the distribution of calcareous sediments in the deep ocean changes with water depth and reasoned that it was related to ocean geochemistry. Calcium carbonate dissolution increases with depth (Peterson, 1966) as a result of decreasing temperature, increasing pressure and, most importantly, increasing undersaturation of calcium carbonate in seawater (Broecker and Peng, 1982). Carbonate profiles reveal that there are two critical depths, the first is a level distinct increase in dissolution, termed the *Lysocline* by Berger (1974) and below it, a point where the rate of supply of calcareous debris from the surface is equaled by the rate of carbonate dissolution. This level defines the Calcium Carbonate Compensation Depth (calcite compensation depth) and below this depth little or no carbonate accumulates (Figure O5). In practice, this depth is defined by the relative abundance and preservation of calcareous fossils (foraminifera, coccoliths) in the sediments and there is some calcite present (typically < 10 percent) even in deep pelagic clays. The calcite compensation depth describes a surface that lies between about 3 km and 5 km but differs in each ocean basin, being deepest in the Atlantic and Indian Oceans (> 5 km) and shallowest in the North Pacific and along the margins of the

oceans. It indicates that the deep Atlantic is nearly saturated for calcite to 4.5 km depth while the North Pacific is undersaturated below about 1 km. The calcite compensation depth marks a major boundary between pelagic red clay and carbonate sediments and divides the ocean into carbonate-rich and carbonate-poor regions.

Siliceous oozes

Siliceous oozes (> 30 percent biogenic siliceous materials) are primarily the accumulation of diatoms and radiolarians with minor amounts of silicoflagellates. In some high latitude abyssal environments and near spreading ridges, siliceous sponge spicules are important. Diatoms, a major part of the phytoplankton, secrete a variety of different types of shells (frustules), commonly pennate- or centric-shaped (5–50 microns) composed of opaline silica. Under ideal conditions, diatom concentrations exceed millions of cells/ m^3 but most of the shell material is redissolved in the water column. Radiolaria are a large, complex group of protozoans that inhabit all depths from the surface to bathypelagic depths. Most secrete shells of hydrated silica; one modern group (acantharians) secretes shells of strontium sulfate that readily dissolves after the death of the organism. The siliceous shells of radiolarians are 50–500 microns in size and many are resistant to dissolution. Silicoflagellates, a minor group of phytoplankton, are golden-brown algae that secrete an internal skeleton of silica. Tiny in size (1–20 microns) they are commonly found in diatom and radiolarian oozes.

Silica secreting phytoplankton controls the silica budget in the ocean. Diatoms alone account for about 35 percent of the primary productivity in oligotrophic regions of the ocean and

75 percent in nutrient-rich coastal and high latitude waters (Nelson *et al.*, 1995; Ragueneau *et al.*, 2000). Maximum production occurs in two major latitudinal belts, along the equator in the Pacific and in high latitudes in the Southern Ocean surrounding Antarctica and North Pacific, and in coastal upwelling regions (Figure O6). These account for about 12 percent of the surface of the ocean (Calvert, 1983; Lisitzin, 1996). In the central ocean gyres, silica production is low. Nelson *et al.* (1995) estimate that biogenic silica production in the ocean is 200 to 280×10^{12} mol Si/yr, about 30 percent lower than previous estimates (Calvert, 1983). Most of it (about 60 percent) is redissolved in the mixed layer (upper 100 meter) and continues to dissolve, more slowly, in transit to the bottom and after deposition. It is generally agreed that less than 4 percent of the silica incorporated in opaline shells in the photic zone is buried. A comparison of surface production and where silica accumulates on the seafloor reveals a strong bimodal pattern. About 15 percent to 25 percent of the silica produced in the waters over diatomaceous-rich sediments is preserved while very little of the silica produced elsewhere in the ocean is preserved on the seafloor (Nelson *et al.*, 1995). Siliceous-rich sediments in the deep ocean are confined to narrow belts directly beneath oceanic divergence zones associated with high diatom production (Figure O6).

Siliceous shells or skeletal parts are all composed of opal, a hydrated form of amorphous silicon dioxide. It is easily dissolved in the water column and when buried in the sediments undergoes diagenetic alteration to more stable forms of silica (Kastner, 1981; McManus *et al.*, 1995; Dixit *et al.*, 2001).

Models of biogenic sedimentation

Biogenic sediments exhibit considerable variation in space and in time. Surface sediments in the modern Atlantic Ocean are predominately calcareous, even at great depths while siliceous oozes are virtually absent in the North Atlantic. In contrast, calcareous sediments in the Pacific Ocean are limited to shallow ($< 3,500$ m) oceanic ridges and plateaus and along the equator. Siliceous rich sediments, however, are widespread in the North Pacific, in a broad belt adjacent to Antarctica and along the equator. The Indian Ocean contains both carbonate- and siliceous-rich sediments. What accounts for these major differences within and between ocean basins? The short answer is a combination of ocean fertility and deep ocean circulation.

Berger (1974, 1976) proposed a “fertility-depth” model for eastern central Pacific sedimentation that links the concentration of nutrients in the euphotic zone to two different biotic responses, which in turn determines the composition and fate of biogenic particles fluxed to the seafloor. These conditions can be simplified as “nutrient poor” and “nutrient rich” and correspond closely to the “carbonate ocean” and “silica ocean” modes of Honjo (1997).

The carbonate ocean mode occurs when sinking particles deliver more carbonate than silica (low Si/Ca ratio) to the seafloor and more inorganic carbon. It prevails when nutrient supply is low and surface waters become nutrient poor, especially in dissolved silica, such as in oceanic gyres and convergence zones. Low nutrient supply favors coccolithophorids and cyanobacteria as the primary producers. Because of their small size (pico- and nanoplankton), first level consumers are small zooplankton (planktonic foraminifera) and long food chains develop. Export production is rich in

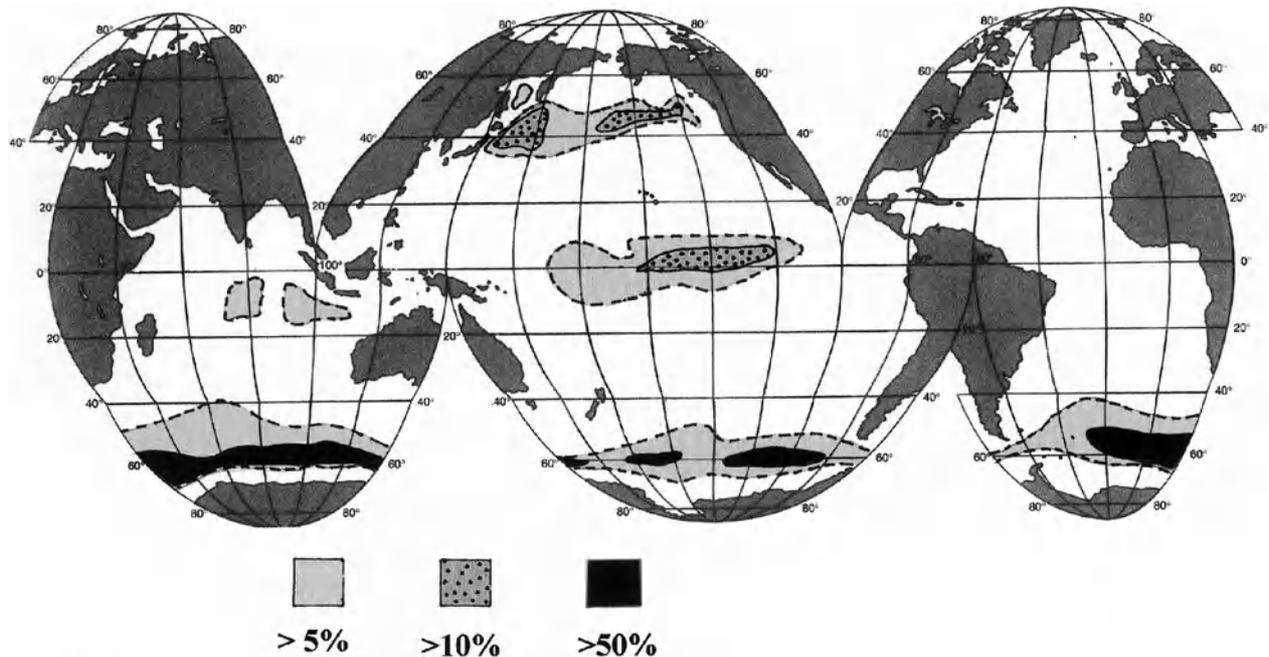

Figure O6 Distribution of Opal siliceous-rich sediments (after many sources, including Calvert, 1983, Kennett, 1982, Lisitzin, 1996 and Nelson *et al.*, 1995).

foraminifera and coccoliths and calcareous sediments accumulate on the seafloor (above the calcite compensation depth).

The silica ocean prevails in oceanic divergence zones and upwelling areas, where high nutrient concentrations in surface waters favor diatoms as the primary producers. Diatoms metabolize nutrients faster than other phytoplankton and reproduce rapidly to create blooms with cell densities of 10^7 per m^3 . Short food chains develop because large diatoms can be eaten by higher consumers (large zooplankton and fish). Export output is high in organic carbon. Sinking particles are silica-rich (diatoms, silicoflagellates) and even though a high proportion of the silica is regeneration in the water column, the high flux rates lead to siliceous-rich sediments. As Berger notes, under these conditions, the bacterial decomposition of organic carbon leads to carbon dioxide, carbonic acid and dissolution of carbonate shells. Despite high production rates, dissolution rapidly removes carbonate from the sediments.

The second factor is differences in deep ocean circulation that controls ocean geochemistry, and therefore dissolution patterns and the general pattern of ocean fertility (nutrient distribution). Berger (1970, 1974) referred to this as Basin-Basin fractionation where deep ocean circulation leads to the fractionation of silica and carbonate between ocean basins. In ocean basins that exchange deep water outflow for surface water inflow (lagoonal-type circulation), like the North Atlantic, bottom waters are young, nutrient poor, well oxygenated and tend to be saturated for calcium carbonate. Such basins accumulate calcareous sediments but dissolve silica. The contrasting system is an ocean basin that exchange surface waters for deep water inflow (estuarine-type circulation), like the North Pacific. Here, deep waters pass through the south Atlantic and Indian Oceans before entering the Pacific and are old, poorly oxygenated but nutrient rich. In the long passage, the microbial breakdown of organic matter uses dissolved oxygen, produces carbon dioxide and regenerates nutrients. These waters become under saturated for carbonate but enriched in nutrients and dissolved silica. As these deep waters are upwelled to the surface they generate high surface productivity and diatom-rich debris. Sediments in this type of system accumulate siliceous-rich sediments with little calcium carbonate.

Today the Pacific is exporting carbonate and depositing silica while the North Atlantic is the reverse. However, it follows from the models that a change in climate or the connections between ocean basins that effect vertical circulation will bring about changes in ocean fertility and chemistry. The result will be changes in biogenic sedimentation like those observed in the Pleistocene and Tertiary record.

Summary

As John Murray observed over a century ago, oozes and clays, with the accumulation of *manganese* nodules and zeolites where sedimentation rates are very low, cover the deep ocean floor. At the margins of the basins, close to the continents, hemipelagic sediments encroach on the deep ocean and mix with pelagic debris. Because hemipelagic sedimentation rates are 10–1,000 times higher than pelagic sedimentation rates, hemipelagics usually mask the contribution from the overlying water. Beyond the reach of turbidite and suspension flows, the terrigenous component of pelagic clays comes from windblown dust, traveling thousands of kilometers across the ocean before finally settling out. This material reaches the seafloor

as part of the pelagic rain as it is ingested by grazers along with other food particles and transported by fecal pellets and phytoplankton aggregates. The most widespread deposits in the deep ocean are biogenic in origin. Foraminiferal ooze covers nearly 50 percent of the seafloor at depths above the calcite compensation depth while radiolarian-foraminiferal-diatom rich sediments dominate beneath the equator in the Pacific and Indian Oceans. In high latitude regions of the North Pacific and in a belt surrounding Antarctica, diatom oozes cover the seafloor. The abundance and distribution of these biogenic sediments indicate much about the fertility of the oceans and the geochemistry of deep waters as it circulates between the major ocean basins.

OFFSHORE SANDS

Many middle and outer continental shelves around the world are covered, at depths from about 50 m to more than 200 m, with sand deposits, a few decimeters to more than 50 m thick. These sands are often remolded by tidal or unidirectional currents and/or storms and form longitudinal sand ridges (or sand banks of some authors) or transverse dunes. They may also appear as large sand sheets (with or without superimposed bed forms) forming a “sand belt” roughly parallel to the shelf edge. Understanding these deposits requires taking into account both present day sediment dynamics and Late Pleistocene glacio-eustatic and sediment flux changes.

Main types of shelf sand bodies and related processes

From a sediment dynamic point of view, offshore sand bodies have been classified on the basis of their orientation with respect to the main current at their origin. Their main characteristics are summarized in Table O5.

Large sand dunes

Large sand dunes (or sand waves of several authors) are observed at any water depths where current velocity near the bed is more than about 0.6 m/second, and sand is available. Even though the relationship between their height (H) and water depth is a matter of discussion, the largest are observed in the deepest environments (i.e., H about 20 m, at water depths around or more than 100 m). In tidal seas or on margins where geostrophic currents are particularly high, such as SE African continental margin, (Flemming, 1980), they are in equilibrium with peak current velocities (for instance spring tidal currents in tidal environments), and they move in the direction of their steeper side. Their migration rate is inversely proportional to their height (Rubin and Hunter, 1982) and reach values of 70 m/year for dunes 8 m high in the Dover Strait (Berné *et al.*, 1989). In places where there is a seasonal change of physical regime, they can seasonally reverse their asymmetry (Harris, 1991). On the outer shelf, sand dunes are often relict and the result of conditions that existed during the last deglacial sea-level rise, but active sand dunes are found along the shelf edge, because of amplification of the energy of internal waves in such areas (Heathershaw and Codd, 1985; Karl *et al.*, 1986). The internal structure of some large sand dunes consists of large foreset beds dipping at the angle of repose, but most display a hierarchy of bounding surfaces that

represent episodic changes of the current and wave regime (Berné *et al.*, 1988; Bristow, 1995) (Figure O7). Offshore sand dunes contain very few (if any) silts, and tidal couplets with mud drapes, typical for estuarine dunes (Visser, 1980) have never been described in modern offshore dunes.

Sand ridges

Sand ridges (or sand banks of some authors) are present on storm and tide-dominated shelves. They are inclined at an angle to the main axis of the tidal flow (or the main direction of propagation of storm waves). The model that best predicts the formation and evolution of offshore sand ridges is that of Huthnance (Huthnance, 1982a,b; Hulscher, 1996), where interaction of friction and Coriolis effect generates vorticity favoring sand accumulation around an initial sea-bed irregularity. A detailed description of this model, and a review of hydrodynamic processes at the origin of sand ridges, is given by Dyer and Huntley (1999). The best documented tidal sand ridges are in the North Sea, the Celtic Sea and the East China Sea (Stride, 1982; Yang, 1989), whereas storm ridges are mainly known from the Mid-Atlantic Bight (Swift and Field, 1981). Some authors claim that ridges formed on the middle continental shelf at or near present day water depths during the last ca. 7,000 years (Rine *et al.*, 1991), however, many more believe that they developed during the last deglacial sea-level rise, in relatively shallow waters. Different scenarios have proposed that, during sea-level rise, sediments are reworked into ridges at the position of ebb-tidal deltas that represent point-sources of sediment (McBride and Moslow, 1991). As sea-level rise proceeds, ridges may be disconnected from the shore (if sediment is no more supplied), and their orientation will depend upon the rate of coastal retreat and lateral inlet migration. In the tide-dominated Celtic

Table O5 Main characteristics of major offshore sand bodies

Sand bodies	Length or lateral extent (km) E (av.–max.)	Width or spacing L (av.–max.)	Height (m) H (av.–max.)	Main relationships between different parameters (with h, water depth)	Orientation with respect to dominant current (α) And associated near-bed current velocity (V_b)
Dunes	0.5–3 ^a	100–500 m ^a	2–25 ^a	$H = 0.0677L^{0.8098f}$ $H = 0.086 h^{1.19g}$ $L = 4 h^h$	$\alpha = 70^\circ - 90^\circ$ $V_b = 50 - 100 \text{ cm/s}$
Sand ribbons	1–15 ^b	10–200 m ^b	1–4 m	$H/L = 0.003^i$ $E/L > 40^d$ $L = 250 h^j$	$\alpha = 0^\circ$ $V_b = 60 - 100 \text{ cm/s}$
Offshore sand banks					
Tide-dominated					
active					$\alpha = 7^\circ - 15^\circ c$ $\alpha = 28^\circ j$
moribund	5–70	2–30 km	13–43 55 ^{c,d}		$V_b = 50 - 120 \text{ cm/s}$
Storm-dominated	5–200	2–30 km			$\alpha = 35 - 40^\circ c$
Sand patches	1–20	0.5–7 km	7–12 ^{c,d}		$V_b < 50 \text{ cm/s}$
Sand Sheets ^e	1–20		2–5		$V_b = 30 - 55 \text{ cm/s}$ (tide-dominated)
	5–100	10–400 km	5–12

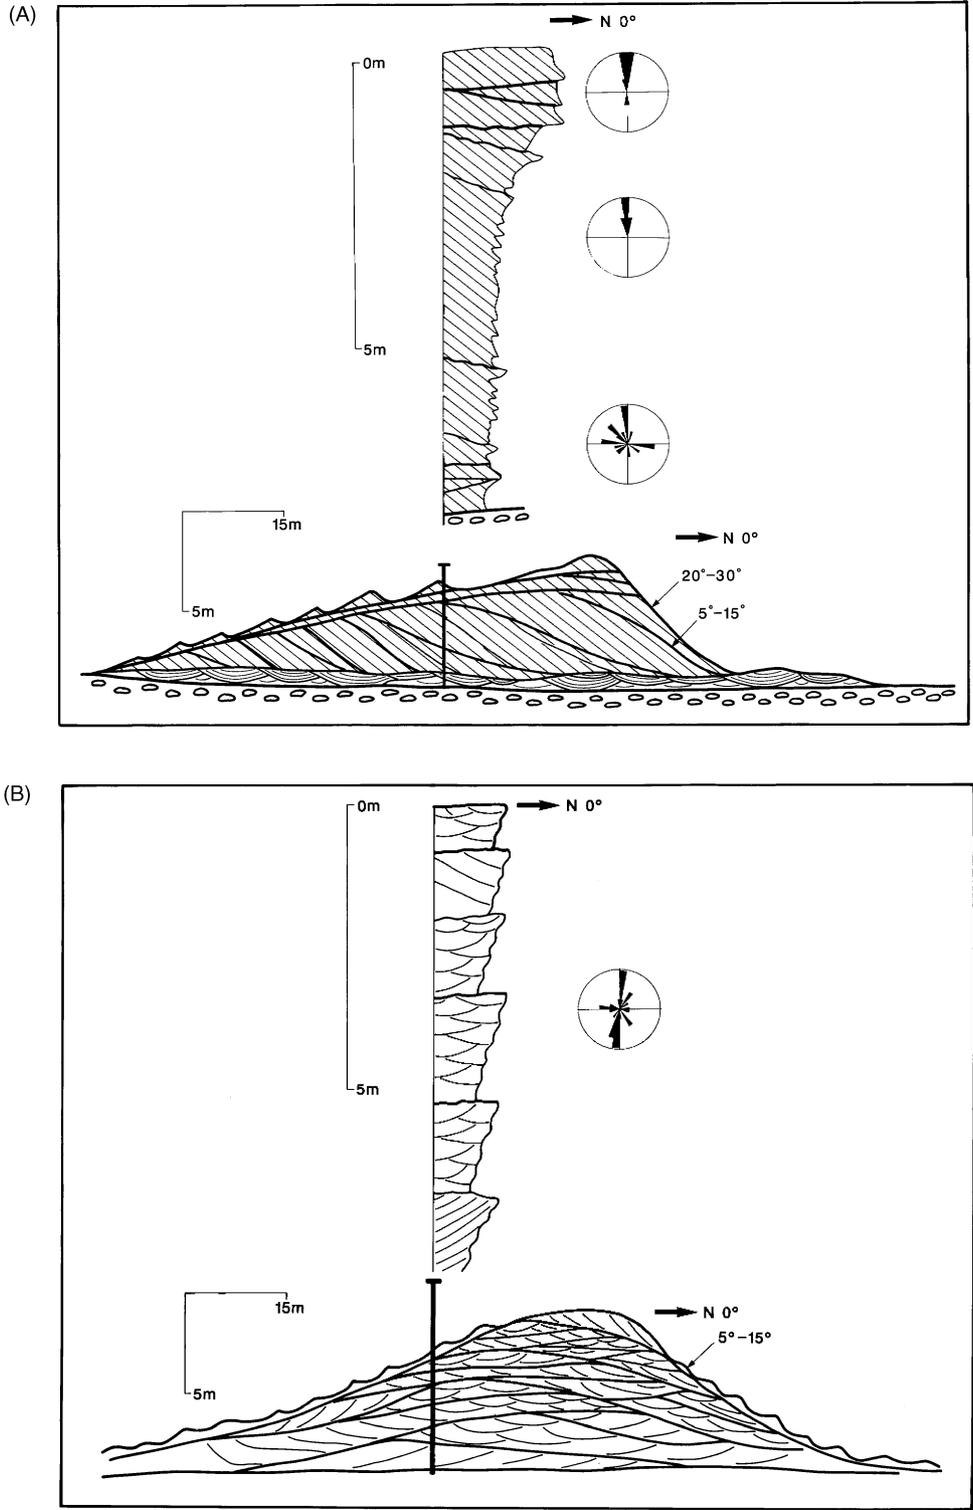

Figure O7 (Continued)

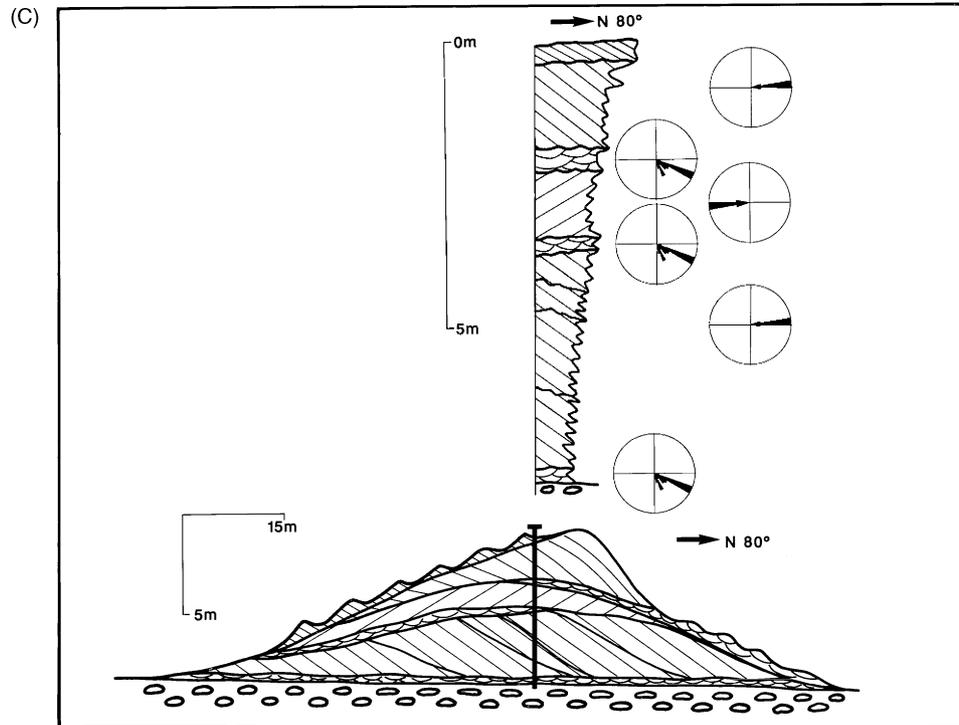

Figure O7 Scenarios for internal structure of large (> 3 m) sand dunes (sand waves), based on seismic and core data (modified from Berné, 1991). The circles represent dipping angles and orientations of megaripple (small dune) cross-beds, for a crest of the large dune with an arbitrary E–W direction. (A) Asymmetrical dune with cosets several meter-thick. The master bedding results from erosion surface formed during storms. The cross-beds within each coset may have an angle of dip as high as 34° . Superimposed bedforms create an erosion surface at the top of the sand wave, and have dip angles in the same range as that of the large sand wave. Medium-scale cross-beds at the bottom of the sand wave have dip angles almost perpendicular to that of the sand wave, due to the secondary circulation along the lee-side. (B) Symmetrical dune where flood and ebb net sediment transport during spring tides are in opposite directions and of similar magnitude. Medium-scale cross-beds with divergent directions constitutes the core of the sand wave. Major bounding surfaces are related to migration of superimposed small dunes (megaripples), as in estuarine dunes (Dalrymple and Rhodes, 1995). Such dunes are encountered along the great axis of several sand ridges, or in zones of bedload parting. (C) Reversing dunes. This structure corresponds to cases where seasonal changes create inversion of net bedload transport. Large-scale cross beds correspond to periods when asymmetry of the dune is well pronounced. Major bounding surfaces form during periods of reversal of net bedload transport, when the bed form becomes symmetrical. Because no avalanche occurs at that time, megaripple cross-beds (usually dipping parallel or slightly oblique to the great axis of the dune) are preserved. Such structures are observed in estuaries where seasonal changes of stratification occur, but also on open shelves where wind-driven currents reverse seasonally (Le Bot *et al.*, 2000).

Sea, it is believed that ridges formed between the last sea-level lowstand and the early stage of the deglacial sea-level rise (i.e., between *ca.* 20 ka and 14 ka) (Bouysse *et al.*, 1976; Pantin and Evans, 1984; Stride *et al.*, 1982). This interpretation is supported by numerical modeling of the M2 tidal constituent for a sea level lowered by 100 m, which indicates that the shelf currents would have been about twice as strong as at present, with an offset of 12° to 23° between the regional peak tidal flow and the axis of the ridges (Belderson, 1986). A similar numerical model has shown that the orientation of tidal ellipse for a sea-level lowered by 80 m matches the orientation of tidal ridges in the East China Sea (Oh and Lee, 1998). Some sand ridges display on seismic records an internal structure characterized by clinofolds dipping at about 5° in the same direction as the steeper side (presumably the direction of sand ridge migration) (Houbolt, 1968). Others present a core of coastal deposits suggesting that the ridges cannibalized pre-existing deposits (Berné *et al.*, 1994; Laban and Schüttenhelm,

1981). This observation led Snedden and Dalrymple (1999) to classify sand ridges as a function of the amount of their migration: juvenile ridges retain their initial nucleus that represent the initial irregularity necessary for ridge development in the Huthnance model, whereas “fully evolved” ridges have migrated sufficiently that they contain no trace of their origin. Alternatively, it has been proposed that “cored” ridges represent situations where substrate is erodible and sand supply limited (Berné *et al.*, 1998). In such situations where the spatial derivative of the transport rate is negative, ridges (or any other type of bedforms) are migrating with a negative angle of climb and incorporate previous deposits of different origins (Rubin, 1987). In any event, an important observation is that such sand ridges may in fact contain a relatively large fraction of non-sandy material.

Most of the cores from modern sand ridges show massive sand with an overall coarsening upward trend. In the East China Sea, the bottomsets of the clinofolds from sand ridges

lying at about 90 m display alternating sand and silt bedding with burrowed tidal rhythmites, whereas the topsets consist of homogeneous fine to medium sand (Berné *et al.*, 2002). Cores from the Middelkerke bank in the North Sea show, in the upper part of the ridge, ripple to medium dune bedding, with some herringbone cross-beds (Trentesaux *et al.*, 1999). The lower part of the bank consists of estuarine sediments incorporated into the ridge.

Lowstand and transgressive shorefaces and delta fronts

In areas where erosion due to wave and tidal ravinement is limited, shoreface deposits and sandy delta fronts that formed at period of lower sea-level may be preserved and represent another type of offshore sand bodies, where the initial geometry is only partly preserved.

Forced-regressive and lowstand deposits are preserved at depths close to the position of shorelines during the Last Glacial Maximum (i.e., about 90 m to 120 m water depth). In the moderate energy, storm-dominated Western Mediterranean Sea, they form large sand bodies, up to 35 m thick and 15 km wide, that extend parallel to bathymetric contour lines along distances more than 100 km (Rabineau *et al.*, 1998). On seismic profiles, they display internal clinofolds dipping seaward at an angle of 2° to 5° (Figure O8). They formed as prograding sandy deposits migrating seaward in response to sea-level fall, following a mechanism initially described from outcrop studies in the stratigraphic record (Plint, 1988). The clinofolds consist of glauconitic sand with shells and shell debris, passing progressively to silty bottomsets corresponding to a lower shoreface/prodeltaic environment (Berné *et al.*, 1998). The “sand ridges” that lie parallel to the shelf edge at water depths between 75 m and 100 m in the Indian Ocean off Bombay (Wagle and Veerayya, 1996) could have the same origin, but in this case, higher wave energy has subsequently reworked the deposits. Deltas that formed during lowstand of the sea have similar shapes in two dimensions, but more lobate geometries. They are described from examples in the Eastern Mediterranean Sea (Aksu *et al.*, 1987; Skene *et al.*, 1998), the

Gulf of Mexico (Suter and Berryhill, 1985), the South China Sea (Hiscott, 2001).

Such stranded sand bodies do not only form during the falling and low stand stages of glacio-eustatic cycles. During the last deglacial period, slowing of sea-level rise and/or increase in sediment supply have also favored formation of transgressive shoreface deposits that are now isolated on the middle or inner shelf. For instance, sand banks of the inner shelf Trinity/Sabine incised valley system in the Gulf of Mexico are interpreted as stranded shoreface deposits that formed during a phase of relatively slow sea-level rise, and were stranded on the shelf during a rapid sea-level rise (Anderson and Thomas, 1991; Rodriguez *et al.*, 1999). An alternative interpretation for shore-parallel sand shoals lying at about 50 m water depth in the NE Gulf of Mexico is that they developed at the position of an escarpment formed during the transgression, but that they consist solely of post-transgressive deposits (McBride *et al.*, 1999).

Sand sheets and sand patches

Sheet-like bodies of sand largely covered by sand waves (large dunes) are described in “low energy” tidal environments (where current velocity near the bed is around 55 cm/second) such as the Southern Bight of the North Sea (Belderson, 1986; Stride *et al.*, 1982). They have no preferential orientation and their internal structure is that of (tidal) dunes (large and medium scale cross beds). In areas dominated by unidirectional currents, such as the southeast African shelf, sand sheets with very asymmetric bed forms are observed (Flemming, 1980). Where the sand cover is discontinuous, sand patches resting on a coarse lag of fluvial or transgressive deposits are observed. These patches may or may not have a preferential orientation, depending on the local hydrodynamic regime. On the Californian shelf dominated by swells of the Pacific Ocean, they form transverse sand patches or very flat dunes migrating seaward in response to large bottom stresses generated by combined waves and currents (Cacchione *et al.*, 1987). Similar sand patches are also described in the Bay of Biscaye at depths ranging from 30 m to 90 m. Cores display stacked fining upward elementary sequences 1 cm to 10 cm thick, with erosional base, typical of storm deposits (Cirac *et al.*, 2000).

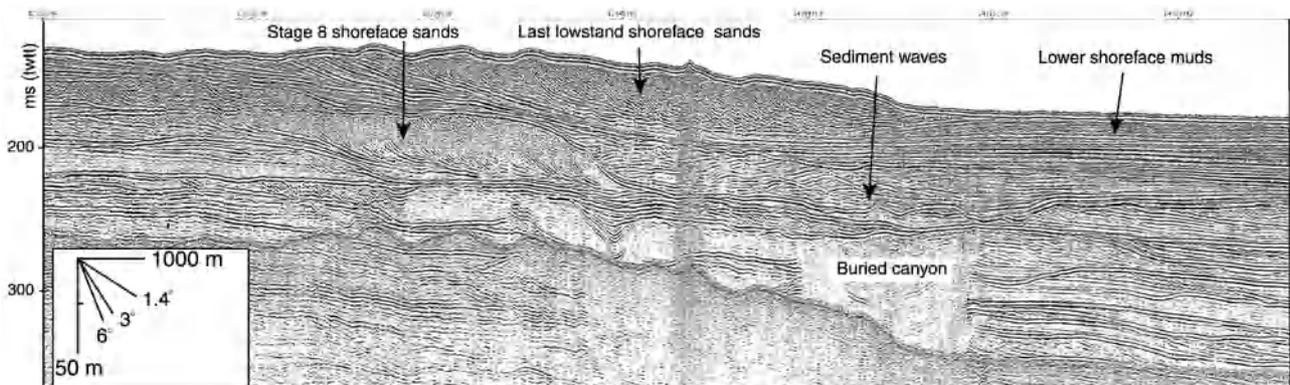

Figure O8 Recent and buried shoreface sands in the Western Mediterranean Sea. Offshore sands in the Gulf of Lions cover the outer shelf at water depths from 90 m to about 120 m. Note the abrupt seaward transition between sands and mud, marked by a step in the sea-floor morphology. Similar sand bodies formed during other glacial periods (corresponding to isotopic stage 8) are now buried and encased into prodeltaic muds. Vertical scale is in milliseconds two way travel time (mstwt).

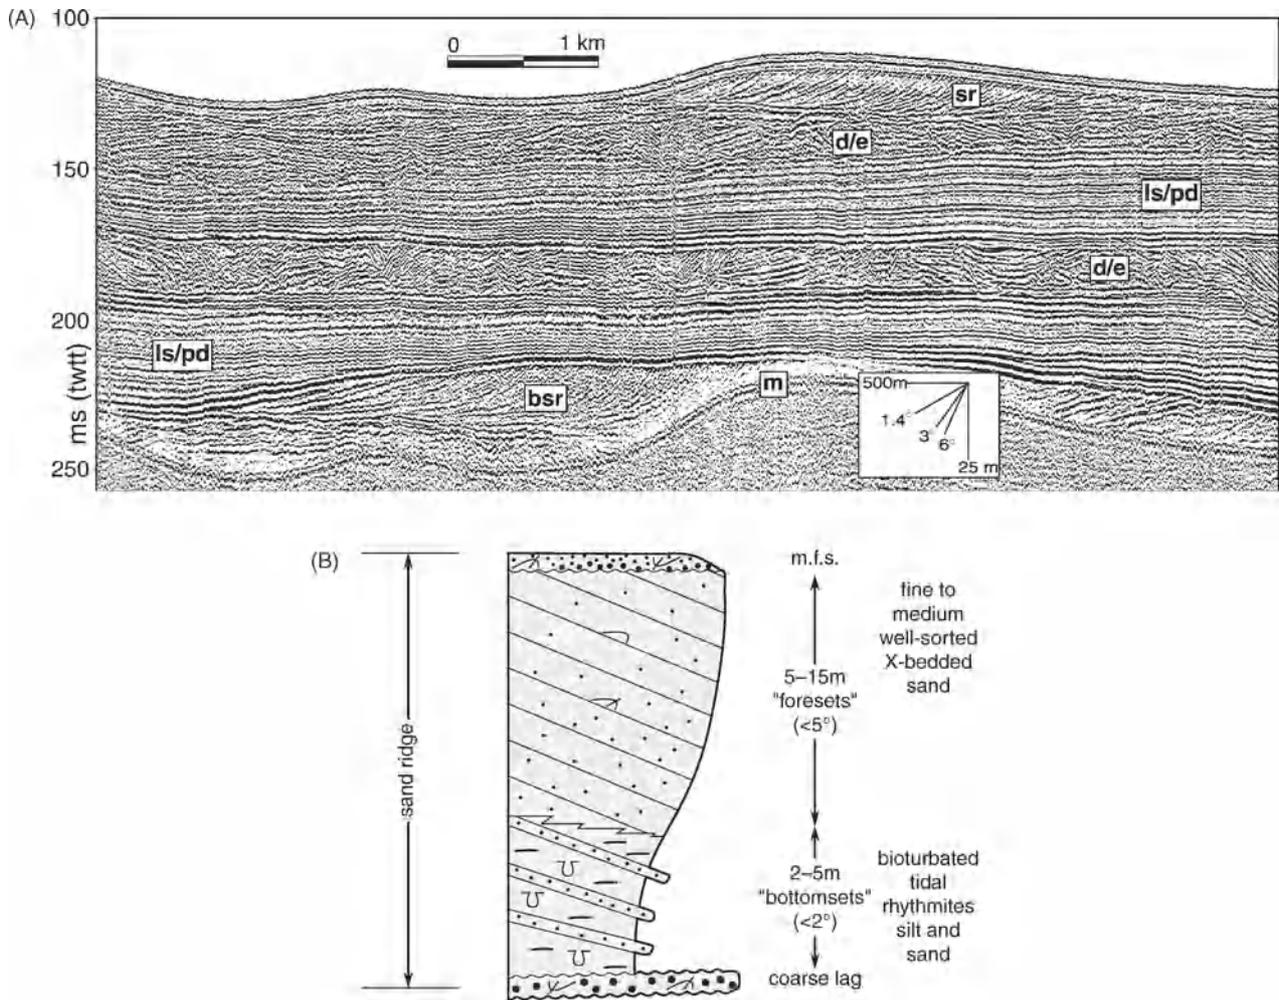

Figure O9 Seismic (A) and synthetic log (B) for a sand ridge on the outer shelf of the East China Sea (water depth about 80 m). The seismic profile, perpendicular to the great axis of the sand ridge, display internal clinoforms dipping at about 2–3° in the same direction as the “steep” side of the ridge. A buried Pleistocene sand ridge (bsr) is also observed, overlain by lower shoreface or prodeltaic silts (ls/pd) and deltaic/estuarine heterogeneous sediments with numerous channel structures (d/e). The external morphology of this buried has been preserved. “m” is the seismic multiple. Vertical scale is in milliseconds two way travel time (mstwt). The synthesis of several cores across the ridge shows (Figure O9(B)) that the upper part of the clinoforms (“foresets”) consists of fine to medium sands, whereas the “bottomsets” display tidal rhythmites. The top of the ridge is blanketed by a carpet of sediment in equilibrium with modern hydrodynamic regime, but the ridge is believed to have form during the last deglacial sea-level rise.

Preservation of Pleistocene offshore sands

There are contradictory explanation about the origin of many sand bodies encased in mudstones, for instance the Shannon Sandstone in Wyoming, that are interpreted either as fossil sand ridges (Tillman, 1999) or as regressive shoreface deposits (Bergman and Walker, 1999). Examples from modern (Pleistocene) continental shelves demonstrate that both types of sand body may be preserved. This discovery is rather recent, because most of the early studies on continental shelves focused on NW Europe and North American margins where low subsidence, limited sediment supply and strong bottom currents favor reworking of deposits during each glacial cycle. In contrast, seismic surveys and geotechnical boreholes on (deltaic) margins with high sedimentation rate and relatively

high subsidence rates (around 250 m/million years at the shelf edge) demonstrate the high potential of preservation of shelf sand bodies in such areas, where they are generally encased in prodeltaic/lower shoreface regressive silty deposits. Examples of Pleistocene buried sand bodies include regressive, lowstand and transgressive shorefaces (Rabineau *et al.*, 1998), lowstand (shelf edge) deltas (Hiscott, 2001; Skene *et al.*, 1998; Suter and Berryhill, 1985; Sydow and Roberts, 1994; Winn *et al.*, 1998) and transgressive sand ridges (Berné *et al.*, 2002; Yang, 1989). These sand bodies are typically 10 m to 30 m thick, with a lateral extent of several km to more than 100 km, and their initial shape is sometimes preserved (Figure O9). Most authors agree in attributing a major role to 4th order glacio-eustatic cycles (i.e., about 100 kyr) in the construction of these sand bodies, even though shorter time-periods are the

dominant factors controlling the up-building of transgressive parasequences.

OIL SANDS

Oil sands constitute an immense petroleum resource on a worldwide scale (Figure O10) and Canada, at 1,700 billion barrels (AEUB, 1996), dominates the current estimates (Meyer, 1995, 1996). The petroleum resource in the Orinoco Oil Belt (OOB) of Venezuela is thought to be similar in size at 1,200 billion barrels (Fiorillo, 1987) and dominates the world heavy oil resources (Meyer, 1998).

Oil sands (also known as tar sands) are defined as petroleum deposits where the viscosity of the oil (bitumen) is greater than 10,000 centipoises (cP) at reservoir conditions (Meyer, 1995). The general definition applied to oil sands is a petroleum deposit where oil viscosity is so high that there is no commercial inflow to a well at reservoir conditions (AEUB, 1996; Butler, 1997).

Bitumen is deficient in the lighter hydrocarbon molecules (Meyer, 1998) and is generally in the 6°API (1,029 kg/m³) to 12°API (986 kg/m³) range. However, oil viscosity is greatly affected by temperature, and heavier bitumens experience large reductions in viscosity with an increase in temperature. Bitumen in the Clearwater Deposit, Alberta, Canada is lighter (10–12°API) than the oil in many of the heavy oil deposits in the OOB (8–14°API; Starr *et al.*, 1981). However, higher reservoir temperatures (40–70°C) in the OOB give the oil mobility.

All of the significant oil sands deposits in Canada occur in the northeastern part of Alberta (Figure O11). The bitumen is thought to be a conventional oil that was degraded, mainly through biodegradation, as it migrated updip into the shallower portions of the basin (Creaney and Allan, 1992). The Wabiskaw–McMurray and Grand Rapids deposits in the

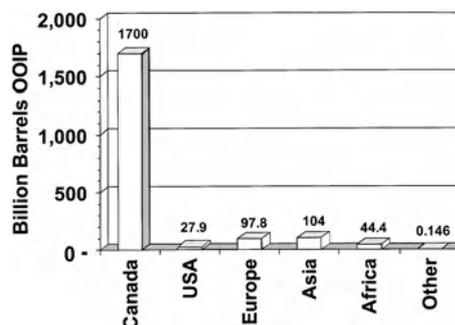

Figure O10 World oil sands resources, Original Oil In Place (OOIP).

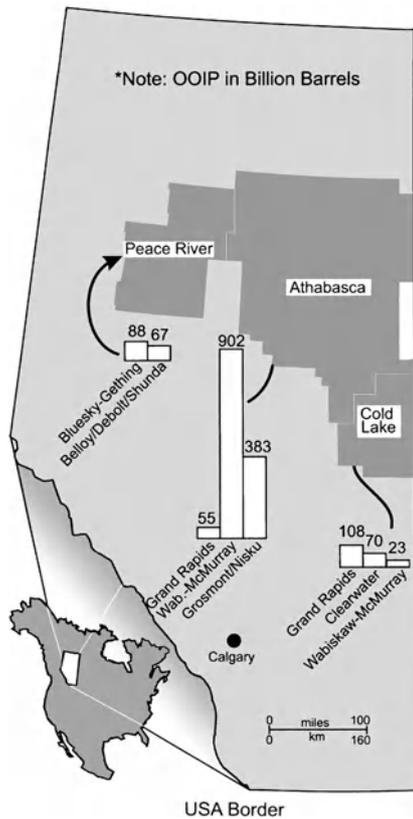

Figure O11 Oil sands areas and OOIP estimates for deposits in Alberta, Canada.

Athabasca Oil Sands Area have no discernible structural or stratigraphic closure; apparently the oil was biodegraded into immobility and trapped itself (Wightman *et al.*, 1995).

Data are sparse for many other oil sands deposits but most occur in the shallow (less than 1,000 m), updip or marginal portions of basins (Phizackerley and Scott, 1978; Roadifer, 1987). These deposits also represent conventional oils that have been biodegraded into bitumen through contact with meteoric water (Meyer, 1996).

Most of Alberta's oil sands are comprised of consolidated (but mostly uncemented) sand, bitumen and water. The exceptions occur in Mississippian and Devonian carbonates but these are classified as oil sands because of the bitumen (AEUB, 1996). With the sand and carbonate, water coats the mineral matter and bitumen fills the remainder of the pore space (Figure O12).

Bitumen distribution and oil sands quality (porosity, permeability and oil saturation) are directly controlled by depositional facies in most of the clastic oil sands and heavy oil deposits around the world (Phizackerley and Scott, 1978). This is the result of shallow depths of burial (limited diagenesis) in basin margin settings. Clean, well sorted sands form the best oil sands whereas sands with abundant matrix material, mudstones and shales contain little or no oil. Depositional environments are generally continental to marine shoreline (Phizackerley and Scott, 1978).

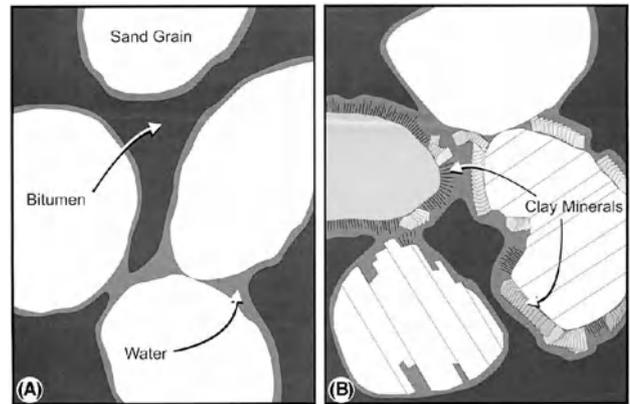

Figure O12 Schematic diagram of thin sections of water wet oil sands. (A) Clean quartz sand with low water saturation. (B) Arkose or litharenite with authigenic clay minerals and higher water saturation; porosities can be higher than in (A).

In Alberta, the Lower Cretaceous Mannville Group contains most of the oil sands resource and within it, the Wabiskaw-McMurray Deposit is the largest with 902 billion barrels (AEUB, 1996). The rich oil sands generally occur in channel deposits, so lateral continuity is problematic. Trough cross bedded sand, with little or no interbedded mudstone, in the lower parts of channel deposits represents the best oil sands (33–38 percent porosity, 80–95 percent pore oil saturation and 5–10 D of permeability, up to 20 D in gravel; Wightman *et al.*, 1995). The overlying lateral accretion beds are comprised of interbedded sands and mudstones. The mudstones reduce ore grade for surface mining operations and the lower permeabilities (generally 10–300 mD) have a significant, adverse effect on *in situ* operations (Strobl *et al.*, 1997).

The sedimentological characteristics of a deposit influence the type of *in situ* recovery process that is most applicable. Fining upward channel deposits are particularly suited to Steam Assisted Gravity Drainage (SAGD) as the best oil sands are located in the lower part of the reservoir (Figure O13). Cyclic Steam Stimulation (CSS) is being utilized in the coarsening upward Clearwater Deposit of Alberta (Butler, 1997); pressure parting induces vertical permeability, especially in the lower portions of the reservoir (Figure O14).

Oil sands have several types of associated water sands (Figure O15) which occur within and adjacent to the bitumen (Wightman *et al.*, 1995; Barson *et al.*, 2001). Water sands reduce overall reservoir quality; in particular, top water can be very detrimental to *in situ* operations (Barson *et al.*, 2001).

Oil sands currently (September, 2001) contribute about 650,000 barrels of oil/day in Canada, with 340,000 barrels of synthetic crude from mining and 310,000 barrels of *in situ* bitumen. Production is increasing, with predictions of up to 1,650,000 barrels/day by 2015 (NEB, 2000). Worldwide production from oil sands is also expected to increase as conventional oil supplies decline in the future.

OOLITE AND COATED GRAINS

Oolite is a sedimentary rock, most often limestone, composed of smoothly laminated, spherical to ellipsoidal coated grains that are cemented together (Figure O16). The grain components of oolite are called *ooids* (or *öoids* or *ooliths*), terms derived from the Greek word for fish roe (“oon”), which ooids resemble. The terms “oolite” and “oid” are considered distinct with oolite pertaining to rock and oid referring to an individual grain (Teichert, 1970). Not all workers adhere to this technical distinction. In geologic descriptions, the term “oolitic” refers either to oid-rich sediment or to oid-bearing rocks. The term “pisoid”, by convention, refers to those ooids larger than 2 mm. Historically, the term oolite was first used in 1727 by F.E. Bruckman (Cayeux, 1935, p.211). “Oolitic grains” were described by Lyell (1854, p.12) and Sorby (1879, p.74). The term oid was first introduced by Kalkowsky (1908, p.72).

Ooids have rounded grain shapes and generally spherical to ellipsoidal grain forms (Figure O17). Internally, ooids consist of a *nucleus* surrounded by an evenly laminated *cortex* which increases in sphericity with distance from the nucleus. The nucleus commonly consists of a shell or fossil fragment, a peloid or a detrital sand grain whereas the cortex consists of concentric layers of calcium carbonate or other minerals.

Ooids are distinguished from other coated grains by descriptive and/or genetic criteria depending upon classification scheme. Most workers readily distinguish ooids from “oncooids” by the even lamination of the oid cortex and the general absence of biogenic features such as algal filaments. Of these, evenness of cortex lamination is probably the most

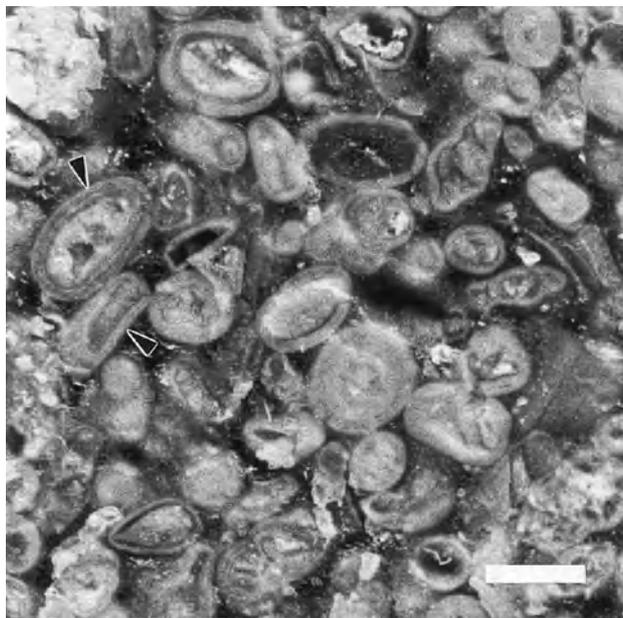

Figure O16 Mississippian oolite, Ste. Genevieve Limestone, Kentucky. Note the laminated cortices surrounding the nuclei of some of the ooids (see arrowheads). Scale = 1 mm.

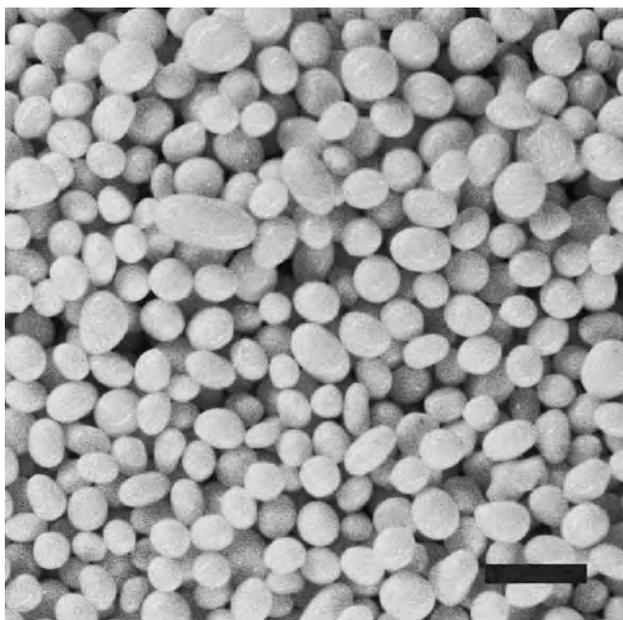

Figure O17 Modern ooids, Joulters Cay, Bahamas. Note the spherical to ellipsoid grain forms and the smooth, polished surfaces of the ooids. Scale = 1 mm.

reliable criterion to distinguish ooids from oncoids, as biogenic features such as mucus films are evident in many ooids (e.g., Newell *et al.*, 1960). Although the arbitrary size distinction separating ooids from pisoids is clear, the term pisoid is additionally used by many workers to refer to nonmarine oolitic grains (e.g., Flügel, 1982). Because of this, some recent

workers (Sumner and Grotzinger, 1993) have begun to use the term “giant ooid” when describing large (>2 mm) oolitic grains that appear to have formed in marine environments. Comprehensive reviews and information about ooids and other coated grains can be found in the works of Bathurst (1975), Simone (1981), Flügel (1982), Peryt (1983) and Tucker and Wright (1990). Reviews of ooids composed of iron-bearing minerals can be found in the work of Young (1989). Reviewed here are calcareous ooids and oolitic rocks as these form the majority of modern and ancient ooid-bearing deposits.

Modern environments of formation

Ooids form in a wide variety of modern depositional settings. Most form in shallow, tropical marine settings of moderate to high wave activity, at depths <10 m (often ≤2 m), where the water is supersaturated with respect to calcium carbonate. Well-studied areas of modern marine ooid formation include the Great Bahama Bank and the Persian Gulf. Oolitic sands in these settings typically occur along the edges of platforms, in lagoons, in tidal deltas and mid-channel bars, and in beaches and tidal flats. Most marine ooids occur in or near the environment in which they are forming, although pelagic and eolian occurrences clearly indicate significant transportation. Ooids and pisoids also form in hypersaline lakes and lagoons, such as the Great Salt Lake, Utah and Baffin Bay, Texas as well as in brackish water lakes such as Pyramid Lake, Nevada (Sandberg, 1975; Land *et al.*, 1979; Popp and Wilkinson, 1983). Other environments where oolitic grains form include freshwater lakes, calcareous soils (calcrete), rivers, caves, hot springs and human-constructed features such as drainage pipes and water treatment plants.

Mineralogy and microfabric of modern ooids

Calcareous ooids are composed of aragonite, high Mg-calcite, low Mg-calcite or, in the case of bimineralic ooids, some combination of aragonite and calcite. Modern marine ooids have primarily an aragonite cortex; those with a high magnesium calcite cortex occur but are much less common. The cortex of ooids from nonmarine settings has a variable composition depending on the Mg/Ca ratio of the precipitating water and the salinity. Ooids from hypersaline settings with a high Mg/Ca ratio are dominantly aragonite, and to a lesser degree high Mg-calcite, or they are bimineralic with a cortex composed of a combination of aragonite and high Mg-calcite (e.g., Sandberg, 1975; Land *et al.*, 1979). Ooids from Pyramid Lake, Nevada, a brackish water ensialic lake with a fluctuating Mg/Ca ratio, are bimineralic with cortices composed of aragonite and low Mg-calcite (Popp and Wilkinson, 1983). Ooids from more dilute lakes as well as streams, caves and calcareous soils are commonly composed of low Mg-calcite.

The ooid cortex exhibits a range of crystal fabrics depending upon original mineralogy, the energy level of the depositional setting, organic influences and subsequent diagenesis. Most modern aragonitic ooids from the Bahamas have a *tangential microfabric* consisting of small (1–3 μm) aragonite rods and submicron nannograins oriented parallel to the cortex laminae. In thin section under cross-polarized light, modern tangential ooids commonly display a distinctive pseudouniaxial cross (Figure O18). The tangential microfabric appears limited to those ooids composed of aragonite and is considered by most workers to reflect relatively high energy conditions

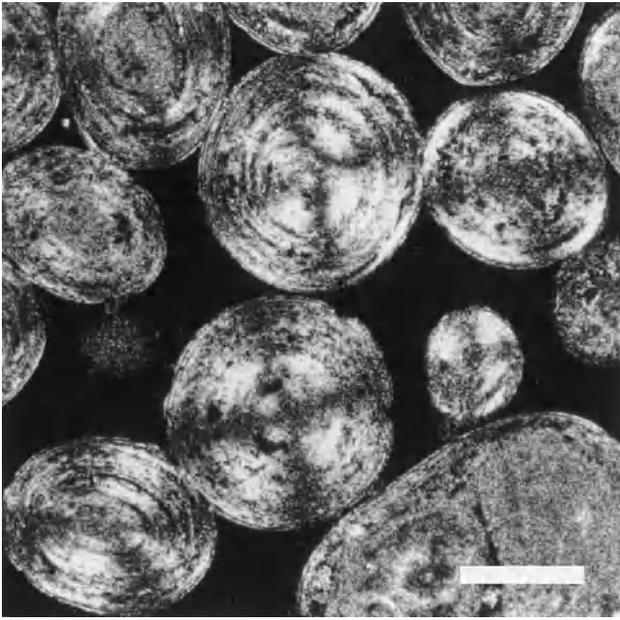

Figure O18 Thin section view of modern tangential ooids under cross-polarized light, Joulter's Cay, Bahamas. Note the pseudotaxial crosses exhibited by several of the ooids. Scale = 0.1 mm.

characterized by numerous grain collisions. Some workers assert that tangential microfabrics are influenced by biological processes (e.g., Fabricius, 1977).

Modern ooids may also have a *radial microfabric* consisting of fibrous or bladed crystals of aragonite oriented normal to the ooid nucleus. Aragonitic ooids with radial microfabrics are well described from the Persian Gulf, the Great Barrier Reef and from the Great Salt Lake (Loreau and Purser, 1973; Davies and Martin, 1976; Sandberg, 1975). High Mg-calcite ooids with radial microfabrics are uncommon but have been described from the Great Barrier Reef (Marshall and Davies, 1975). Isolated radial laminae of low Mg-calcite occur in some ooids from Pyramid Lake (Popp and Wilkinson, 1983; Wilkinson *et al.*, 1980). Although exceptions are known, radial ooids are more common to low-energy settings, settings characterized by fewer grain collisions.

Ooids lacking an orderly tangential or radial microfabric are described as having a *random microfabric* and are commonly referred to as micritic ooids. Modern examples generally consist of a random arrangement of aragonite rods or crystals, an arrangement that is more often a product of micritization rather than an original depositional fabric. Micritic ooids have been described from a variety of low and high-energy settings. Numerous additional ooid microfabrics have been described from some modern and ancient oolitic deposits (e.g., cerebroid ooids; half moon ooids). These special types are summarized in Richter (1983).

Origin of ooids

Ooids may form by a variety of physical, chemical and biological processes; however the exact mechanism(s) by which ooids form is still unresolved. The strictly physical origin proposed by Sorby (1879) involving vertical accretion (snowballing) of calcareous grains is often discounted, because grain

interactions during ooid growth tend to polish the ooid surface rather than contribute to physical accumulation of calcium carbonate. The only site where substantive physical accumulation occurs is in borings within the ooid cortex (Gaffey, 1983). Formation by chemical (inorganic) processes is favored by many workers, particularly for radial ooids (Tucker and Wright, 1990). In the marine environment, inorganic formation of ooids requires supersaturated water, abundant nuclei, normal to elevated salinity, and warm temperatures ($> 20^{\circ}\text{C}$). Significant agitation may or may not be required for inorganic carbonate precipitation. Laboratory experiments mimicking such conditions have produced tangential ooids similar to modern Bahamian ooids (Davies *et al.*, 1978).

Biological processes leading to the formation of ooids have been suspected since the late 19th century (Rothpletz, 1892). However, the degree to which organic compounds and organisms are involved in ooid formation is still a matter of debate. Several experimental studies have shown that the presence of organic compounds, particularly humic acids, can facilitate the formation of high Mg-calcite radial ooids, at least under laboratory conditions (Suess and Fütterer, 1972; Davies *et al.*, 1978; Ferguson *et al.*, 1978). Interestingly, in those solutions lacking any humic compounds, only aragonite needles or aragonite ooids with tangential fabrics formed. The role of algae and cyanobacteria in the formation of ooids remains largely unresolved, despite significant study by some workers (e.g., Fabricius, 1977). While algae and cyanobacteria certainly have a role in the formation of ooids, their importance in the formation of ooids is less clear, especially those forming in caves or other settings with no light. Recent investigations of freshwater ooids from Lake Geneva (Davaud and Girardclos, 2001) demonstrate that nucleation of calcitic oolitic coatings can occur in close association with mucus films produced by the activities of diatoms and cyanobacteria. Those films appear to act as a catalyst or at least a substrate for carbonate precipitation and cortex growth. Similar associations between mucus films and crystal growth were described by Folk and Lynch (2001). They found minute crystals of aragonite with peculiar "baton" and composite needle morphologies imbedded in the mucus-rich laminae of some Bahamian aragonitic ooids. The formation of these crystals is attributed to the activities of minute "nannobacteria" in a manner similar to carbonate precipitation induced by larger bacteria (e.g., Chafetz and Buczynski, 1992). If nannobacteria truly exist—a matter still under debate—their presence and their micro-environmental influence strongly suggest that biological processes greatly influence the formation of ooids. Further work is needed to firmly establish the role of organic compounds and biological processes on the formation of ooids. This work will likely be the most active area of ooid research in the coming years.

Ancient ooids and oolite deposits

Oolite has a long geologic history extending at least to the late Archean. The environment of deposition of ancient oolitic deposits has been studied extensively, as has the texture and mineralogy of the ooids they contain. Ancient ooids commonly have radial textures, with or without clear concentric laminations; other ancient ooids consist of large neomorphic calcite crystals or are filled with clear calcite cement. Although radial-concentric ooids were previously thought to represent a diagenetic replacement product of aragonitic ooids, research

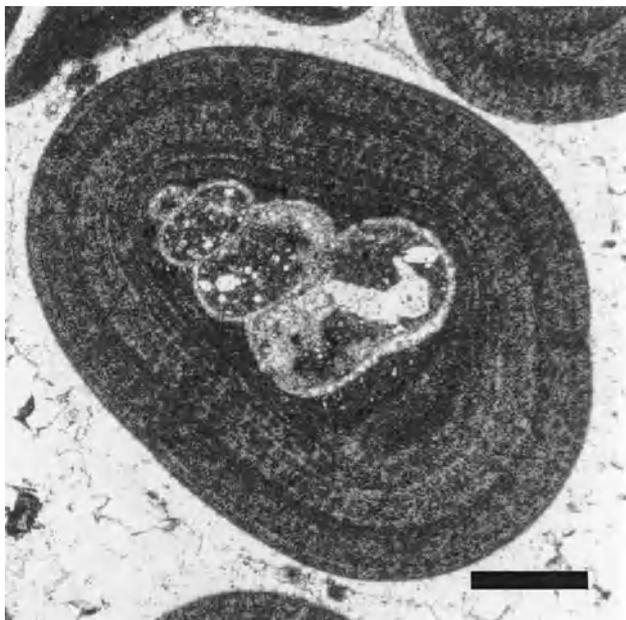

Figure O19 Thin section view of a Mississippian radial ooid, Ste. Genevieve Limestone, Illinois. The once aragonitic gastropod in the nucleus of the ooid has been replaced by clear calcite cement. The fact that no such replacement is seen in the cortex suggests strongly that the cortex was originally calcite. Scale = 0.1 mm.

has shown that these ooids were originally calcitic (Sandberg, 1975) (Figure O19). Originally aragonitic ooids have textures similar to that resulting from replacement of known aragonitic skeletal grains (Sandberg, 1985). These ooids contain coarse neomorphic spar, commonly with relic inclusions of aragonite. Aragonitic ooids are susceptible to dissolution in meteoric waters and also tend to develop oomoldic porosity that may later be filled with clear calcite cement.

Detailed petrographic studies have shown that mineralogy of ooids has oscillated throughout the Phanerozoic (Sandberg, 1983). Ooids that were originally composed of aragonite and possibly Mg-calcite occur primarily in rocks deposited during “icehouse” times (Late Precambrian–Early Cambrian, Middle Carboniferous–Triassic, and Tertiary–Recent). Ooids that were originally composed of calcite occur primarily in rocks deposited during “greenhouse” times (Ordovician–Mississippian and Jurassic–Cretaceous) (Sandberg, 1983). A few anomalies have been reported (e.g., Upper Jurassic Smackover Formation of the Gulf Coast) where aragonitic ooids occur during a calcite-facilitating episode. This may be due to local conditions such as evaporite deposition, leading to an increase in Mg/Ca ratio (Heydari and Moore, 1994). The oscillatory trend in the mineralogy of ooids has been linked to fluctuations in ocean-atmosphere $p\text{CO}_2$ level (Sandberg, 1983), although more recent investigations suggest that fluctuations in marine Mg/Ca ratios driven by plate tectonic processes are the governing factor (Stanley and Hardie, 1998). The general secular trend in the mineralogy of ooids correlates with the first-order, global sea-level, which is also tied to plate tectonic processes. High sea-level stands or submergent/greenhouse episodes are associated with high rates of sea-floor spreading and low Mg/Ca ratio. Such conditions favor the precipitation

of low Mg-calcite ooids. Low sea-level stands or emergent/icehouse episodes are associated with low rates the sea-floor spreading rate and a relatively high Mg/Ca ratio. These conditions favor the precipitation of aragonite and high Mg-calcite ooids (Wilkinson *et al.*, 1985; Stanley and Hardie, 1998). There were apparently four peak periods of ooid deposition during the Phanerozoic, including the Late Cambrian, Late Mississippian, Late Jurassic, and Holocene (Wilkinson *et al.*, 1985). Peak ooid production occurred during times when overall sea-level was either rising or falling, rather than at maximum (highstands) or minimum (lowstands) sea-levels.

In addition to variations in the composition of ooids with time, recent studies have shown that ooid size has varied over geologic time, particularly during the Precambrian. Most Phanerozoic ooids are less than 2 mm, whereas those from the Precambrian have sizes up to 18 mm (Sumner and Grotzinger, 1993). Neoproterozoic ooids are particularly large, a phenomenon attributed to low nuclei supply, high growth rates and high average water velocity during that time (Sumner and Grotzinger, 1993).

Oolitic limestones form prolific petroleum reservoirs (see Keith and Zuppann, 1993). Intergranular porosity is preserved during greenhouse periods because of the calcitic mineralogy of the ooids. Calcitic ooids are resistant to dissolution compared to their aragonitic counterparts. This resistance limits the formation of oomoldic porosity and the occlusion of primary pores by secondary cements. Examples of petroleum reservoirs in oolitic rocks include the Jurassic Arab sequence in the Middle East, the Jurassic reservoirs of the Paris Basin, and the Jurassic Smackover reservoirs of the Gulf of Mexico (Moore, 2001, p.271). Significant reservoirs occur in Mississippian oolitic rocks as well. These include the Ste. Genevieve Limestone of the Illinois Basin, several Middle and Late Mississippian formations in the Anadarko Basin and Hugoton Embayment, the Greenbrier and Monteagle limestones of the Appalachian Basin, and the Madison Group of the Williston Basin (Keith and Zuppann, 1993, p.5).

OPHICALCITES

Introduction

Serpentinites and ophiolitic mélanges (*q.v.*) locally contain carbonatized ophiolitic breccias known as ophicalcites. The best-documented cases are from the Jurassic of the Swiss Alps (Weissert and Bernoulli, 1984; Bernoulli and Weissert, 1985; Früh-Green *et al.*, 1990) and of the Italian Apennines (Folk and McBride, 1976; Barbieri *et al.*, 1979), and from the Cretaceous of the USA. Rockies (Carlson, 1984). Paleozoic ophicalcite is only known from the Ordovician of the Canadian Appalachians (Lavoie and Cousineau, 1995).

Hypothesis of origin

The origin of ophicalcites is controversial (Folk, 1986; Bernoulli and Weissert, 1986). In the second edition of the AGI *Glossary of Geology* (1980, p.437), ophicalcites (or ophicarbonates) are described as “a recrystallized metamorphic rock composed of calcite and serpentine, commonly formed by dedolomitization of a siliceous dolostone.” Before ophiolites were interpreted to represent oceanic crust, ophicalcites were assumed to result from contact metamorphism between intrusive ultramafics and older sedimentary hosts (Peters, 1963) or from regional metamorphism (Trommsdorff *et al.*, 1980). Since plate tectonics, near-to-seafloor high temperature processes have been suggested: hydrothermal weathering (Barbieri *et al.*, 1979) and combined tectono-sedimentary and hydrothermal events (Lemoine, 1980; Bernoulli and Weissert, 1985; Früh-Green *et al.*, 1990; Lavoie and Cousineau, 1995). Cold processes have also been suggested: carbonate precipitation from methane seepage on serpentine seamounts (Haggerty, 1991; Fryer, 1992) and pedogenic alteration of ophiolite (Folk and McBride, 1976).

Modern occurrences of ophicalcite

Carbonatized serpentine fragments have been dredged from hydrothermally active transform-fault settings along the mid-Atlantic ridge (Bonatti *et al.*, 1974) and were also recovered from serpentine seamounts in a forearc setting (Haggerty, 1991). Void-filling pelagic and coarser-grained carbonates are locally interbedded with lithic (ophiolite-derived) laminae. In voids, carbonate cements consisting of magnesium calcite or aragonite are present. A near-to-seafloor

origin was proposed: water reached the ultramafic part of an oceanic crust and transformed it to serpentine resulting in density inversion and diapiric rise of the serpentinite. Brecciation and carbonatization follow as the serpentine diapir reaches the ocean floor (Bonatti *et al.*, 1977).

Rock record of ophicalcite

Paleozoic ophicalcite

In the Canadian Appalachians, ophicalcites have been reported in Ordovician ophiolitic mélanges located along major terrane-bounding faults (Cousineau, 1991). The mélanges consist of serpentinitized ultramafics locally brecciated and carbonatized (ophicalcites) as well as metasedimentary and igneous rocks fragments. An oceanic transform-fault setting has been proposed for the formation of the Ordovician ophiolitic mélange (Cousineau, 1991).

The ophicalcite is a breccia; it is composed of angular, millimeter- to meter-size, clast- to matrix/cement-supported carbonatized ultramafic blocks. The ultramafics were first intensely serpentinitized and variably deformed and carbonatization of ultramafic material followed. The degree of carbonatization ranges from faintly fractured serpentinite with carbonatized phenocrysts and some micrite infills, up to intensely brecciated material showing various carbonates with few preserved indicators of the protolith including chromite grains and serpentinite minerals. The relative chronology between the various void fillings is obscured by complex crosscutting patterns of fractures. In many cases, fractures with the complete spectrum of sediments and cements (see below) cut through older ones totally occluded by a similar succession. Meter-sized fragments of well-cemented ophicalcites are found in the micrite. All these suggest a complex history of sedimentation—cementation—fracturing.

Carbonate sediments in the ophicalcite

Besides the pervasive initial metasomatic carbonatization of brecciated ultramafics, discrete cavity-filling carbonates are recognized. The most important consists of laminated micrite interlayered with graded coarser-grained lithic (serpentinite, chromite, mafic minerals) calcarenite. In the most carbonatized cases, the sediments can constitute up to 50 percent of total carbonates. In the least altered ultramafics, it commonly is the only carbonate phase.

Carbonate cements in the ophicalcite

Isopachous layers of calcite cement coat micrite and were precipitated either over undisturbed infills or on clasts of indurated sediment, suggesting synchronicity with some fracturing. Remaining void spaces are healed, as seen under cathodoluminescence, by multiple generations of blocky carbonate cements (calcite and minor dolomite). These cements are volumetrically important in large fractures and voids that were not totally occluded by the previous carbonates.

Geochemistry of carbonate elements

For the Appalachian ophicalcite, the oxygen and carbon stable isotope ratios of the micrite fall in the range of values for

Ordovician marine carbonates. Based on oxygen stable isotope and fluid inclusions microthermometry, following cements were precipitated by hot saline fluids. The carbon isotopic values for cements indicate marine waters with input of hydrothermal-derived fluids as also suggested from low radiogenic strontium isotopic ratios of cements (Lavoie and Cousineau, 1995; Lavoie, 1997; Chi and Lavoie, 2000).

Proposed origin for Paleozoic ophicalcite

Crosscutting relationships between sediments, cements, and clasts of cemented ophicalcite together with carbonate geochemistry provide evidence for complex early seafloor fracturing, sedimentation/cementation, and fluid circulation. For the Paleozoic ophicalcite, a tectonically active seafloor hydrothermal vent system was proposed to explain the synchronicity of micrite sedimentation, fracturing, and cementation (Lavoie and Cousineau, 1995).

The Mesozoic ophicalcites

Detailed studies of Mesozoic ophicalcites have documented a similar complex pattern of crosscutting relationships between micrite, carbonate cements, and ophicalcite/ophiolite clasts altogether with multiple fracturing events. Repetitive micrite and serpentinite arenite infills coeval with diverse carbonate cements is documented. Based on these observations and stable isotope geochemistry, a similar scenario of early tectonosedimentary origin on the deep seafloor was also proposed for Jurassic ophicalcites (Früh-Green *et al.*, 1990).

Life on the deep seafloor

Methane-based bacterial chemosynthesis associated with ophicalcites is reported from the Mesozoic of North America (Carlson, 1984). Limited biological activity occurred around the hydrothermal vents responsible for the formation of the Paleozoic ophicalcite (Lavoie, 1997). Peloidal mats coated clasts and are followed by bacterially mediated botryoidal calcite precipitation. Carbon stable isotope ratios of peloidal mats and botryoidal cements indicate that the exhalatives were hydrocarbon-free. The lack of corrosion of carbonates suggests minimal rate of H₂S venting and indicates that the venting system was similar to H₂S-poor white smokers. Thermophilic bacterial sulfate reduction was active around these Ordovician vents.

PALEOCURRENT ANALYSIS

Introduction

The configuration of sedimentary bodies, from the smallest patch of sand or gravel to the deposits of entire depositional systems, is determined in part by the pattern of air or water currents prevailing during deposition. Evidence of the orientation and strength of these currents can commonly be deduced from evidence preserved within the rocks.

There are two types of paleocurrent evidence:

- (1) Sedimentary structures and fabrics that preserve a record of the direction and orientation of the current that formed them;
- (2) Rock properties that change in the direction of flow as a result of the transport process;

Paleocurrent analysis may provide information on one or more of the following:

- (1) the direction of local or regional paleoslope, which reflects tectonic subsidence patterns;
- (2) the direction of sediment supply (in unimodal systems, only);
- (3) the geometry and trend of lithologic units; and
- (4) the depositional environment.

Paleocurrent indicators

Sedimentary structures that may contain useful paleocurrent information include:

- (1) *Ripple marks (q.v.) and crossbedding (see Cross-lamination)*. Dune and ripple crests are typically oriented transverse to flow, while the foresets of crossbed structures normally dip in a downstream direction. Because of local turbulence of flow, the direction indicated by foreset dip may not always correspond exactly to local flow direction, and so it is usually advisable to use a large number of orientation measurements to ensure reliable results. This is the only type of sedimentary structure from which paleocurrent

data may be obtained from the subsurface using petro-physical techniques such as the dipmeter or microresistivity scanning tools.

- (2) *Channels and scours* occur in many environments and may indicate the orientation of major erosive currents, such as those generating river or tidal channels and delta or submarine fan distributaries. The larger channels, which are those most likely to be of regional significance, are usually too large to be preserved in outcrops, but may be spectacularly displayed by reflection-seismic data, especially in horizontal (time-slice) sections.
- (3) *Parting lineation (q.v.) or primary current lineation*, the product of plane-bed flow conditions, is only visible on bedding-plane exposures. It usually yields directional readings of low variance because it forms during high-energy flow in river, delta, or tidal channels, when bars or other obstructions to flow are under water and flow-sinuosity is low. The structure indicates orientation but not direction of flow, because of the ambiguity between two equally possible readings at 180° to each other. Usually, this can be resolved with reference to other structures nearby.
- (4) Clast transport by traction or in sediment-gravity flows commonly produces a measurable *gravel fabric*. Imbrication (*q.v.*) in traction current deposits occurs where platy clasts are stacked up in a shingled pattern, with their flattest surface dipping upstream and resting on the next clast downstream. Because gravel is only moved under high-energy flow conditions, it tends to show low directional variance, like parting lineation.
- (5) *Sole markings* are typically associated with the deposits of turbidity currents and fluidized or liquified flow, where vortex erosion may occur at the base of a flow (see *Scour, Scour Marks*), and “tools,” such as pebbles, twigs or bone fragments, can be swept down a bedding surface (see *Tool Marks*). They also occur less commonly in other clastic environments. Their greatest use, however, is in the investigation of submarine-canyon and fan deposits. They are best seen on the undersides of bedding surfaces, where sandstone has formed a cast of the erosional feature in the

underlying bed. Tool markings yield information on orientation but not direction, like parting lineation; flute marks are longitudinally asymmetric, with their deepest end lying upstream.

- (6) *Oriented plants, bones, shells, etc.* do not respond systematically to the aligning effects of currents unless they are elongated. There may be ambiguity as to whether they are oriented transverse or perpendicular to current patterns, and there are other difficulties, for example, the tendency of fossils such as high-spined gastropods to roll in an arc. Fossils are usually only useful for local, specialized paleocurrent studies.
- (7) Oriented sandstone samples may be studied in the laboratory to explore such parameters as sand-grain orientation and magnetic anisotropy.

Paleocurrent patterns may also be deduced from regional changes in rock properties such as clastic grain size and clast roundness, the downstream decrease in thickness of sediment gravity flows, or the change in proportions of detrital components.

Data collection and processing

Paleocurrent data should be carefully documented in the field, including the following information:

- (1) location and (if relevant) precise position in a stratigraphic section;
- (2) structure type;
- (3) indicated current direction;
- (4) scale of structure (thickness of crossbed, depth and width of channel, mean or maximum clast size in imbricate gravels); and
- (5) local structural dip.

Current directions should be measured to the nearest 5° with a magnetic or sun-compass and corrected to true north wherever necessary. In the case of parting lineation and tool markings, the correct orientation of two possibilities at 180° can usually be identified by referring to other types of current structures nearby. Measurement accuracy greater than $\pm 5^\circ$ is difficult to achieve and is, in any case, rarely important. Difficulties in field measurement commonly arise because of incomplete exposure of crossbed sets. For example, two-dimensional exposures in flat outcrop faces cannot provide precise orientation information.

Indicated current directions may need to be corrected for structural dip and fold plunge, otherwise significant directional distortions may result. For linear structures such as parting lineation or sole markings, structural dips as high as 30° can be safely ignored, as they result in errors of less than 4° . However, the foreset dip orientation of crossbedding is significantly affected by structural dip, and should be corrected wherever the structural dip exceeds 10° . This subject was discussed further by Potter and Pettijohn (1977, chapter 10), who illustrated a correction technique using a stereonet. Ramsay and Huber (1983) provided graphical solutions. Middleton (2000) referred to computer routines for the necessary trigonometric calculations. Wells (1988) and Miall (1999) provided practical guides to field procedures, and recommended the use of a pocket calculator to perform structural corrections and data synthesis in the field.

Sooner or later the question will arise as to how many readings should be made? There is no single or simple answer

to this problem because it depends on how many measurable current indicators are available for observation and what the objectives of the study are. Olson and Potter (1954) discussed the use of grid-sampling procedures and random selection of structures to measure, followed by calculation of reliability estimators to determine how many readings were necessary in order to be sure of determining correct directional trends. In this study, they were concerned only with determining regional paleoslope. We now understand a great deal about air and water flow patterns in different depositional environments, and a case could be made for measuring and recording every visible sedimentary structure. Such detailed data can be immensely useful in amplifying environmental interpretations and clarifying local problems. Some selection may have to be made in areas of particularly good exposure. A practical compromise is to record every available structure along measured stratigraphic sections and to fill in the gaps between sections with spot (gridded or random) samples. This procedure permits the elaboration of both local and regional paleocurrent trends. When constructing lateral profiles of large outcrops, it is essential to document these with abundant paleocurrent determinations. Such data provide the third dimension to a two-dimensional outcrop and yield essential information regarding the shape and orientation of architectural elements.

If the trend itself is important, 25 readings per sample station is commonly regarded as the minimum necessary for statistically significant small samples. However, the same or fewer readings plotted in map or section form can yield a great deal of environmental detail, whether or not their mean direction turns out to be statistically significant. Several hundred or a few thousand readings may be necessary for a thorough analysis of a complete basin.

A variety of statistical data-reduction and data-display techniques is available for paleocurrent work. The commonest approach is to group data into subsets according to stratigraphic or areal distribution criteria, display them visually in current-rose diagrams, and calculate their mean and standard deviation (or variance). The method of grouping the data into subsets has an important bearing on the interpretations to be made from them, as discussed in the next section. A current rose diagram is simply a histogram converted to a circular distribution. The compass is divided into 20, 30, 40, or 45° segments, and the rose is drawn with the segment radius proportional to number of readings or percent of total readings, but this exaggerates the importance of modes. A visually more correct procedure is to draw the radius proportional to the square root of the percent number of readings, so that the segment area is proportional to percent. Examples are given in Figure P1. Wells (2000) warned that the choice of origin for rose diagrams and the method of subdivision of the segments can affect the visual appearance of the resulting diagram and the orientation of the modes. The calculation of means, which is done from raw data, is not affected, but Wells' warning indicates the need for caution in the visual interpretation of rose diagrams.

Arithmetic and vector methods may be used for calculating mean, variance, vector strength, and statistical tests for randomness (Curry, 1956; Potter and Pettijohn, 1977; Wells, 1988).

Statistical procedures, such as moving averages and trend analysis, are available for smoothing local detail and determining regional trends. A moving average map is constructed from gridded data. An arbitrary grid is drawn

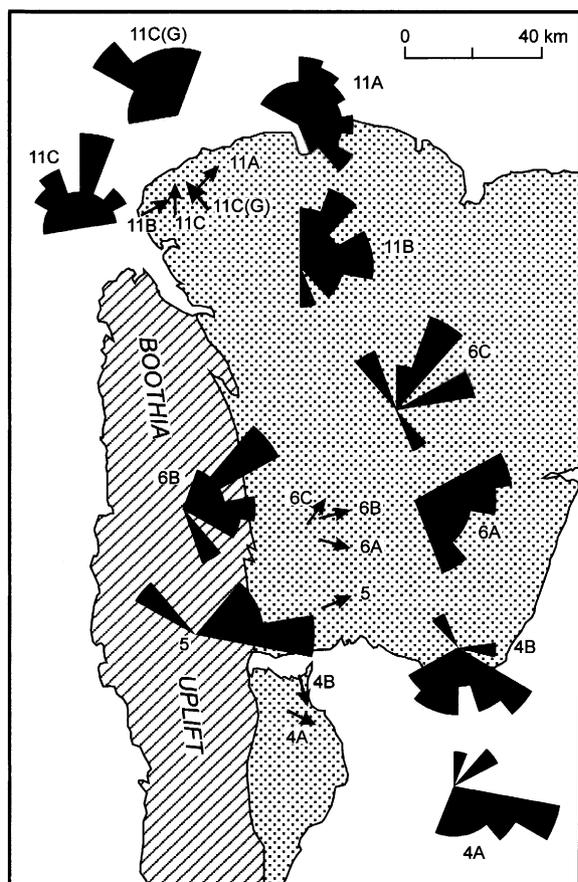

Figure P1 The use of paleocurrent rose diagrams to illustrate the spread of readings at a given location. In this case (a Devonian fluvial system in the Canadian Arctic; from Miall and Gibling, 1978), each segment of each rose is an arc of 25°, and mean flow directions for each location are shown by arrows. The arrow corresponding to each rose diagram is indicated by the location number.

on the map; the mean current direction for the data in each group of four squares is then calculated and shown by an arrow at the center of this area. Each data point is thus used four times (except at the edges of the map).

The basin analyst should be wary of becoming too deeply enmeshed in the refinements of statistical methods. The use of probability tests is a useful curb on one's wilder flights of interpretive fancy, but there is a vast literature on the statistics of the circular distribution that seems to detract attention from very simple questions: do the data make geological sense? Can they be correlated with trends derived from other methods, such as lithofacies mapping or petrographic data? Moving average and trend analyzes are useful techniques for reducing masses of data to visually appealing maps, but they inevitably result in a loss of much interesting detail.

Environment and paleoslope interpretations

A recommended first level of analysis is to plot current-rose diagrams and mean vectors for each outcrop or local outcrop group (Figure P1), separating the readings according to major

facies variations. If contemporaneous basin shape and orientation can be deduced from these data or from other mapping techniques, the paleocurrent data can be used interactively with lithofacies and biofacies criteria to interpret the depositional environment and to outline major depositional systems, such as deltas or submarine fan complexes. The geologist should examine the relationships between mean current directions in different lithofacies and in different outcrops. The number of modes in the rose diagrams (modality) and their orientation with respect to assumed shoreline or lithofacies contours are also important information. Another useful approach is to plot individual readings or small groups of readings collected in measured sections at the correct position in a graphic section.

Paleocurrent distributions are commonly categorized as unimodal, bimodal, trimodal and polymodal. Each reflects a particular style of current dispersion. For example, the rose diagrams in Figure P1 are unimodal to weakly bimodal, and vector mean directors are all oriented in easterly directions, roughly normal to the basin margin, with the exception of station 11C(G). The data were derived mainly from trough and planar crossbedding and parting lineation, and the environment of deposition is interpreted as braided fluvial (Miall and Gibling, 1978). In some areas, for example, stations 6A, B, and C, there is a suggestion of a fanning out of the current systems, indicating possible deposition on large, sandy alluvial fans. The anomalous data set of station 11C(G) was derived from giant crossbed sets ranging from 1 m to 6 m in thickness. They may be eolian dunes or large sand waves in a trunk river draining the basin east of Boothia Uplift. Field evidence is inconclusive, but the paleocurrent data can be reconciled with either interpretation.

Coastal regions where rivers debouch into an area affected by waves and tides can give rise to very complex paleocurrent patterns (Figure P2). Bimodal, trimodal, or polymodal distributions may result. However, time-velocity asymmetry of tidal currents can result in local segregation of currents, so that they are locally unimodally ebb- or flood-dominated. This could cause confusion at the outcrop level, because the tidal deltas showing such paleocurrent patterns may consist of lithofacies that are very similar to some fluvial deposits. In wave-dominated environments, current reversals generate distinctive internal ripple-lamination patterns and herringbone crossbedding. Paleocurrent analyzes of these bimodal crossbeds may yield much useful information on the direction of wave attack and hence on shoreline orientation. The term paleoslope means little in this environment because there are a diversity of local slopes and because waves and tides are only marginally influenced by the presence and orientation of bottom slopes. Paleocurrent data cannot be used to infer provenance in such situations.

Paleocurrent data formed part of the basis for a long-standing debate regarding the formation of hummocky cross-stratification in shallow-marine environments. Some workers attributed this structure in part to geostrophic currents flowing obliquely across the continental shelf; others argued that shore-normal paleocurrents indicate an origin as a result of wave-generated oscillatory and return flow across the shelf floor (the debate is summarized in Walker and Plint, 1992).

Submarine-fan and other deep-marine deposits show three main paleocurrent patterns: (1) Individual submarine fans prograde out from the continental slope and therefore show radial paleocurrent patterns with vector mean directions

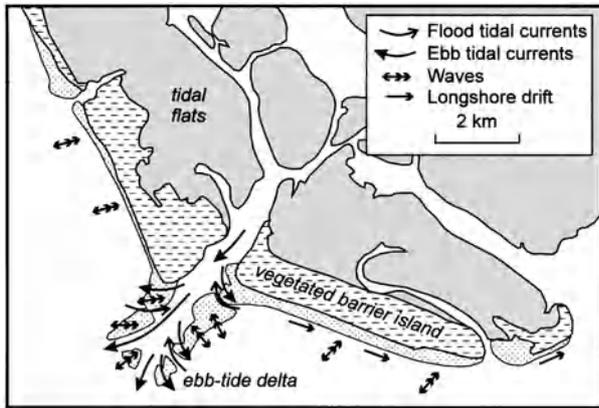

Figure P2 The complex flow patterns around a tidal inlet. Waves typically approach a shoreline obliquely, but are deflected to arrive at the shoreline with a nearly perpendicular orientation. Tidal currents are locally ebb- or flood-dominated. In such cases recorded paleoflow may be nearly unimodal. However, partial preservation of all wave and tide influences is typical, and can generate very complex paleocurrent patterns. Longshore currents are generated by wave and tide pressures at the shore, and may be particularly active during storms.

oriented perpendicular to the regional basin strike. This pattern is typical of many continental margins, particularly divergent margins. (2) In narrow oceans and many arc-related basins, deep-water sedimentation takes place in a trough oriented parallel to tectonic strike. Sediment-gravity flows, particularly low-viscosity turbidity currents, emerge from submarine fans and turn 90°, to flow longitudinally down-slope, possibly for hundreds of kilometers. Current directions may be reversed by tilting of the basin. (3) Contour currents or boundary undercurrents flow parallel to continental margins and generate paleocurrent patterns oriented parallel to basin margins.

On a basinal scale paleocurrent trends may reveal large-scale paleogeographic features. For example, the east to northeastward-directed flow indicated by all the rose diagrams in Figure P1 (except 11C(G)) indicates a regional paleoslope dipping in that direction, a fact confirmed by other stratigraphic and sedimentologic data. In fluvial environments, flow directions transverse and parallel to basin axis may indicate the presence of tributary and trunk river systems. In coastal regions paleocurrents may indicate the orientation of shorelines, and deep marine paleocurrents may be used to determine the orientation of the continental slope and submarine canyons.

PARTING LINEATIONS AND CURRENT CRESCENTS

Introduction

Parting lineations and current crescents are structures that are commonly preserved on the bedding surfaces of generally planar bedded sandstones and siltstones. Such structures are useful in determining paleocurrent directions and the nature of the current that transported the sediment. The structures can form in response to unidirectional or oscillating (long and short period) currents and they may be present in the deposits of a range of environmental settings, including fluvial, beach, shallow marine, and deep marine (turbidites) deposits.

Parting lineations

Parting lineations include two related structures that may be commonly seen when a planar laminated (horizontal or inclined) rock is split, or parted, along internal bedding planes. This general term refers to any low relief, linear structure that is present on such surfaces (Crowell, 1955). Two common forms of parting lineation are termed “parting-step lineation” and “current lineation” and both may be present on the same bedding surface.

Parting-step lineations (McBride and Yeakel, 1963), are structures that reflect the manner in which a rock breaks, parallel to original bedding. Indurated stratified sandstones will commonly split parallel to bedding but not perfectly so. When such rocks are split, steps form on the top bedding surface which are remnants of immediately overlying bed that have not separated from its basal surface. These remnants

form lamina-thick (a millimeter or less) steps on the surface that are longer than they are wide; these elongated steps make up parting-step lineation (Figure P3(A)). McBride and Yeakle (1963) demonstrated that the orientation of the trend of the length of these steps is approximately parallel to the orientation of the long axes of sand grains within the rock. Due to the relatively strong preferred alignment of the sand grains, when laminae break as a rock is parted, the broken laminae form elongate ridges, or steps, that are longest in the direction parallel to the grain long axes. The orientation of sand grains in such rocks is well-known to be determined by the direction of the depositing flow; the grains are aligned parallel to the current. Therefore, the orientation of parting step lineation similarly trends parallel to the depositing current. It is important to note that parting-step lineation is not a primary structure but is a reflection of the primary internal fabric which, in turn, reflects the sense (but not the absolute direction) of the depositing current.

Current lineations are primary sedimentary structures that are made up of more-or-less parallel, linear mounds (a few grain diameters high) extending parallel to parting-step lineations, internal fabric and, therefore, the depositing current (Figures P3(A) and P4(B)). The lineations may extend from a few centimeters to several tens of centimeters along their length and their transverse spacing ranges from a few millimeters to

over a centimeter. Allen (1964) explained the formation of current lineation by the action of flow-parallel rotating vortices near the boundary of the flow, which sweep grains laterally into the linear mounds that characterize this structure. More recently, Allen (1982) suggested that current lineations form as sand grains are swept into low speed streaks within the viscous sublayer of a current. Weedman and Slingerland (1985) found that the spacing of "sand streaks" (active current lineations) was comparable to that of viscous sublayer streaks when fine and medium sand is in transport and that spacing increased as the flow strength and sediment transport also increased. Current lineations are most commonly reported in the deposits of unidirectional flows (e.g., fluvial deposits, B-division of turbidites) but have also been reported on bedding surfaces in hummocky cross-stratified sandstones.

Both current and parting-step lineation are useful indicators of the sense of the paleocurrent direction. They can be used in conjunction with other directional indicators to infer the absolute paleocurrent direction. Thin sections, cut perpendicular to bedding and parallel to the lineation, will show the imbrication direction of grains which, providing the absolute paleocurrent direction. In the field, heavy mineral shadows and current crescents can indicate the absolute paleocurrent direction along the lineations.

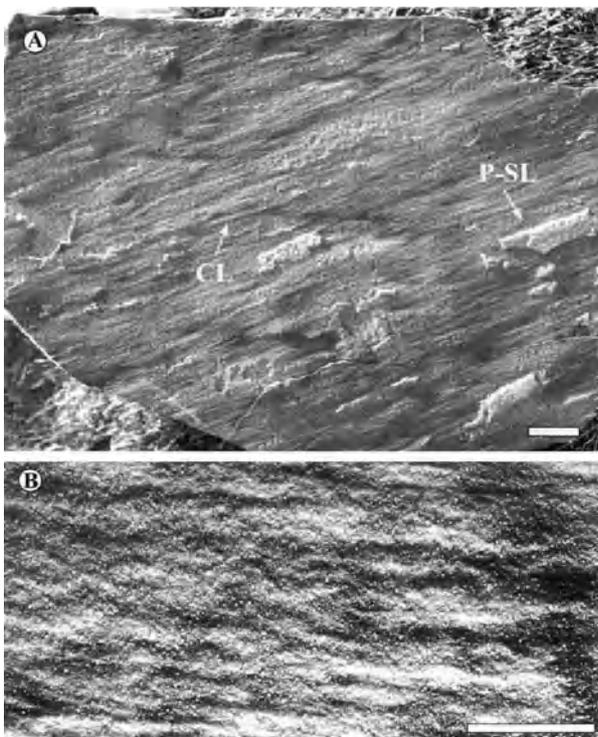

Figure P3 (A) Parting-step (P-SL) and current lineations (CL) on a bedding surface from the Silurian Whirlpool Sandstone of southern Ontario. Note that one of each structure is labeled whereas there are several examples of each on in the photograph. The white scale bar is approximately 5 cm long. (B) Current lineation on a fine sand bedding surface that was deposited under upper flow regime plane bed conditions. The white scale bar is approximately 8 cm long.

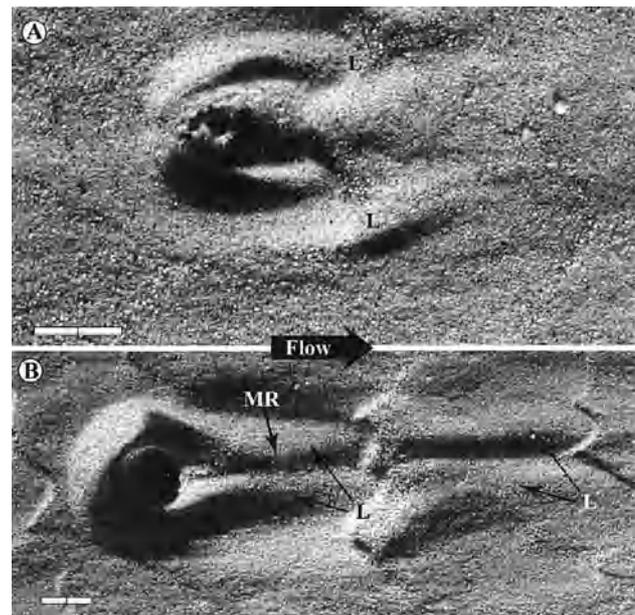

Figure P4 (A) A current crescent formed in a flume on a bed of fine sand under flow strengths just fast enough to move sand over the bed; the ripples are the stable bedform for the flow conditions; this crescent formed after one minute of flow. The object was a metal sphere but it has been removed for the photograph. Note that only the scour along the leading edge and sides of the crescent are well developed whereas the depositional lobes (labeled "L") are poorly developed. (B) A current crescent on the same sand bed after approximately 2 min of flow. Note the pair of well-developed lobes separated by a medial ridge (labeled "MR"). The lobes extending from the scour (black "L") have generated a second set of ripple-like lobes (white "L").

Current crescents

Current crescents are arcuate scours that may be preserved on bedding surfaces (Figure P4). The scours form as a current flows around an obstacle on the bed (e.g., a single particle, shells, debris). The form of the crescent reflects the pattern of flow around the obstacle. At the leading edge of the obstacle, a rolling vortex develops which produces a curved scour with "arms" extending downstream from the sides of the obstacle (Figure P4). Further downstream sediment that has been eroded from the bed is deposited in two lobes, on either side of the object (but downstream from it) forming areas of higher relief than the ambient bed. In well-developed crescents a medial ridge separates the two lobes (Figure P4(B)). The combination of erosional and depositional features collectively make up the current crescent.

The form of a current crescent appears to depend on the size and shape of the obstacle, the flow conditions and the duration of time over which the structure forms. In general, when flows are of short duration or if the obstacle is moved away from the scour shortly after the current becomes active the structure may resemble a small, crescent-shaped scour immediately around the upstream edge and sides of the object; there may be little deposition such that the depositional lobes are difficult to recognize (Figure P4(A)). In contrast, when the current is of significant duration and the obstacle remains stationary the depositional lobes may generate two trains of low ripples that can extend for decimeters to meters downstream (Figure P4B), depending on the size of the obstacle.

Unlike lineations, current crescents may be used to infer the absolute paleoflow direction and their orientation can be measured with a compass in the field. Current crescents are most commonly unidirectional (pointing in one direction, the paleoflow direction), particularly when found in the deposits of unidirectional currents (e.g., rivers, turbidity currents). However, it is a common structure on beach faces (foreshore) where they can form in response to both the swash and backwash. In this setting the structures may be bidirectional. Furthermore, swash- and backwash-oriented crescents may not be at 180° to each other, depending on the angular relationship between incoming waves and the orientation of the slope of the beach face.

PEAT

Peat is a highly variable substance. It is highly variable in space because there are a diverse number of plant taxa characteristic of the different geographic biomes that contribute to peat formation. Peat, ranging in age from less than a year to hundreds and thousands of years, is also highly variable in time because it changes character as it ages.

It is difficult to consider peat without considering how it originates and the landform in which it occurs. Functional criteria must be considered, especially hydrological conditions and associated biological features that give rise to peat and peatland formation (Ingram, 1978). Not doing so has led to much confusion and misunderstanding of the nature of peat and peat lands. Von Bülow (1929) and Overbeck (1975) are good examples of attempts to characterize peat and peatlands.

Peat has different meanings to different people in many disciplines, which has also confounded the problems. Peat, as a fresh material or as a source of various chemical and biotic compounds extracted from it, has a number of industrial applications in horticulture, energy generation, medicine, mining, and specialized product industries (Fuchsman, 1980). Pristine and managed peatlands are of interest in ecology, soil science, biogeochemistry, hydrology, archaeology, cultural histories, agriculture, horticulture, forestry, and engineering. All of these have developed, to varying degrees, a discipline-specific and sometimes conflicting vocabulary to describe peat.

Functional criteria

After plants and animals living in waterlogged soils complete their life cycle, their dead remains become peat. Given that plants are the dominant component of the living community and its litter, peat is considered to be largely plant matter. The newly dead plant matter undergoes a series of changes, the onset of which is variously referred to as decay, decomposition, humification or breakdown processes. The processes involve: (a) weakening of plant structure and loss of organic matter, as gas or in solution, as a result of leaching and of attack by living aerobic soil microfauna and bacteria; (b) loss of physical structure of broken plant parts; and (c) change of chemical state (Clymo, 1983). This occurs in a near-surface layer, or *acrotelm*, which is characterized by oscillating water table, variable water content, high hydraulic conductivity, periodic oxygen entry, and de-watering. Not all of the plant matter decays before new plant matter from the following year is added to that of the previous year. The addition of new peat to the older leads to accumulation. The addition of peat year after year gives rise to thick accumulations and to the buildup of peat landforms or peatlands (Clymo, 1984). Eventually the deeper and older peat will become completely engulfed by the water table and will no longer be influenced by oscillations in the water table. It will have a more or less constant water content and negligible oxygen entry, small hydraulic

conductivity, and be devoid of aerobic microfauna and bacteria. A lower layer or *catotelm* will develop with characteristics quite distinct from the acrotelm layer on the surface (Ingram, 1978). Decay processes are generally fast immediately following death of the plant and slow down considerably as the peat enters and continues to reside in the catotelm. The acrotelm is the primary peat-forming layer where decay processes predominate compared to the catotelm. Decay continues in the catotelm but at rates several orders of magnitude less than in the acrotelm. Peat that makes it into the catotelm is preserved for several hundreds and thousands of years following death of the plants.

Waterlogging, therefore, is the key ingredient leading to peat accumulation. Because the diffusion of oxygen is many orders of magnitude slower in water than in air, the low oxygen regime brought about by waterlogging, leads to accumulation. If waterlogging is interrupted in any one year, no peat will make it into the catotelm and no net accumulation will occur. If dry conditions persist over several years, it is possible that catotelm peat may become re-exposed to oxygen, and the peatland will degrade.

Peat landforms with acrotelm and catotelm layers, and hence, actively forming and accumulating peat are referred to as *mires*. Such two-layered mires are *diplotelmic* (Ingram, 1978). The term *peatland* originates from the early writings where *peatland* was used to describe any land area covered by peat (Gorham, 1953). It is also probably a shortened version for "peat landform" in geomorphology that refers to the biotic landforms formed of peat. In North America *mire* is generally not recognized, and instead, *peatland* is used in the broadest sense to denote any peat landform irrespective of whether it is diplotelmic or not and whether it is actively forming and accumulating peat or not. In Europe and Russia, there is a tendency to differentiate actively peat-accumulating mires from the more generic peatland term, which applies to all peatlands regardless of actively peat-accumulating or not.

The term *haplotelmic* is used when only the catotelm remains (Ingram, 1978). Erosion or human alteration are the primary forces responsible for eliminating the acrotelm. Whether natural aging of the peat-accumulating system can also contribute to disappearance of the acrotelm is less clear, such as polygon peatlands in Arctic Canada (Vardy and Warner, 2002).

A maximum depth for peatlands is unbounded. Average depth globally has been estimated to be 1.3–1.4 m (Lappalainen, 1996) and a maximum of 15 m is rarely exceeded (Clymo, 1983). At the other end of the spectrum, it has been customary to take an arbitrary minimum depth of 30, 40, or 50 cm. In diplotelmic systems, the catotelm is the thicker being several meters compared to the thinner acrotelm, which usually is not much more than 0.5–0.75 m.

Attributes of peat

It is possible to define *peat* in two ways. The first, and most common, is to define peat as a substance derived from peatlands and/or mires that is composed of the partially decomposed remains of plants with over 65 percent organic matter (dry weight basis) and less than 20–35 percent inorganic content (Clymo, 1983; Heathwaite *et al.* 1993). It is also possible to define peat in its intact or natural state (i.e., in the mire or peat land) as 88–97 percent water, 2–10 percent dry matter and 1 percent to 7 percent gas (Heathwaite *et al.*,

1993). Botanical composition and state of decomposition are generally agreed upon as the two most important characteristics.

Botanical composition

It is the plant communities that will dictate the litter source for the formation of the peat under them. This has led to first-order classifications that differentiate peat into four broad categories: *moss*, *herbaceous*, *wood* and *detrital* or *humified peat*. Moss is often subdivided into *Sphagnum* (i.e., Sphagnaceae—the peat mosses) and brown mosses (i.e., Amblystegiaceae) because both groups are common peat formers. *Sphagnum* is the single most important moss genus. Few other moss groups, except for members of the Polytrichaceae are important peat-formers, for example, in the southern hemisphere (Clymo, 1983). Identification of the moss remains to family and genus is often possible in the field with a hand lens, and where preservation is good, it is possible to identify to species level with the aid of a microscope (e.g., Janssens, 1983). The same is true for flower and seed parts, leaves, stems and roots of sedge (i.e., Cyperaceae), grass (i.e., Poaceae) and rush (i.e., Juncaceae) remains, which are probably, the most important groups comprising herbaceous peats. It is easy to differentiate, *Carex*, *Eriophorum*, *Phragmites*, *Cladium*, *Juncus* peats, and in the case of the Andes in South America, for example, *Oxychloe* peats (Earle *et al.*, 2003).

Woody peats are common in forested and shrub-dominated peatlands. Wood, if there were trees or tall and dwarf shrubs, is commonly encountered in peat. Much of it is identifiable depending upon the state of preservation. Stumps, logs or large branches can be sectioned and identified using standard wood identification techniques. Seeds, nuts, samaras, strobili, cones, leaves, needles, buds and bud scales, and bark can also be identified, almost certainly to family, often to genus and even species.

The last major category refers to peat where the plant remains are so disarticulated (i.e., detrital peat) or decomposed (i.e., humified peat) that the bulk of the plant is no longer recognizable and identifiable. Where macroscopic remains are no longer recognizable, it is possible to use paleoecological techniques such as pollen and spores analyzes to infer plant origins of the peat. Other plant groups including lichens, such as *Siphula* or *Cladina* communities in western Canada, and algae may leave distinctive thin horizons in moss or herbaceous-rich peats, but not usually in accumulations of any significance.

State of decomposition

This character, usually called the state of humification, is partly assessed by the extent to which plant structure is visible, and partly by color. Field assessment is usually made using the H scale (Von Post and Granlund, 1926). The scale is a subjective description by a numerical scale of 1–10 based on the color of the water squeezed in the hand. Numerous other more sophisticated techniques to assess density of color of water or chemical extractants also exists (Tolonen and Saarenmaa, 1979), but comparisons of techniques show reasonable agreement, so the simplest H scale technique, is the one most often used.

Other characteristics

Other important characteristics that can be measured to further characterize peats are inorganic matter content, inorganic solutes (i.e., calcium, potassium), cation exchange capacity, microorganism activity, bulk density (dry matter mass/volume), water content, gas content, water-retaining capacity, proportion of fibre (i.e., as size class), structure, heat of combustion, color, and age (Clymo, 1983).

Occurrence and distribution of peatlands

Peatlands develop where geological stability and physiography allow water to collect on the land surface long enough in a growing season to support peat-forming plant communities. A positive or balanced hydroperiod is, therefore, required in order to maintain waterlogging and to sustain the peat-forming plants and peatland.

Peatlands are cosmopolitan in distribution. About 95 percent of the worlds peatlands occur in North America, Asia and Europe (Lappalainen, 1996). Canada has the largest area of peatlands in the world with 1.1×10^6 km² (Tarnocai *et al.*, 2000). Most of the peat in the world lies in the Boreal and Temperate Biomes of the northern hemisphere where geological history, cool and moist climate and productive plant communities have given rise to widespread peatland formation. These are regions where water is especially abundant, waterlogging is widespread, thus favoring peat-forming plants and peatlands.

PETROPHYSICS OF SAND AND SANDSTONE

Introduction

Porosity in sand is the only component that forms during the sedimentation process. During most of its existence porosity does not represent a simple void but the presence of a fluid or gas. Many of the physical properties of sand and sandstone (hereafter referred to as “sandstone”) are functions of the details of the porous part of sandstone. Porosity differs from other constituents of sandstone in that it forms a physically continuous three-dimensional web-like complex. The intimate properties of this complex strongly affect such properties as permeability (Ehrlich *et al.*, 1991b) and fracture toughness (Ferm *et al.*, 1990).

Models for porous microstructure prior to image analysis

For most of the 20th Century sandstone porosity was the domain of physicists and engineers. They deduced structure consistent with physical measurements, especially permeability. Darcy’s permeability carries with it no intrinsic information concerning the microstructure. Darcy’s Law relates flow (caused by a differential between input and outlet pressure) in a cylinder containing a porous medium to the geometry of the cylinder. Taking the geometry into account, the rate of flow through each cylinder is proportional to the difference between input and output pressures. However the constant of proportionality (commonly called the “permeability”) varies from sample to sample. Permeability thus involves the nature of the porous medium. However an infinite number of significantly different porous microstructures can yield the same value of permeability. Permeability would reach a maximum if the cylinder were simply an empty tube. Hence one way to form a geometric model of the microstructure is to assume a homogeneous (or “homogeneously heterogeneous”) medium where the micro flow paths are longer than the length of the sample cylinder; that the flow “sees” a greater length than the length of the sample cylinder. This added length was postulated to be due to the tortuous flow paths through the medium. Although the concept of “tortuosity” was very effectively demolished by Scheidegger, (1974) on theoretical grounds, and by Ehrlich *et al.* (1991b) on empirical (quantitative petrographic) grounds, the concept of tortuosity is very popular with probabilistic modelers (Dullien, 1979). As discussed below, the permeability (holding grain size constant) is due to the presence of hyper efficient flow paths along packing flaws.

Pores and pore throats

The porosity complex consists of two major parts: pores and pore throats (Berg, 1975; Dullien, 1979). Pores account for all of the volume of porosity and tend to occupy the interstices between grains thus providing a cusped shape bearing concave facets each representing the boundary between a pore and an adjacent sand grain. Adjacent pores communicate at the cusps, the cross sectional area of minimum volume of a plane cutting through a cusp is termed a “pore throat” (Scheidegger, 1974). Pore throats, then, are the bottlenecks that affect transmissivity of fluids, pressures, diffusion, and other transport properties. Pore throats are important mediators of the rate of diagenesis (Prince and Ehrlich, 2000) and are extremely important in hydrocarbon reservoirs. Pores, on the other hand, represent the capacity of the sandstone but are seldom important in fluid transport.

Analysis of the porous microstructure

A functional description of sandstone porosity should produce output that consistent with subjective porosity classification but also quantitative and precise in order to describe physical properties that are continuous variables. This calls for the application of digital data acquisition and an image processing capability. Such capabilities only became commonly available after 1975, so the preexisting subjective classification (intergranular pore, intra-granular pores and moldic pores) was really most valuable in tracking diagenetic processes than relating thin section data to physical response.

Imaging

Commonly sandstones are studied by imaging a planar section *via* a light microscope, a scanning electron microscope or an electron luminescence apparatus. The plane of section interacts with the three-dimensional sample by (given simple assumptions) such that the ratio of the total area of each constituent to the others approximates the volume of the ratios of the components.

Pore types and throat sizes

Information concerning the size and shape of grains or pores is hazy in that the plane of section can penetrate a grain anywhere between the “equator” and the “pole” such that a wide size range of two-dimensional representatives represents each grain size class. Pore throats are seldom encountered by the plane of section as shown by the abundance of “isolated” intergranular pores in most sandstones, (the pore throat lying above or below the plane of section). Even when throats are encountered, their true size is impossible for estimate from section. Accordingly additional ways to observe sandstone must be used to supplement two-dimensional images. These include permeameters, mercury injection apparatus, and measurement of electrical properties of saturated media (Etris *et al.*, 1989; Ehrlich *et al.*, 1991a,b). By building a model consistent with all of these, we can deduce the values of the critical parameters that control the porous complex.

Petrographic image analysis

“Petrographic Image Analysis” (“PIA”) (Ehrlich *et al.*, 1984, 1991a,b) is a generic term associated with the move from

subjective totally visual microscopic analysis to acquisition and processing of digital imagery. Areas containing the entire plane of section can be imaged and the collection of image may form a seamless mosaic before the porous complex is analyzed. Having stated that only throats direct influence on transport properties, one might infer that analysis of pores in section would be fruitless. For instance the relationship between porosity and permeability is commonly very weak. However it can be demonstrated that there is a strong correlation between pore type and throat size (McCreesh *et al.*, 1991b). For this to occur and be relevant to transport properties, some types of pores must form continuous networks that are relatively efficient with respect to transport. Quantitative determination of pore types can only be accomplished by deducing the three dimensional sizes and shapes of pores from their two dimensional sections. We define the porosity objects exposed in section as *porels* (*Porosity Elements*) (Ehrlich *et al.*, 1991a). A porel is defined as a patch of porosity that is internally continuous with all of its parts. In a loose packed sand for instance, the porosity may represent a lacelike filigree in section and so the image might contain only two or three really extensive porels. As porosity declines as a consequence of diagenesis, porels systematically evolve into small isolated patches of porosity when viewed in section. One form of PIA involves the use of a variant of a common image analysis algorithm termed “erosion/dilation differencing” (Ehrlich *et al.*, 1991a) that produces porosity size and shape spectra that can be analyzed by a spectral unmixing algorithm, Polytopic Vector Analysis, an offshoot of factor analysis, (Johnson *et al.*, 2001) into an objective classification of pore types, including their sizes, shape, and volumetric proportions. This provides a link to earlier subjective pore type classifications as well as to physics. The output of this procedure can be related to the physical measurements in order to construct a plausible three-dimensional model of the porosity consistent with all methods of measurement.

Mercury injection—determination of throat size

Mercury injection porosimetry is the prime physical test, followed by permeability (Ehrlich *et al.*, 1991b) and electrical conductivity / resistivity (Etris *et al.*, 1989). Mercury injection involves placing a sample (commonly a core plug about 2 cm in diameter) into a sealed pressure vessel connected to a supply of mercury. Mercury is a strongly nonwetting phase and will not imbibe into the sample spontaneously. Pressure is progressively increased until mercury is forced into the sample. At the lowest pressure of injection only a fraction of the porosity is invade. The relationship between injected volume and pressure is recorded. The volume of porosity invaded in a pressure increment represents the amount of porosity that can be accessed by pore throats of a given size range through the Laplace equation (Scheidegger, 1974; Dullien, 1979). Thus mercury porosimetry carries strong throat size information and poor pore type information, the inverse of imaging in that regard. At a high enough pressure, almost all porosity is filled except for isolated inclusions within grains. The injection data can be precisely related to the pore type information obtained by image analysis *via* multiple regression with care taken that the imagery is taken from a section at the end of a sample cylinder before injection. The results consistently show a strong relationship between pore type and throat size (McCreesh *et al.*, 1991). For this to occur pores of like type

must be mutually connected into circuits characterized by a common size range.

Relationship between microstructure and physics

The results of this combination of image analysis and mercury injection data are sufficient to successfully estimate permeability and electrical properties such as conductivity of the sample when saturated with fluids.

Microcircuits and packing flaws

The concept of hyper efficient microcircuits (those associated with the largest throats) dominating transport was directly verified by another image analytical procedure involving analysis of the Fourier transform of the binary image (porosity 1.0, matrix 0.0) (Prince *et al.*, 1995). Filtering the transform produces images where the circuits are prominently displayed. The Fourier transform is exactly equivalent to an X-ray diffraction pattern and so the numerical tools used in the analysis are much the same. Both the optical transform of sandstones and the X-ray transforms of crystals, share common characteristics in that in neither are the particle/atoms perfectly arrayed. Instead packing flaws separate closely packed domains. Graton and Fraser (1935) demonstrated *via* a series of experiments with monolayers of equal size spheres the nature of the flaws and their inevitability just about the same time as crystal chemists were using bead packs to illustrate packing flaws in ionic crystals. Unfortunately the work of Graton and Fraser has largely been ignored due to its proximity and length.

Origin of packing flaws: the Graton and Fraser model

According to Graton and Fraser (1935) the packing flaws are a consequence of sedimentation. A depositional episode commonly occurs as the sedimentation of a collection of suspended grains that accumulate in a layer that is many grains thick under the influence of gravity. Closest packing is the arrangement of lowest potential energy and so nearby grains tend to cluster in this fashion. Such clusters form spontaneously throughout the sedimenting mass but there is no process that will force the clusters into a common orientation. As the accreting closely packed clusters grow, the eventually interfere with one another producing bounding compromise zone (packing flaws) characterized by large pores connected by large throats—the permeability circuits. In theory and observation, once generated, packing flaws propagate without limit, ending only when intersecting another set of flaws. This provides the continuity that ensures agreement between two-dimensional images and the volumetrically based physical measurements such as mercury injection porosimetry.

Graton and Fraser (1935) also came up with the basis of a natural history of packing flaws. As mentioned above, sand is commonly deposited episodically producing a sand accumulation consisting of a large number of sand on sand beds. The trivial unconformities defined by bed boundaries represents a sand water interface of relatively long duration resulting in a sort of annealing (densification) of the sand exposed to the moving water. The impulse of the next episode of sedimentation results in a major oriented mismatch between that interface and the newly deposited sand. Thus packing flaws are more densely spaced just above bedding planes. Outcrop

observation verifies that many outcrops “weep” from a small interval (few cm thick) from the base of an overlying bed. As discussed below, this effect is also observed in partially oil-saturated core, where the dark oil decorates the bases of beds and may be absent in the middle and upper parts of a bed.

Multiphase flow

The porous microstructure is critically important in the case of multiphase flow such as oil and water. In this case two mutually immiscible fluids are competing for the pore space. Commonly but not always water is a “wetting” phase and so can spontaneously imbibe into the sandstone *via* capillary forces (Berg, 1975). Oil is commonly a “nonwetting” phase and must be forced into the sandstone by pressure just as mercury (another extremely nonwetting phase) is forced into a sandstone sample. Thus water will tend to segregate and be held in parts of microporosity containing small throats and the nonwetting phase will initially be forced into the porous circuits connected by the largest throats. The wetting phase will also coat all mineral surfaces and so be somewhat of a thin barrier between the oil and the pore walls. “Relative permeability” tests measure the degree of mobility of either phase as a function of saturation. Such are in agreement with the microstructural model described above (Prince and Ehrlich, 2000). The nonwetting phase is loosely held in pores with large throats (packing flaws) and the wetting phase is tightly held in pore complexes connected by small throats. Presumably water completely fills the pores of sandstone before migration of petroleum. The buoyant force of the oil column provides the pressure needed for to displace this initial water with oil. The longer the oil column, the greater the pressure gradient from the oil water content to the seal (Berg, 1975). Thus oil near the top of a reservoir displaces more water than rock near the oil water contact. However changes in grain size (which also affects throat sizes) as well as disordered zones near bed boundaries will ensure various values of water saturation for a given height above the oil water contact.

Summary and conclusions

The petrography of sandstones and other porous media can best be determined by a combination of image analysis and physical measurement. The two dimensional information taken from plane of thin section can be turned into a three dimensional microstructural complex by convolving that data with physical properties that arise from the three dimensional volume. The common availability of high quality relatively inexpensive digital image capability along with a wealth of image processing algorithms allow such analysis to be undertaken at almost any level. The nuances gained have shown their worth in the petroleum industry and also as a way to quantify the nature and extent of diagenesis. This field is still very young and many opportunities exist for new findings. A caveat is that the practitioner must have intermediate-level competence in multivariate analysis.

PHOSPHORITES

Introduction

Phosphorites are rocks enriched in phosphorus relative to average crustal abundances, an enhancement usually expressed in terms of P_2O_5 concentrations. Whereas the average P_2O_5 content of continental crustal rocks is estimated as 0.23 percent (Ronov and Yaroshevsky, 1969) and sedimentary rocks average 0.03–0.16 percent (McKelvey, 1973), rocks typically designated as phosphorites have 15–37 percent P_2O_5 (Bentor, 1980). Phosphorites thus have phosphate contents that are 60 to 160 times greater than the crustal average and on the order of 100 to over 1,000 times greater than the averages for common sedimentary rocks. The most contentious issues concerning phosphorites center on the mechanism or mechanisms by which this enrichment has taken place in the geologic past and whether formation of phosphorites

represents a significant perturbation of the biogeochemical cycle for phosphorus, questions discussed below.

The element phosphorus averages about 70 ppb ($\sim 2.3 \mu\text{mol/L}$) in seawater, is a limiting nutrient to biological productivity on geological timescales, and regulates the global carbon cycle and climate. Because of its low abundance and because it is closely tied to short-lived biological–chemical cycles of growth and decay, phosphorus has a relatively brief residence time in the ocean, estimated for the surface ocean by Mackenzie *et al.* (1993) as 0.07 years based on phytoplankton uptake. The overall oceanic residence time for phosphorus is estimated to range between *ca.* 10,000 years and 40,000 years (Delaney, 1998; Colman and Holland, 2000; Guidry *et al.*, 2000).

Initial interest in phosphorites stemmed from their importance as a raw material for the production of fertilizer phosphate. Along with potassium and nitrogen, phosphorus is critical for plant growth; but, whereas K and N are readily available from several sources (seawater, evaporite deposits, the atmosphere), phosphorus can only be obtained in large quantities from phosphorite deposits. Following the discovery in the mid-19th Century of the role of mineral nutrition in plant metabolism by the German chemist Justus von Liebig, phosphorite deposits began to be exploited after more readily available P sources such as guano, manure, and crushed bones became inadequate to support expanding agricultural systems. Phosphorites are now the main source of fertilizer P, and mining of phosphorites is a world-wide enterprise, with major centers of production in the USA, Morocco, and several countries in the Middle East. Excluding China, global production in 2000 was close to 92,200 thousand metric tons (IFA, 2001).

The main mineral in phosphorites is carbonate fluorapatite (CFA) or francolite, which according to Slansky (1986) has the simplified general formula $\text{Ca}_{10}[(\text{PO}_4)_{6-x}(\text{CO}_3)_x]\text{F}_{2+x}$, with numerous substitutions of both cations and anions (Nathan, 1984; Jarvis *et al.*, 1994). The most important ancient deposits are marine, granular phosphorites that formed in continental margin or epeiric sea settings (Figure P5). Two of the key questions about this kind of phosphorite concern: (1) *phosphogenesis*: how do CFA particles initially form in marine environments? (2) *concentration*: how do such particles become dominant in granular phosphorites?

Phosphogenesis

Studies in modern environments in which CFA forms have demonstrated that this mineral commonly precipitates during early diagenesis in the upper few tens of centimeters of sediment. The most notable of these environments are the continental margins of Perú, Baja California [México], southwest Africa, and eastern Australia. Whereas the first three of these are regions of pronounced eastern boundary currents, strong coastal upwelling, prominent oxygen minimum zones, and organic-rich sedimentation (1–20 percent organic carbon), the eastern Australia margin is an area of low productivity, oxygen-rich bottom waters, and sediments low in organic matter (<0.5 percent organic carbon). These differences suggest that CFA may form in different ways, depending upon the environmental conditions. Studies of Perú margin sediments, for example, have linked phosphogenesis with high organic carbon burial rates and anoxic diagenesis (Burnett, 1977). In this setting, microbial degradation of organic matter

Tectonic and Oceanographic Settings of Marine Phosphorites

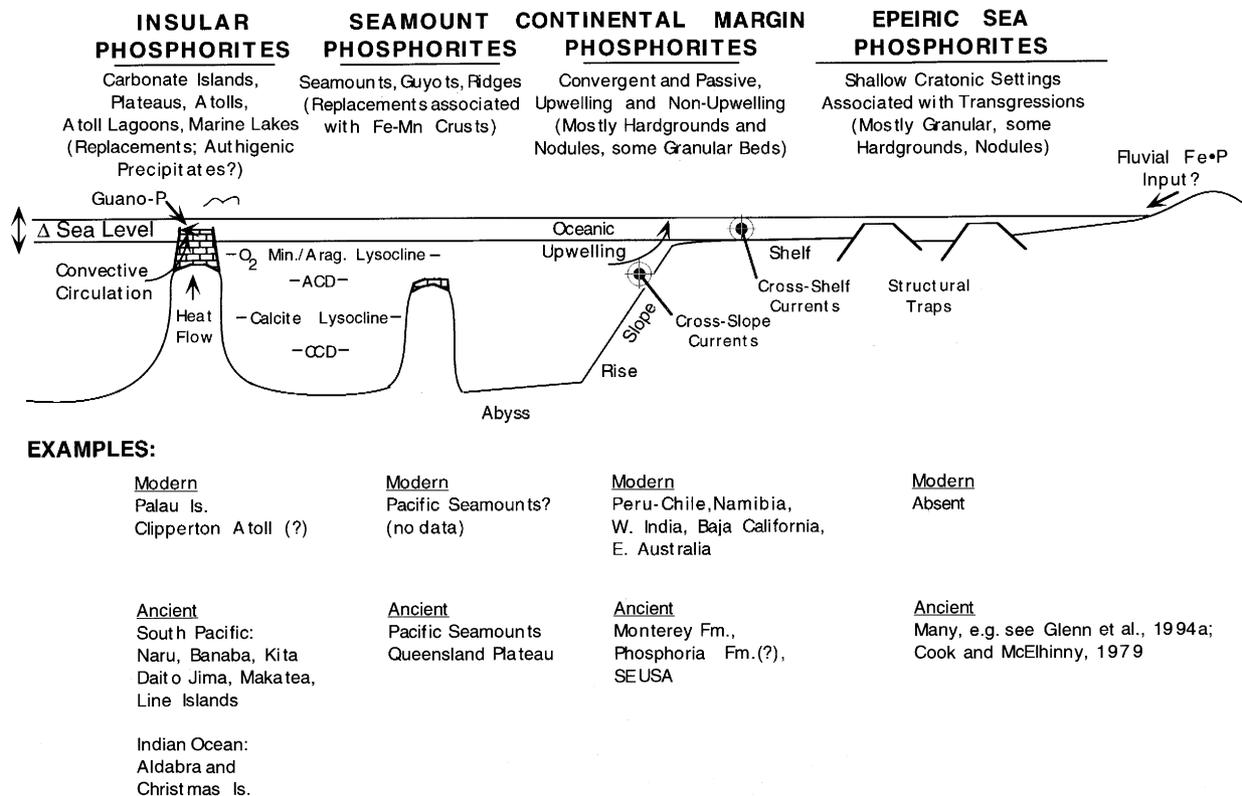

Figure P5 Tectonic and oceanographic settings of marine phosphorites as derived from studies of the modern and ancient record (after Glenn *et al.*, 1994a, reprinted with permission of Birkhäuser Verlag AG).

increases reactive dissolved phosphate (PO_4^{3-}) in pore waters to supersaturation levels with respect to CFA, probably via transformation from a metastable amorphous precursor phase (e.g., see Jarvis *et al.*, 1994). Froelich *et al.* (1983, 1988) measured pronounced increases in dissolved phosphate in pore waters in the uppermost few centimeters of Perú margin sediments (an interfacial "P-spike"), directly below which dissolved F^- decreased rapidly in concert with declining phosphate concentrations. They interpreted this pattern as reflecting CFA precipitation, with diffusion of seawater-derived F^- acting to limit the zone of phosphogenesis to very shallow burial depths. In addition, Glenn *et al.* (1988) postulated that CFA precipitation was also confined to the sediment-water interface due to mineral lattice poisoning by excessive carbonate ion concentrations with sediment depth. Although continued increases in dissolved phosphate are provided to Perú margin pore waters deeper in the sediment column (due to progressive bacterial organic matter degradation), the locus of CFA precipitation thus appears to be most strongly associated with the interfacial phosphate maxima that occurs closely adjacent to the sediment-water interface. Similar interfacial phosphate spikes are also found in association with the formation of Recent phosphorites along the Mexican continental margin (Jahnke *et al.*, 1983; Schuffert *et al.*, 1994) and off the eastern coast of Australia (Cook and O'Brien, 1990; Heggie *et al.*, 1990).

To account for the formation of CFA in organic-poor sediments on the eastern Australian margin, O'Brien *et al.* (1990) outlined a mechanism whereby iron oxyhydroxides scavenge F^- from seawater and PO_4^{3-} derived both from seawater and from organic matter subjected to oxic and suboxic microbial degradation within the top few centimeters of sediment (Figure P6). When these particles are buried into the suboxic zone, they dissolve, releasing both F^- and PO_4^{3-} to pore waters, thus promoting CFA precipitation. Ferrous iron along with any remaining F^- and PO_4^{3-} then diffuses upward into the oxic zone to be refixed by ferric oxyhydroxides and become available for further recycling. This iron redox-P cycle may also promote the formation of glauconite which is commonly associated with modern and ancient phosphorites. Froelich *et al.* (1988) invoked a similar process to help explain phosphogenesis in Perú margin sediments.

Other potential sources for the buildup of PO_4^{3-} in pore waters include dissolution of fish debris, metabolic activities of sulfide-oxidizing or other bacteria, and P release to solution by bacteria in response to redox changes. Microbial microstructures are present in many CFA grains, and microbes may affect elevation of phosphorus concentrations in pore waters, but it has not been convincingly demonstrated that they are directly involved in the formation of CFA (see discussion in Krajewski *et al.*, 1994).

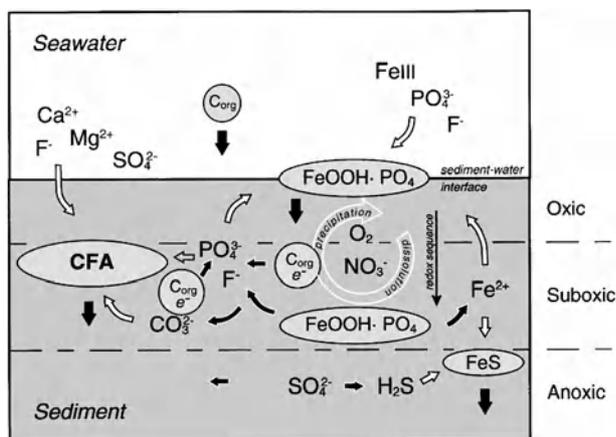

Figure P6 Schematic of CFA precipitation in surficial marine sediments illustrating phosphorus derived from either the Fe-redox cycle or directly from the microbial breakdown of organic matter. Light stippled areas represent solid phases, black arrows are solid-phase fluxes. White-outlined black arrows indicate reactions, white arrows are diffusion pathways. Phosphorus for CFA precipitation may be derived from either or both of direct microbial decomposition of organic matter (Corg) or from a redox-coupled iron oxyhydroxide-phosphorus pumping mechanism (right side of illustration). During burial and mixing, microbial decomposition of organic matter utilizes a sequence of electron acceptors in order of decreasing thermodynamic advantage. Oxygen is used first, followed by nitrate (and nitrite), manganese- and iron-oxyhydroxides and sulfate, in that order (Froelich *et al.*, 1979). Degradation of organic matter liberates PO_4^{3-} to solution, and dissolution of FeOOH liberates Fe^{2+} , PO_4^{3-} , and F^- causing elevated concentrations of these ions in porewaters. If sufficient levels are attained, PO_4^{3-} reacts with Ca^{2+} , Mg^{2+} , SO_4^{2-} and F^- ions diffusing into the sediment from seawater, and CO_3^{2-} derived from the oxidation of organic matter, to precipitate a precursor phosphate mineral which subsequently recrystallizes to CFA (francolite; see text). Excess PO_4^{3-} may also diffuse upward toward the sediment-water interface where it is resorbed by ferric iron oxyhydroxides. Iron may diffuse both downward to be fixed as glauconite (e.g., Glenn, 1990) under suboxic conditions, or as FeS under anoxic conditions, and upwards to the oxic layer where it is reprecipitated as FeOOH . In this later case, the Fe-redox cycle provides an effective means of trapping PO_4^{3-} in the sediment and promotes precipitation of CFA, especially in more organic-lean sediments (*cf.* O'Brien *et al.*, 1990). Modified after Jarvis *et al.*, 1994, reprinted with permission of Birkhäuser Verlag.

Types of phosphate particles and concentration processes

The precipitation of CFA may produce a variety of particle types, including peloids, coated grains, laminae, and small nodules dispersed in muds. In this type of sediment, termed "pristine" phosphate by Föllmi *et al.* (1991), the primary phosphate particles appear to be *in situ*, with no reworking by mechanical or biological processes. For the most part, however, these dispersed forms have whole rock P_2O_5 concentrations well below those of economic phosphorites. Baturin (1971) accounted for this disparity by proposing a model of sea level "highstand" phosphogenesis alternating with "lowstand" reworking by currents to produce winnowed phosphorite layers in Quaternary deposits from the continental shelf of southwest Africa.

Marine phosphorites in the stratigraphic record commonly have two attributes: (1) they are grain-supported, granular concentrations of silt-, sand-, and pebble-size phosphatic grains; and (2) they occur as stratified sediment bodies that display evidence for transport and redeposition by bottom currents. The most common grains are structureless peloids, which are probably mostly authigenic rather than phosphatized biogenic fecal pellets. Other grain types may include concentrically coated grains, phosphatic intraclasts and nodules, primary phosphatic bioclasts (inarticulate brachiopods, vertebrate bones, teeth, fish scales), and phosphatized carbonate skeletal grains. The richest phosphorites have CFA cements, but granular phosphorites may also be cemented by carbonate or silica minerals.

Some stratified phosphorites have traction current structures such as cross-bedding (Glenn and Arthur, 1990), others have characteristic of turbidites and indicate deposition from gravity flows (Grimm and Föllmi, 1994), still others appear to be tempestite beds (Trappe, 1992). Many phosphorites occur in condensed intervals that contain evidence for multiple episodes of primary phosphogenesis, shallow burial, exhumation, and hydraulic reworking (Föllmi, 1989, 1990; Glenn and Arthur, 1990). Phosphatic hardgrounds are common in such condensed sections. Depositional and biological amalgamation may lead to the formation of thick (meter scale) phosphorite beds, and it appears that post-depositional burrowing may commonly destroy current induced structures in many massive phosphorite beds.

The characteristics above lead most workers to accept Baturin's (1971) notion of a two-stage mechanism (i.e., primary phosphogenesis followed by reworking) for the formation of large, granular phosphorite deposits. However, nontransported phosphorites such as hardgrounds are associated with some granular phosphorites, and only in a few cases are the primary phosphatic mudrocks, the supposed parental sediment for the redeposited phosphatic grains, clearly identifiable in the accompanying sediment layers. Moreover, the dominant types of Proterozoic phosphorites are primary phosphorite mudrocks and stromatolitic phosphorites which were clearly not transported (see papers in Cook and Shergold, 1986a).

Classification of sedimentary phosphorite rocks

Most past attempts to classify phosphorites were based on petrologic characteristics such as grain types and/or textures (e.g., Riggs, 1979; Cook and Shergold, 1986b; Slansky, 1986). More recent schemes have focused on field-based characteristics such as sedimentary structures and bedding properties. Among the most useful of these is the classification of Föllmi *et al.* (1991), who recognized three interpretive genetic categories based on relative rates of sediment accumulation and erosion (Figure P7):

- (1) *Pristine*: phosphates which lack any signs of reworking; this includes phosphatic rocks as well as more concentrated phosphorites such as phosphatized stromatolites and phosphatic hardgrounds.
- (2) *Condensed*: phosphatic particles, laminae, and beds which have been concentrated by winnowing and reworking processes or bioturbation.
- (3) *Allochthonous*: phosphatic particles that were entrained by and redeposited from turbulent or gravity-driven flows.

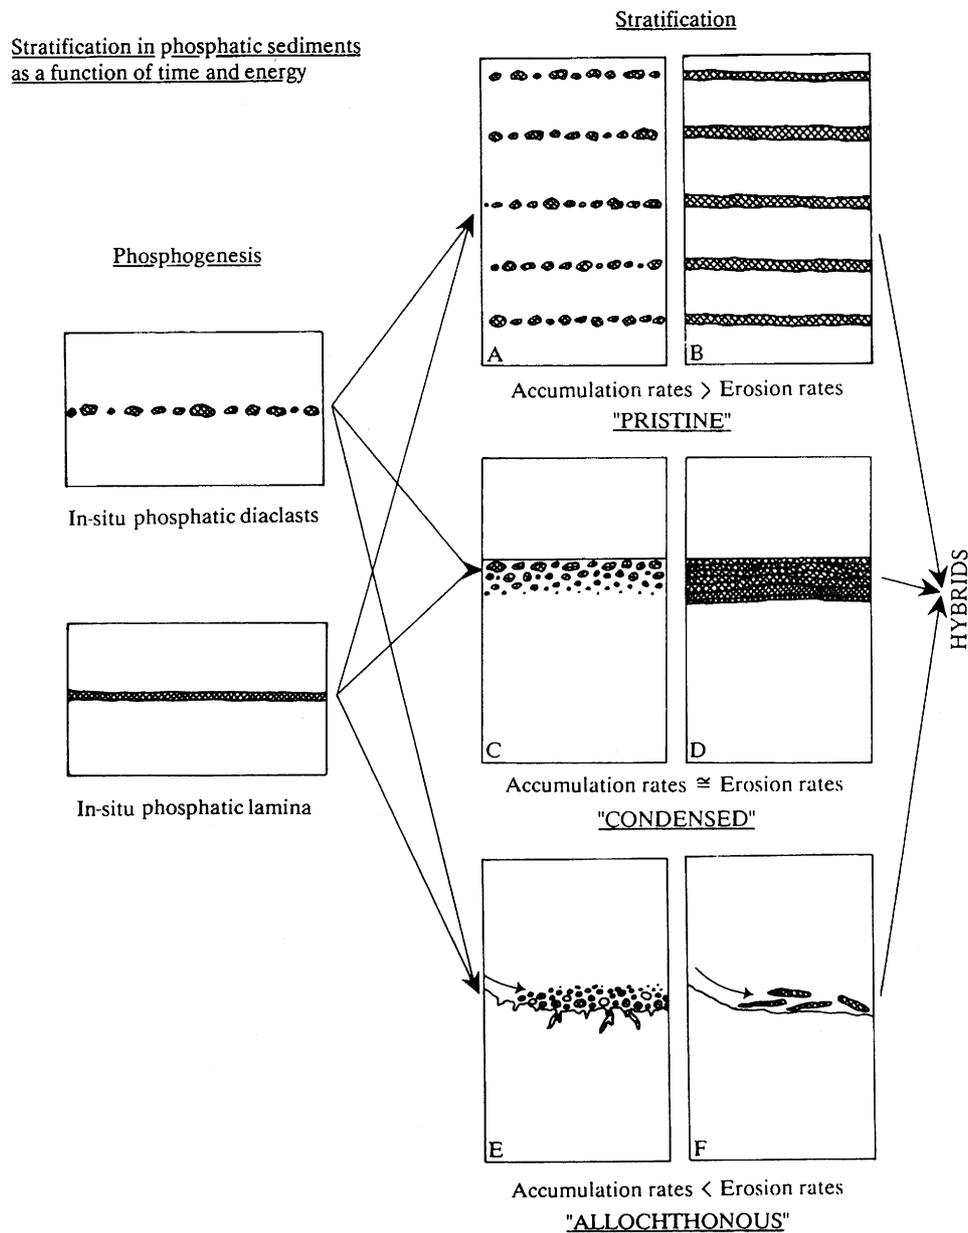

Figure P7 Genetic classification of stratification types (from Follmi *et al.*, 1991 and Glenn *et al.*, 1994a). Reprinted with the permission of Springer Verlag.

Hybrids of these categories are common. One example is that pristine phosphatic grains may experience redeposition followed by multiple episodes of burial, renewed phosphogenesis and phosphatic cementation, and subsequent erosional exhumation, resulting in a complex and laterally variable phosphorite condensed bed.

The formation of "phosphorite giants"

Very large phosphorite deposits (typically with reserves greater than 10^9 metric tons of P_2O_5) have been termed "phosphorite giants" by Glenn and Arthur (1990) and account

for a substantial proportion of world phosphate production. Examples include the Cretaceous-Eocene Tethyan deposits and the Permian Phosphoria Formation of western North America.

Kazakov (1937) made one of the first attempts to explain such deposits by invoking upwelling and inorganic precipitation of apatite from seawater in coastal regions, an idea subsequently modified to include the role of organic degradation in shallowly buried sediments, as outlined above. Most phosphorite giants were deposited beneath relatively shallow waters of marginal seas and epeiric platforms (Figure P5), and most seem to correlate in a general way with elevated sea levels

and, more specifically, with marine transgressions. The interrelated factors involved may include (Glenn *et al.*, 1994a): (1) highstands of sea level increase the potential surface area for phosphorite accumulation on shelves and in continental interiors; (2) highstands may also increase the potential for upwelling into shelf seas; (3) sediment starvation and phosphogenesis may be favored during transgressions by the trapping of diluting siliciclastic sediment in proximal parts of depositional systems; (4) wave-induced and other cross-shelf currents may develop along flooded margins and platforms, thus aiding in winnowing, reworking, and concentration of pristine CFA particles. In addition to transgressive phases, relative falls in sea level would lower wave base and may aid in reworking and concentrating such particles, in the manner proposed by Baturin (1971). The majority of phosphorite giants are of the condensed or allochthonous variety (Föllmi *et al.*, 1991).

The abundance of modern phosphorites in upwelling regions has led many workers to postulate similar settings for ancient phosphorites. Sheldon (1980), for example, subdivided large phosphorites into those associated with equatorial upwelling (e.g., the Cretaceous Tethyan deposits) and those associated with mid-latitude boundary currents and trade-wind upwelling (e.g., the Phosphoria Formation). However, the efficiency of sustained upwelling within large, shallow epeiric seas far from the open ocean, the setting for many phosphorite giants including the Tethyan deposits, has been questioned. Alternative models include the delivery of fluvial-borne P derived from intensively weathered continental regions to epeiric platforms (Glenn and Arthur, 1990).

Episodicity of phosphorite giants and the global phosphorus cycle

The distribution of phosphorite giants in the Phanerozoic is episodic, with peaks in abundance in the Early Cambrian, Ordovician, Permian, Late Cretaceous–Eocene, and Miocene (Cook and McElhinny, 1979). This has been variously explained as the consequence of favorable positions of continental margins *vis a vis* upwelling zones, equable climates, global cooling, widespread anoxia in the oceans, paleolatitude, and other conditions. However, as noted by Glenn *et al.* (1994a), none of these mechanisms provides comprehensive explanations for all phosphorite giants, each of which has its own particularities.

A related question is whether phosphorite giants record accelerated P withdrawal from the ocean into continental margin and epicontinental sediments, or whether they represent a combination of unusual and localized geological circumstances unrelated to global controls. Sheldon (1980), for example, postulated that the episodicity of marine phosphorite deposition resulted from variations in global deep-ocean circulation. A number of recent studies, however, suggest that several phosphorite giants required a net P withdrawal rate comparable to that observed in modern Perú margin sediments (*cf.* Filippelli and Delaney, 1992; Glenn *et al.*, 1994b; Compton *et al.*, 2000). Thus, if phosphorite giants of the past do indeed record episodic accelerated P withdrawal, the present day must be included among these episodes.

The global phosphorus cycle is complex and poorly understood. Phosphorus input to the ocean is mainly from rivers, secondarily from eolian phosphorus particle transport. Major oceanic sinks include organic matter, fine-grained disseminated

authigenic CFA in detrital-rich continental margin sediments, and adsorption on iron oxides formed at mid-ocean ridges and in non-upwelling continental margin sediments (Delaney, 1998). Due to variations in sedimentation rates, phosphorus accumulation rates are several orders of magnitude higher in upwelling-phosphogenic and detrital continental margin settings than in open ocean sediments (Filippelli, 1997). Present consensus holds that past variations in the phosphorus cycle were responses to changes in rates of chemical weathering, sea-level fluctuations, spreading rates of mid-ocean ridges, glaciation, and oceanic circulation. Compton *et al.* (2000) postulated that phosphorite giants most likely formed during episodes of marine transgression that coincided with increased chemical weathering rates and decreases in production of iron oxides at mid-ocean ridges and, for the last 25 million years, convincing showed that major phosphorite accumulations occurred in near-synchronicity with proposed periods of episodic uplift of the Himalayan-Tibetan Plateau. Elevated sea levels shift primary biological productivity to enlarged shallow water settings where organic phosphorus is released in sediments to form CFA. Subsequent sea level fluctuations make such sediments susceptible to reworking, generating phosphorites. Viewed in this manner, phosphorites may be a proxy for times in which phosphorus input to the oceans was greater than the sinks provided by organic carbon and iron-oxide burial.

Phosphorites, condensed sections and sequence stratigraphy

Condensed sections or sequences represent extremely slow net sedimentation over long periods of time. Such intervals have been long recognized as characterized by the following features: (1) enrichment of well preserved fossils and fossil fragments; (2) faunal mixing, fossils from different paleontological zones within a single bed; and (3) widespread distribution of sediments with negligible thicknesses. In addition, it has become increasingly recognized that intervals of stratigraphic condensation are also frequently marked by the occurrence of authigenic minerals, including phosphorites and glauconites. With the advent of “sequence stratigraphy,” condensed sections have taken on new significance as an integral component in the stratigraphic architecture of sequences controlled by fluctuations in relative sea level. Loutit *et al.* (1988) and their colleagues define condensed sections in light of sequence stratigraphy as thin marine units of pelagic to hemipelagic sediments that: (1) are characterized by very low sedimentation rates that are areally most extensive at the time of maximum transgression and coincident with the surface of maximum flooding; (2) are associated with apparent marine hiatuses; and (3) occur as omission surfaces or marine hardgrounds. They result from sediment starvation during times of maximum rates of sea level rise. These occur along the break separating transgressive and highstand systems tracts (Figure P8). Assuming that seismic reflectors reflect time-lines, sequence condensation may, hypothetically, also occur anywhere that reflectors converge such as, for example, along surfaces of onlap, backstepping, downlap and toplap (Kidwell, 1991; Figure P8). In addition, while phosphorites may be generally associated with transgressive phases of second and third orders changes of sea level (5–50 and 0.5–5 Ma, respectively), much reworking of these may occur during intervening higher orders of sea level change (fourth, fifth, and sixth order; 0.1–0.5, 0.01–0.1, and <0.01 Ma, respectively).

However, as noted above, most major episodes of phosphorite genesis do appear to be related to transgressive phases, although the occurrence of reworked deposits within the upper portions of highstand systems tracts may also reflect episodes of condensation and bypassing that occur in association with the convergence of toplapping seismic reflectors (Figure P8). In sum, the actual distribution of condensed deposits within seismic sequences is probably more complex than depicted by recent models.

Other types of phosphorite deposits

In addition to phosphorites formed in continental margin or epeiric sea environments (Figure P5), lesser quantities of phosphorites occur in three other settings:

(1) *Island or insular phosphorites* are commonly composed of guano and the replacement products of reactions between bird droppings and the underlying host rock; the latter is commonly a carbonate, and these types of phosphorites are important economic resources on Quaternary carbonate islands in the Pacific and Indian Oceans. The largest deposits of this kind occur on the island of Nauru in the western equatorial Pacific (Piper *et al.*, 1990). As noted by Glenn *et al.* (1994a), not all island phosphorites are

associated with guano, and some may have precipitated in insular marine lakes or other settings.

(2) *Seamount and Guyot phosphorites* and phosphatized limestones, many associated with iron-manganese encrustations, are common on elevated portions of the seafloor in all the world's oceans. Although a few are submerged insular deposits, most appear to be of marine origin and formed in areas of slow sedimentation and a pronounced oxygen minimum zone. Burnett *et al.* (1987) suggested they formed preferentially at low latitudes, possibly in equatorial upwelling regions of high productivity. They linked the association of iron-manganese crusts to the enhanced concentration of phosphate and metals within an oxygen minimum zone that bathes the upper parts of seamounts.

(3) *Igneous rocks* such as carbonatites and other alkaline igneous intrusive complexes which are enriched in fluorapatite, $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$ (Slansky, 1986). Important economic deposits of this kind occur in northern Russia, Brazil, and eastern and southern Africa (Cook, 1984).

Environmental issues connected to phosphorites

Along with rises in world populations and living standards, exploitation of phosphorites as a source of fertilizers will inevitably also increase. This may be accompanied by several

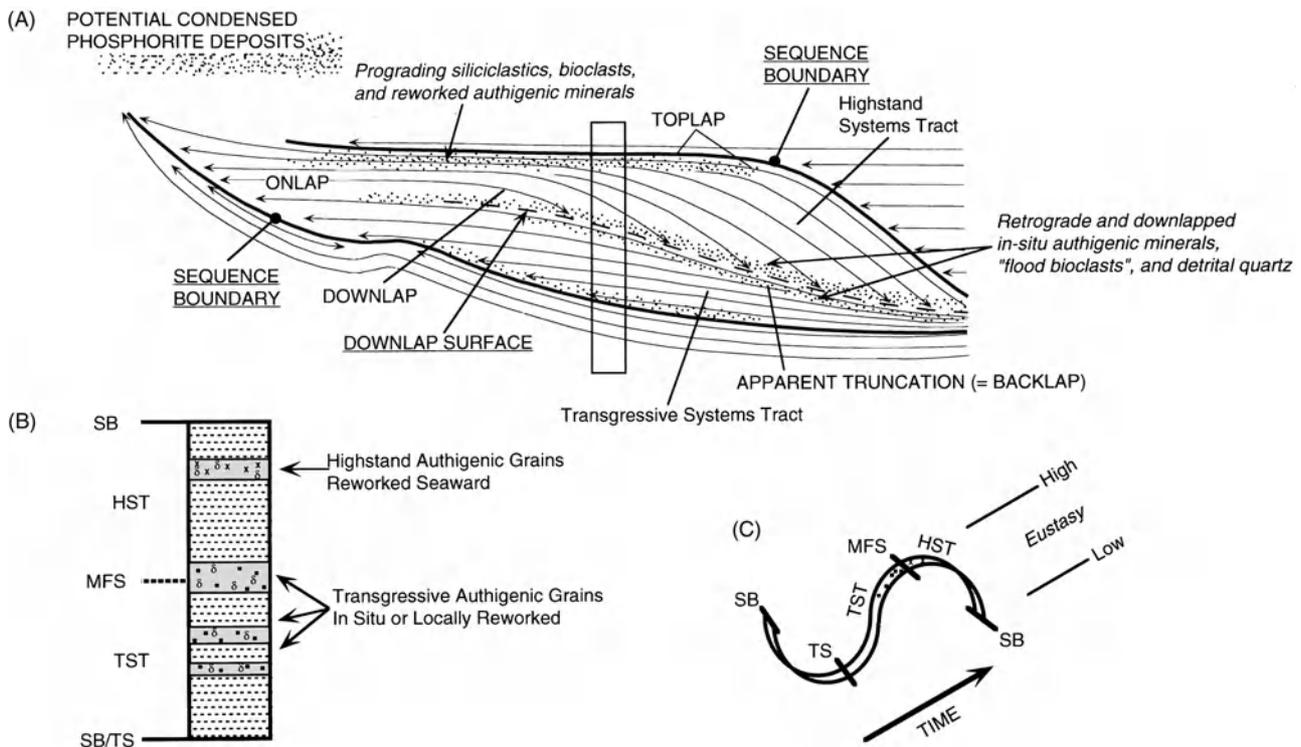

Figure P8 Potential relationships between sequence stratigraphy, condensed sections and phosphorites. (A) Possible positions of sequence condensation within an idealized depositional sequence (stipples), (after Kidwell, 1991). (B) Schematic illustration of the placement of non-reworked pristine authigenic phosphorite (and/or glauconite) and reworked phosphorite (and/or glauconite). Pristine phosphates may form within transgressive systems tracts and at the maximum flooding surface, whereas later phases are reworked seaward within highstand systems tracts. (C) The timing of systems tracts development with respect to one cycle of sea level change. LST lowstand systems tract, TST transgressive systems tract, HST highstand systems tract, TS transgressive surface, MFS maximum flooding surface, SB sequence boundary. Dots on the sea level curve represent locations of maximum phosphorite emplacement. (After Glenn *et al.*, 1994a, reprinted with permission of Birkhäuser Verlag AG).

environmental problems (see Jarvis *et al.*, 1994), among which three are especially significant:

- (1) *Mining and processing*: most phosphorites are extracted from open-pit mines with their attendant problems of landscape disruption and disposal of mine tailings. In addition, beneficiation processes commonly produce phosphatic “waste clays” which are extremely fine-grained and have poor settling properties, hence may need decades to settle and thus require numerous settling ponds covering large areas.
- (2) *Phosphogypsum*: phosphogypsum is a by-product of the conversion, using sulfuric acid, of phosphorite ore to phosphoric acid, an intermediate compound in the manufacture of phosphatic fertilizers. The amount of phosphogypsum produced is substantial. Jarvis *et al.* (1994) estimate worldwide annual production on the order of 100 metric Mt. Although this form of gypsum has commercial applications in many parts of the world, governmental regulations in the USA prevent its usage, in part due to an association with radionuclides (apparently in a separate phase) in the ^{238}U decay chain, especially radon. Stockpiling of this material is thus necessary, leading in turn to potential problems of air and water contamination in the vicinity of the stockpiles.
- (3) *Trace elements*: many phosphorites contain small but significant amounts of potentially toxic elements (e.g., cadmium, selenium, arsenic) or radionuclides, particularly uranium. The possibility thus exists that harmful amounts of these elements could be released into the environment during the processing of phosphorite ore or the application of fertilizers produced from phosphorites.

Summary

Phosphorites are unique sedimentary deposits that have piqued the interest of academicians and economic geologists for decades. Due to their high phosphorus content, they are the world's most important economic resource of elemental phosphorus and thus are an essential additive for fertilizers and phosphate-based chemicals. The most common phosphate-bearing mineral in the majority of phosphorites punctuating the geologic record is carbonate fluorapatite (CFA), which has an abbreviated chemical formula of formula $\text{Ca}_{10}[(\text{PO}_4)_{6-x}(\text{CO}_3)_x]\text{F}_{2+x}$, but actually also contains numerous substitutions of both cations and anions. Field observations plus isotopic and pore water studies of modern marine phosphorite occurrences demonstrate that most form initially as “pristine,” nonreworked deposits during early diagenesis within the upper few tens of centimeters beneath the seafloor. Most occur beneath strong upwelling systems which provide a high delivery rate of phosphorus-bearing sedimentary organic matter to the seafloor; this material is subsequently broken down by microbial degradation processes in pore waters. Many are then in turn “upgraded” to what are termed “condensed” or “allochthonous” phosphorites by processes such as sediment winnowing and reworking, largely by bottom currents. Most ancient examples of these deposits thus usually occur as stratified granular phosphorites containing admixtures of silt to very large sand-sized phosphatic grains, the most common cements of which are silica or carbonate minerals. Concretionary and hardground phosphorites also occur in both modern and ancient deposits. Additionally, there

is evidence that phosphorus may also be delivered to the sites of phosphogenesis by a redox cycle whereby phosphorus sorbed to iron oxyhydroxides is released as soluble reactive P in suboxic pore waters and thus becomes available for solid phase fixation into the CFA compound. Very large phosphorite deposits, termed “phosphorite giants,” occur episodically throughout the Phanerozoic during discrete time periods. Most were deposited on oceanic slopes and shelves and in epeiric seaways. In addition, phosphatic sediments are also found on oceanic islands and atop seamounts, guyots and submarine plateaus. Present consensus holds that past variations in the phosphorus cycle and phosphorite output of the oceans were responses to a variety of factors including sea-level fluctuations, changes in rates of continental chemical weathering, shifts in the paleolatitudes of continental margins and in positions of coastal upwelling zones, and in patterns of oceanic circulation.

PHYSICS OF SEDIMENT TRANSPORT: THE CONTRIBUTIONS OF R. A. BAGNOLD

During the twentieth century a huge amount of time, money and research effort was expended in attempting to develop accurate and reliable models of sediment transport by wind and water. Amongst the numerous significant contributions that resulted, that of R. A. Bagnold is characterized particularly by his appreciation of the pivotal importance and great usefulness of fundamental physics in describing and defining sediment transport mechanisms and processes.

It was as an officer in the British Army, stationed in Egypt and India between 1926 and 1932, that Bagnold's fascination with sediment movement began. Bagnold and a small group of like-minded officers began exploring the Libyan Sand Sea using Model T Ford motor cars. Early forays quickly evolved into serious geographical exploration and the group were responsible for mapping an area of desert the size of India, work that earned Bagnold the Gold Medal of the Royal Geographical Society in 1934.

During these expeditions Bagnold became fascinated by the movement of sand by wind and he wished to understand the physics of the processes responsible for the formation of desert dunes. Bagnold was astonished and appalled to find that no theory of dune formation existed and that no serious scientific investigation of the movement of sand by wind had at that time been performed. He decided that, despite having no formal training in research and no higher degree, he would retire from the army and devote all of his time and energy to the study of wind blown sands.

After making preliminary measurements of the physical properties of desert sands and the near-boundary wind speeds, Bagnold built himself a wind tunnel with glass sides, for easy observation and photography, within which to perform controlled experiments. He used high-speed cinematic photography (then in its infancy) to observe and trace the entrainment of individual sand grains. His results showed that detaching grains left their pockets at very steep angles, proving that lift forces were of equal importance to drag forces in detaching grains. His movie-films demonstrated that entrained sand grains move along ballistic trajectories, unaffected by turbulence—a motion he described as “a series of bounds”, and that moving grains dislodge further grains when they bounce—a process later described as saltation. Bagnold compared the hopping distance of saltating grains to the crest to crest spacing of ripples formed in the sand surface, concluding that,

“The length of the characteristic path from impact to impact was found in all experiments to be the same as the measured wavelengths of the ripples formed on the surface” (Bagnold, 1936, p.23).

These early experiments further established that, not only does the rate of sand transport vary with the cube of the wind speed, but also the presence of moving sand itself generates drag that affects the velocity profile in a transport-limiting mechanism (Bagnold, 1936).

Having obtained controlled data elucidating the transport process, Bagnold returned to the field to check his results against reality. After spending eight days alone in the desert waiting for a sandstorm, he obtained reliable measurements

that confirmed the wind-tunnel results. He was also able to apply his understanding of the saltation process to explain why sand moving over a rocky plain becomes size sorted and tends to collect into patches. Patches occur because grains moving over a bare rock surface bounce very efficiently, maintaining motion, while the grain–grain collisions of a grain moving over a sand surface sap energy from the moving grain, tending to damp transport so that sand accumulates in a patch.

The complete results of his research on sand transport by wind during the 1930s were published in *The Physics of Blown Sand and Desert Dunes* (Bagnold, 1941), a book that has been reprinted many times and which remains a standard text.

In 1937, Bagnold was persuaded to perform experiments on the shock pressures generated by waves breaking against a sea wall (Bagnold, 1939, 1940), but characteristically, he took the opportunity to extend this work to the inter-action of waves in shallow water with a mobile sand bed. This line of research was interrupted by World War II, but resumed and published immediately afterward (Bagnold, 1946, 1947). From his wave-tank experiments, Bagnold was able to explain the formation of rolling-grain ripples under oscillatory flow, their evolution into vortex ripples and the occurrence of “brick pattern” ripples under certain conditions. He further related ripple formation to increased drag on the moving water and produced a simple expression for the first disturbance of a planar sand bed by oscillatory water motion.

Recalled to the army at the outbreak of World War II, Bagnold returned to Cairo and used the results of his desert exploration and mapping expeditions to persuade General Wavell that a real threat existed of an Italian raid on the Aswan dam from a base deep within the Libyan Desert. Commissioned to establish the Long Range Desert Group (LRDG), identify any threat and nullify it, Bagnold then performed what may be the quintessential example of application of sedimentology to warfare. He used his knowledge of the physics of wind blown sands and the morphology of desert dunes to take LRDG vehicles deep behind enemy lines, scouting and reporting troop movements, mapping enemy positions, collecting intelligence and creating havoc through lightening raids on forts, convoys and airfields. When enemy forces attempted to follow and track down the LRDG they quickly became stuck in the soft sand of dune troughs (Bagnold knew that you must drive over the “accretion deposits” of the dune crest) or got hopelessly lost in the maze of sand dunes. Without Bagnold's grasp of sedimentology and geomorphology, pursuit was impossible. The formation and leadership of the LRDG uniquely combined Bagnold's talents as a scientist and soldier and must rank as one of his most noteworthy achievements. A contemporary account of the exploits of the LRDG may be found in Bagnold (1945) while for a longer term perspective readers should consult his autobiography (Bagnold, 1990).

Bagnold again retired from the army in 1944 and, after a period as Director of Research for Shell, during which he was instrumental in the establishment of the Hydraulics Research Station at Wallingford, England, he again decided to pursue fundamental research full time.

Bagnold's post-war work focused on the movement of sediment by water. His approach rested on the application of theory to identify key variables and formulate relationships between them, supported by carefully conceived and executed experiments to quantify physical constants and material

properties. The conception and construction of experimental apparatus and instrumentation continued to be incidental to his work, but stemmed from a Bagnold family tradition that, “a properly equipped workbench was as important to study as was a well stocked library”.

He began by conceiving a series of fundamental experiments on the physics of sediment movement conducted in a rotating-drum test rig he himself designed, to quantify the physics of the gravity-free dispersion of large, solid spheres in a Newtonian fluid (Bagnold, 1954). He demonstrated that collisions between suspended solids generate a “dispersive pressure” on the boundary resisting further dispersion. This experiment established for the first time that the coefficient of solid-to-solid friction for sheared dispersion of granular solids is virtually the same as for the same solids in continuous contact—a piece of knowledge that lies at the heart of practically every sediment transport equation in common usage today. A further discovery of some portent was summed up eloquently by Bagnold himself in his autobiography,

“The rate of mass transport of an immersed weight of solids is easily measured, in the laboratory at least. And the fluid shear stress times the velocity of its action is the rate at which the fluid does transporting work. So I now saw clearly that the transport rate of solids must depend primarily on a rate of fluid energy supply, or, in other words on *stream power* and not as previously thought, on either stream velocity or bed shear stress, but the product of the two. This, I felt, began to put the subject of solids transport by water flows on a sound footing.” (Bagnold, 1990, pp. 163–164). In 1956 Bagnold was approached by Luna B. Leopold, then Head of the Water Resources Division of the United States Geological Survey to “help stir the pool of complacent tradition with the stick of reality” concerning sediment transport. The first area of co-operative research concerned river meandering (Leopold, *et al.*, 1960; Bagnold, 1960). Bagnold and his co-workers challenged the “square-law” then generally accepted as governing flow resistance in alluvial rivers. The “square law” argued that flow resistance should increase with the square of the mean velocity because this was known to be the case for simple boundary layer flow past a flat plate, provided that boundary conditions remain unchanged. Their results showed that, while the square law holds for straight channels, deformation of the water surface due to transverse deflections of all or part of the flow in meandering rivers could lead to a doubling of the rate at which resistance increases with the square of the velocity (Leopold *et al.*, 1960). Further theoretical analysis, coupled with carefully designed experiments, demonstrated that energy losses at bends were minimized for ratios of bend radius to width between 2 and 3. A great deal of subsequent empirical research has demonstrated that natural meanders do, in fact, tend to evolve to a bend ratio to width ratios in this range (Hickin and Nanson, 1984).

Another Anglo-American research initiative, with Douglas Inman of Scripps Oceanographic Institute, led to Bagnold’s main contribution to the understanding of beach and near-shore sedimentation. Application of knowledge gained through earlier studies of wave mechanics, the transport of grains by fluids, the movement of sand by waves and the concept of stream power was employed to construct a comprehensive explanation of on-shore and long-shore sediment dynamics in the littoral zone (Inman and Bagnold, 1963). Embedded within this treatise were a power-based sediment transport equation for waves, a theoretical explanation of the

mechanics of auto-suspension in off-shore turbidity currents, a theoretically-based explanation of the equilibrium beach-profile, and a power-based model for the transport of sand by long-shore currents.

It was in the realm of sediment transport by rivers that Bagnold’s final and possibly most lasting contribution was made. Adopting an approach to the sediment transport problem based in general physics, he was able to attribute the suspension of granular material in a fluid shear flow to the effect of anisotropic turbulence creating an upward supporting stress (Bagnold, 1966). He went on to differentiate definitively between suspended and bed-load components of the total load, recognizing that the immersed weight of the suspended load is supported by turbulence, while the immersed weight of bed-load is supported by (intermittent) solid–solid contact with the bed. This explained why bed-load can therefore occur even under laminar flow, in the complete absence of turbulence while suspension cannot (Bagnold, 1973).

Discovery of the difference between the physics of suspended and bed loads allowed Bagnold to derive sediment transport equations for each process from a fundamentally sound basis (Bagnold, 1973; 1980). It is perhaps his bed-load equation which has proven the most useful in practical applications and this equation remains in widespread use, especially in the UK. His use of stream power has also been replicated in several of the most popular sediment transport equations used in North America (see, e.g., Yang, 1976 and Chang, 1988).

Advances in fluid mechanics, turbulence theory and the sophistication of instrumentation in the late twentieth have supported new findings that, to varying degrees replaced some of Bagnold’s interpretations, which were necessary based on incomplete knowledge of the nature of turbulent flow structures. However, his contribution to sedimentology lies not only in the original knowledge and useful sediment transport equations that he crafted—both certain to be superseded with the passage of time, but also in his exemplary approach to conducting basic research in this difficult and often frustrating field of enquiry. In sum, his contributions to science and engineering must place him in the first rank of twentieth century researchers in sedimentology and sediment transport.

PILLAR STRUCTURE

Vertical water-escape channels, variously termed pillar structures, elutriation pipes, elutriation columns, fluidization pipes, fluidization channels, tube dewatering structures, and water-escape sheets, are elongated vertical to subvertical zones of sediment that are usually lighter-colored and contain less clay, mica, organic detritus, and other hydraulically mobile grains than surrounding sediments (Figure P9). They form through localized fluidization of sediment along discrete subvertical zones and accompanying elutriation of fine-grained components during either post- or syndepositional water escape. They are frequently associated with dish structures (see *Dish Structure*, figure D26).

The term “pillar structure” was introduced by Wentworth (1966) from studies of turbidites in western California. He interpreted the “pillars” as vertical fluid-escape channels. Similar structures had been previously described in fluvial deposits of the Old Red Sandstone by Allen (1961). Vertical water-escape channels have also been described from

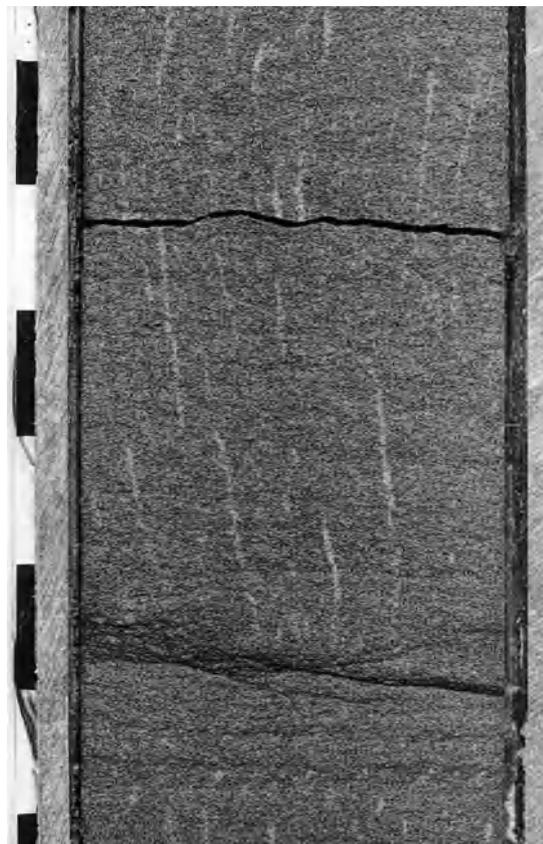

Figure P9 Small subvertical pillar structures (light-colored streaks) in crudely layered muddy sandstone deposited by a sediment gravity flow. Pillars mark sheet-like zones from which darker, argillaceous and organic grains have been removed by water escape. Lower Cretaceous Britannia Formation, North Sea. Scale on left in tenths of a foot (3 cm units).

volcaniclastic mud flows (Best, 1989). Lowe and LoPiccolo (1974) discussed pillar structures associated with dish structures, and Lowe (1975) provided a broader classification and discussion of vertical fluid-escape channels. The formation of these structures has been studied experimentally by Nichols *et al.* (1994) and Druitt (1995).

Vertical water-escape channels occur in sediments ranging from coarse silt to pebbly sand or, more rarely, fine gravel, usually in discrete beds at least a few decimeters thick. Although they were initially thought to have pillar- or column-like geometries, based largely on two-dimensional exposures, most vertical water-escape channels are isolated to anastomosing subvertical sheets. The widths of individual sheets or pillars range from about a millimeter to a few centimeters with heights ranging from a few millimeters to more than a meter. When sediment is moved over significant distances from one bed to others, the terms “sediment intrusion” or “dike” should be used. Subvertical sediment intrusions can be up to several tens of meters high, and their formation is related both to water escape and density instabilities. In most cases, however, water-escape through vertical channels or conduits involves only local fluidization and restricted sediment movement.

Sediment in water-escape channels (pillar structures) is usually homogenized and the margins of the channels may cut sharply across primary sedimentary structures in surrounding sediments.

Localized fluidization can take place during either rapid sedimentation or post-depositional dewatering. Druitt (1995) investigated experimentally the formation of “elutriation pipes” during sedimentation of poorly sorted aqueous dispersions. He observed that at concentrations of 25–55 percent solids vertical water-escape channels propagated upward at the same rate as the depositional surface. A strong upflow of escaping fluid above each escape channel depleted the settling dispersion in fines and resulted in the upward propagation of the stable water-escape channel. At higher concentrations the water-escape channels nucleated throughout the dense dispersion. This behavior resembles the aggregative behavior and self-organized segregation of particles in sedimenting bidisperse systems that lead to the formation of streaming columns and blobs (Weiland *et al.*, 1984; Batchelor and Van Rensburg, 1986).

Mud-rich deep-water sediment gravity flow deposits called slurry beds (Lowe and Guy, 2000) often contain a variety of vertical water-escape channels that appear to develop during the dewatering of sediments possessing strength. Some channels are a few centimeters long and develop in sets with individual pillars spaced 1–2 cm apart (“stress pillars” of Lowe, 1975). They might have formed through a process similar to convective streaming (Weiland *et al.*, 1984). Others occur as sets of small columns, 1–2 mm wide and 1–25 cm long (Figure P9). The wide range of rheological properties, particle densities, and hydraulic sizes in such sediments favors formation of a wide variety of water-escape structures.

PLACERS, FLUVIAL

Fluvial placer deposits form when mechanical sorting causes concentration of heavy minerals of economic interest. The heavy minerals must be chemically stable to survive so placers usually consist of native metals such as gold (SG 15–19) and the platinum group (14–21); resistate minerals, for example, cassiterite (~7), chromite (4–5), ilmenite (4.5–5), rutile (4.2), magnetite (5.2), zircon (4.7); and, diamonds (3.5) and other gemstones. Placer deposits can be of considerable economic importance—for example, the tin (cassiterite) deposits of South East Asia (Taylor, 1986) and the gold paleoplacers of the Witwatersrand (Smith and Minter, 1980).

Small accumulations of heavy minerals can form as planar laminae (Ljunggren and Sundborg, 1968); thin ripples on the upstream slopes of dunes (Brady and Jobson, 1973); or develop on topsets and foresets of dunes (Brady and Jobson, 1973). At intermediate scales heavy minerals accumulate at bar heads (Hanson, 1979; Day and Fletcher, 1991); in zones of flow separation in the wake of obstacles and at channel confluences (Best and Brayshaw, 1985); or where a channel narrows and flow is constricted (Smith and Beukes, 1983; Paopongsawan and Fletcher, 1993).

Cumulative concentration of heavy minerals at small to intermediate scales can upgrade average concentrations in fluvial sediments so they become greater than in their source materials and continue to increase as drainage basin size increases (Fletcher and Muda, 1999; Halfpenny and Mazzucchelli, 1999). Weathering in the humid tropics is probably especially favorable to this insofar as large volumes of bedrock are converted to fine grained weathering products that are easily removed in suspension to leave a coarse bed-load enriched in resistate heavy minerals (Sirinawin *et al.*, 1987). Provided sediment continues to be preferentially transported, changes in stream gradient (Toh, 1978; Day and Fletcher, 1991; Hou and Fletcher, 1996) are often sites of accumulation of heavy minerals within fluvial systems. Exits of rivers from highlands onto plains can be particularly favorable for placers if the upstream basin contains an extensive source of heavy minerals (Toh, 1978).

Placers form because the density of heavy minerals causes them to lag behind similarly sized grains of light minerals during entrainment, suspension and transport of grains, and to settle, by dispersive shearing, within a moving bed (Slingerland, 1984; Reid and Frostick, 1985; Slingerland and Smith, 1986; Fletcher and Loh, 1997). However, grain size of the heavy mineral, and the roughness and nature of the streambed voids are also important factors in their accumulation. For example, cobble-gravels at the heads of point bars have greater accumulations of coarse heavies than sands at bar tails but the difference in concentration between these sites decreases

with decreasing grain size of the heavy mineral (Saxby and Fletcher, 1986; Fletcher and Day, 1989). At larger scales coarse heavy minerals form placers closest to the source whereas finer heavy minerals tend to accumulate further downstream (Toh, 1978).

The association of fine heavies with coarser sediments leads to the concepts of *hydraulic (or settling) equivalence*, *entrainment equivalence*, and *transport equivalence*. *Hydraulic equivalence*, introduced by Rubey (1933), describes particles of different densities and size that settle through a column of fluid at the same velocity, whereas *entrainment equivalence* considers grains of light and heavy minerals that are entrained together at the same critical shear stress Slingerland (1977). *Transport equivalence*, as defined by Fletcher *et al.* (1992), refers to those grains that, despite differences in their physical properties, have the same net average transport rate.

Sorting, transport and grain size equivalence of mineral grains can only be described quantitatively by theories of grain settling, pivoting and entrainment under idealized conditions (see Slingerland, 1984; Slingerland and Smith, 1986; Fletcher and Loh, 1997). Transport of grains of different sizes and densities by unsteady, nonuniform turbulent flows acting on non-uniform streambeds cannot, as yet, be predicted quantitatively. Field observations show that fluvial processes concentrate heavy mineral grains that are small enough to hide in the bed ($d_i/D_m < 0.2$, where d_i and D_m are grain diameter and the median diameter of the bed, respectively). For grain sizes finer than about 100 μm concentration of heavy minerals in bed-load is increased by transfer of fine sand, silt and clay to suspended load at the early stages of sediment transport (Fletcher and Loh, 1997).

Preferential entrainment of light mineral grains becomes less effective as a concentration process as the size of the heavies approaches the upper limit of hiding ($d_i/D_m \sim 0.2$) and their exposure to the flow and the probability of their entrainment increases. However, as flows increase scouring of the bed releases buried heavy minerals and a wide range of grain sizes and densities are mobilized. As discharge falls, and the bed is re-established, coarse heavy minerals are among the first to be trapped at favorable sites such as the voids at bar heads. At the same time fine heavies travelling higher in the flow partly overpass trap sites and develop less spatial variation in concentration on the stream bed (Fletcher and Wolcott, 1991).

Improved understanding of fluvial placer deposits, and hence development of improved exploration guidelines for economic placers, requires more detailed descriptions of their characteristics, at grain to system scales, and the use of these observations to test and refine theories of sediment transport and grain sorting in fluvial channels.

Heavy Minerals
Sediment Transport by Unidirectional Water Flows

PLACERS, MARINE

Introduction

A placer can be defined as a surficial mineral deposit formed by the mechanical concentration of mineral particles from weathered debris (Bates and Jackson, 1984). Marine placers are mostly metallic minerals or gems which have been transported to the seafloor in a solid form. They are mainly mechanically and chemically resistant minerals which have been liberated on breakdown of their parent rocks. Such rocks are usually igneous in origin but metamorphic and sedimentary rock can also liberate placer minerals on breakdown. Marine placers occur almost entirely in shallow continental shelf environments.

Nature of marine placer minerals

Marine placer minerals can be classified by composition (Table P1) or in terms of their specific gravity. Emery and Noakes (1968) defined heavy heavy minerals as those with specific gravities of 6.8–21, light heavy minerals as those with specific gravities of 4.2–5.3, and gems with specific gravities from 2.9–4.1. The heavy heavy minerals include native gold and platinum and the tin bearing placer cassiterite, light heavy minerals generally comprise the resistant accessory minerals of igneous rock and include monazite, zircon, ilmenite and rutile

as important varieties together with magnetite. The most important gem placer mineral is diamond.

Formation of marine placer deposits

The formation of marine placer mineral deposits requires several separate processes. There must be a large primary source of minerals. For this reason major marine placer deposits are much more common off continental margins than off islands because the latter are rarely large enough to contain sufficient source rock. Resistant accessory minerals are liberated on source rock weathering and are released for transport. Chemical weathering is more important than mechanical weathering in this regard, which is one of the reasons why beach and marine placer mineral deposits are more common off mid and low latitude coastal areas than they are off high latitude areas. Mechanical weathering predominates in the latter. Transport of the placer minerals is largely by water, during which the less resistant minerals are separated from the heavier more resistant ones. On reaching the coast, placer minerals are usually concentrated in sinks or traps because of their high specific gravity, or concentrated on the upper parts of beaches by wave action, sometimes leading to a concentration of the deposits to economic grades.

The depositional environments of marine placer minerals have been reviewed in Cronan (1980, 2000) and need not be considered in detail here. In the offshore area, placer minerals can occur in several situations (Figure P10). It should be remembered however that some of the placer mineral deposits currently offshore were formed in river valleys which subsequently became inundated during the post glacial rise in sea level. Certain deposits of cassiterite, scheelite, gold and platinum fall into this category (Cronan, 1992). Further, many placer minerals have been deposited on beaches near the mouths of the rivers down which the minerals were transported and

Table P1 Principal placer minerals and their composition (from Cronan, 1992)

	Specific gravity	Composition and principal element
<i>Gems</i>		
Diamond	3.5	C
Garnet	3.5–4.27	(CaMgFeMn) ₃ (FeAlCrTi) ₂ (SiO ₄) ₃
Ruby	3.9–4.1	Al ₂ O ₃

have subsequently been concentrated in coastal dunes by wind action. Placer minerals transported from the land into the sea can be further transported by wave and current action, but when the energy level of the environment decreases to below that at which the minerals can be transported, they are deposited on the seafloor. Once deposited, a significantly higher energy level is required to pick them up again. For example, Hosking and Ong (1963) noted that off North Cornwall in the UK free cassiterite grains tend to be concentrated in elongate zones below low water and parallel to the coast. Further, Moore and Welkie (1976) have suggested that very fine grained gold and platinum placer deposits can occur in quiet bays and protected estuaries off Alaska. Initially supplied to the offshore area under higher energy conditions, their distribution would be related to circulation gyres of slackening currents within protected embayments, coupled with agglomeration of particles on contact with electrolytes in seawater.

Marine placer mineral deposit types

Light heavy minerals

Certain light heavy minerals, particularly rutile, ilmenite, magnetite, monazite, zircon, sillimanite, and garnet can be concentrated by the huge panning system of sandy beaches (Kudrass, 2000). In the surf zone, various processes tend to separate minerals according to their density, size, and shape. Heavy minerals are concentrated by the combination of these processes in the upper part of the beach where wind may erode them and form heavy mineral rich coastal dune deposits. According to Kudrass (2000), with rising sea level, the amount of sand stored on the beach and shelf, the intensity of long shore currents, the wind direction and wave energy, and the morphology and width of the shelf are all parameters determining the dispersal of heavy mineral bearing sand during marine transgression. In the case of large sand volumes, and a wide gently sloping shelf, the transgressing sea cannot move the total amount of sand stored in the coastal system. The transgression then results in an extensive mixture of the available mobile beach sand and dune placer deposits, and the latter become widely distributed and disseminated. The ilmenite–rutile–zircon placer deposit on the middle shelf off northern Mozambique, which is related to the Zambezi River, is one example of this type of disseminated placer deposit.

Where there are moderate to low volumes of heavy mineral bearing sand stored in the coastal system, and a narrow steep shelf, the transgressing sea moves the deposits by storm washover processes (Kudrass, 2000). Due to the vertical

differentiation of heavy mineral assemblages, some heavy minerals are preferentially concentrated in the landward migrating sand while others are predominantly left behind in the trailing sand sheet covering the transgressed shelf. The sand arriving at the coastline undergoes further differentiation in the surf zone, which leads to the formation of important beach and dune placer deposits, such as those on the south-east coast of Australia.

Tin

As mentioned, drowned river valleys can contain alluvial placer mineral deposits, as for example in the tin deposits off south east Asia. Often in these situations the placer minerals are at the bottom of the sediment column overlying bedrock. In the formation of giant tin deposits on continental shelves, the drowning of old river systems is recognized to be the most important genetic process by far (Yim, 2000). Thus the bulk of the economic tin deposits occurring on continental shelves were formed under subaerial conditions prior to submergence below sea level. Consequently, in terms of understanding the geology of tin placer deposits on continental shelves, it is essential to learn from their comparatively well studied onshore counterparts (Yim, 2000).

Gold

According to Garnett (2000a), the simplest form of offshore gold concentration is, like tin, in a buried fluvial channel which is usually covered by recent transgressive marine sediments. The highest gold grades are usually at the base of the alluvial sequence resting on the bedrock. Examples exist in the Philippines and other areas where tropical and subtropical weathering has eroded coastal primary gold deposits.

In Arctic regions, gold bearing source rocks have been subjected to massive weathering and grain reduction by glaciation. The resulting sediments containing liberated gold have been transported by glacial and fluvial processes to be distributed over relatively large regions. Particulate gold was then further transported by marine processes (Garnett, 2000a). Marine gold deposits of such origin occur off Alaska, southern Chile and Argentina, New Zealand, and elsewhere. Because of its high density, gold is less mobile than other heavy minerals of equal particle size. Only very fine particles travel far under marine conditions. Most economic concentrations of placer gold are thus rarely situated more than a few kilometers from the site of the original accumulation.

The most important marine placer gold deposit is that off Nome, Alaska. According to Garnett (2000a) all writers attribute the spatial distribution of gold in the sediments covering the coastal plain there to glacial events combined with marine transgression and regression. During the Pleistocene glaciation of the region, changing sea levels caused the Bering Sea to intermittently become a coastal plain. Primary gold was released from hard rock sources by extreme frost action to be deposited in down slope alluvial sediments and in fluvial channels which were incised into the coastal plain. These deposits were later swept up together with eroded bedrock by advancing glaciers. Later, as sea level rose, the topography was molded, levelled and partially eroded. The high storm energy, especially in the surf zone and shallow waters, reworked the sediments. Marine invasion alternating with retreat of the sea acted on the exposed glacial deposits, leaving relict thin

gold-bearing layers on the seafloor. Sediment-hosted gold exposed on the seabed was then upgraded by the winnowing action of marine currents to create a lag deposit.

Diamonds

The principal gem placer minerals occurring in the offshore environment are diamonds. These were discovered in south-west Africa in raised beach sands in 1908 (Murray, 1969), the diamond bearing beds extending down to the coast and offshore. The diamonds were derived from kimberlites in the interior and had been transported to the coast by fluvial processes. According to Garnett (2000b), longshore currents combined with high energy wind and wave action during periods of considerable sea-level change concentrated the diamonds in trap sites on paleo coastlines and other marine geological features. The host gravels generally exist as a thin veneer on an irregular bedrock. Discontinuous deposits lie on the inner and middle sections of the continental shelf along the South African and Namibian coastlines.

Diamondiferous deposits on the inner shelf off southern Africa are similar to those onshore. With a density of 3.5 g/cm³ diamond is the lightest of the economic placer minerals. Thus it travels farther than gold and heavy placer minerals. According to Garnett (2000b), the diamonds were redistributed from paleo river mouths along the coast and on ancient beaches that developed in response to sea-level changes. Powerful south-westerly winds, combined with high energy swells, created mostly northward moving longshore drift currents. These transported the diamonds in waters less than about 35 m deep. The resulting diamond-bearing deposits have been continually upgraded by marine action. The winnowing of the host sediments by waves has been the single most important process that contributed to the enrichment (De Decker and Woodborne, 1996). Present day diamond concentrations have resulted from the continual reworking of older deposits and the subsequent redeposition of diamonds in preferred trap sites throughout periods of sea-level change. Deposits in the surf zone were continually sorted, which concentrated the diamonds close to the bedrock. They were trapped in gravels which collected in gulleys, potholes and channels eroded into the wave cut terraces. Their final site of entrapment was usually in a medium energy environment (Garnett, 2000b).

On the middle shelf off southern Africa, resistant ridges up to 8 m high trend generally north-northwest and provide a rough bedrock on which diamonds have been trapped. Cemented diamond bearing gravels on the ridges were submerged during marine transgressive events. Their consequent reworking produced a diamondiferous lag gravel. According to Garnett (2000b), the diamonds are dispersed neither uniformly nor totally at random. Irregularly shaped well mineralized areas exist in places as widely separated "islands" within extensive tracts which are either low grade or barren. Inside such areas, the diamonds exhibit very localized distribution characteristics.

PLANAR AND PARALLEL LAMINATION

Laminae are defined as sedimentary strata that are less than 10 mm thick, according to McKee and Weir (1953). *Laminae* are recognizable because of variation in sediment texture and/or composition within and between them (Figure P11). For example, the grain size within a lamina may increase or decrease upward, or be different in adjacent laminae. Other laminae may have distinctive concentrations of dark (heavy) minerals. *Planar laminae* have planar bounding surfaces. The term planar lamination is commonly taken to indicate planar laminae that are more-or-less horizontal (within a few degrees) when originally deposited, and that have more-or-less parallel bounding surfaces (but laminae do vary in thickness laterally). Hence, planar lamination has also been called horizontal lamination, even lamination and parallel lamination. The term *parallel lamination* has also been used to describe laminae with parallel but nonplanar boundaries (Figure P11). Planar laminated sandstones (popularly known as flagstones) are valuable building materials. Commonly, these sandstones contain near-parallel ridges of sand grains along lamina

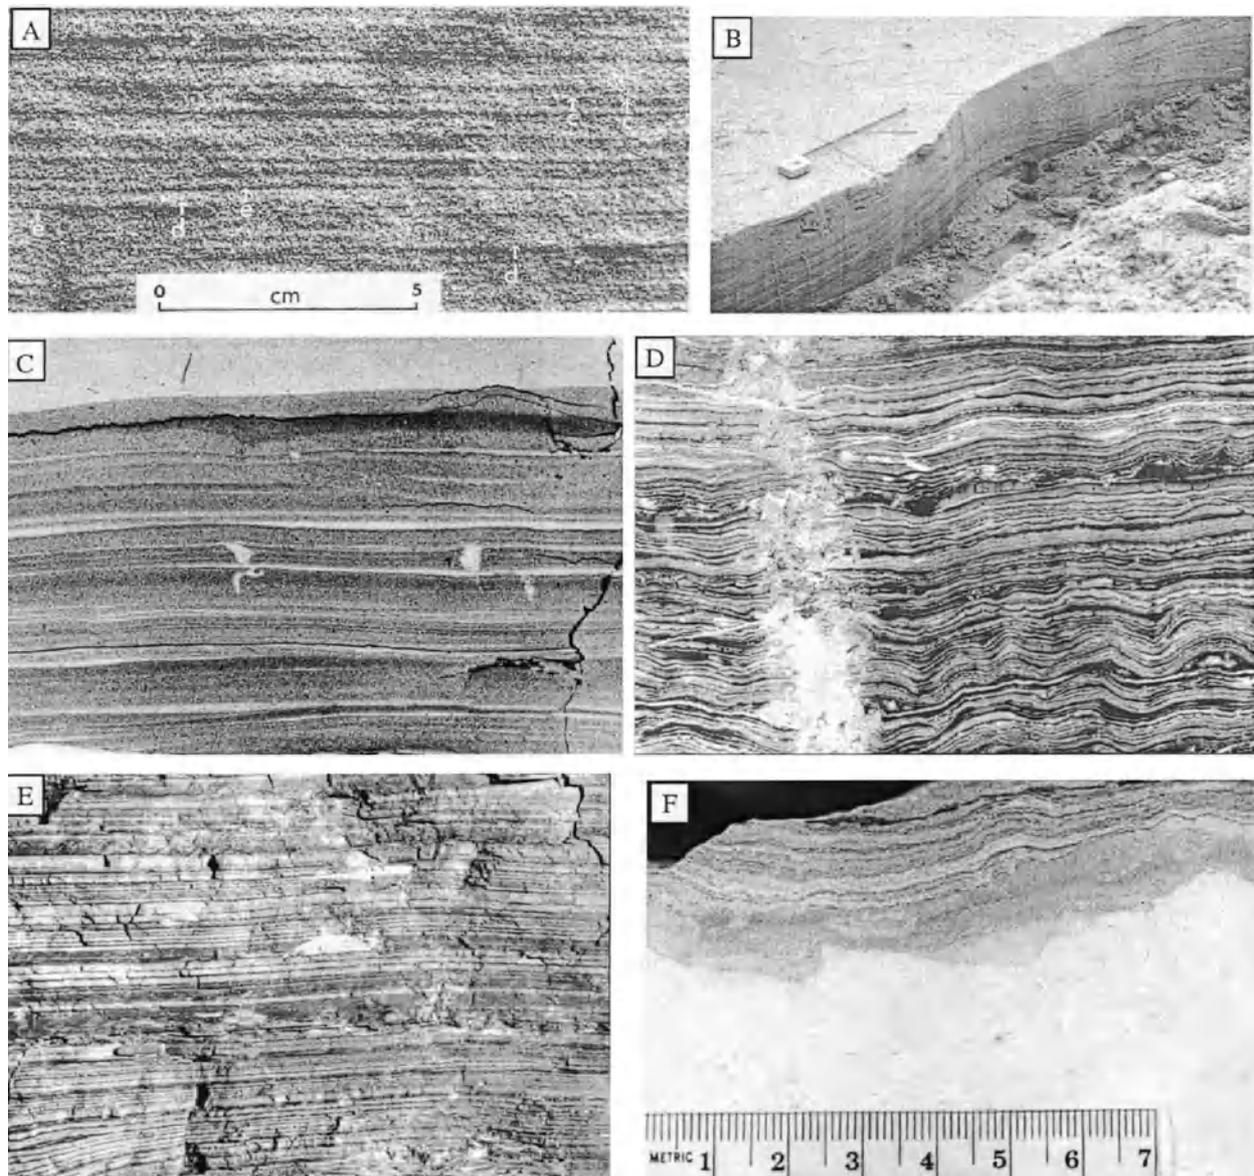

Figure P11 (A) Planar laminae thought to have formed on an upper stage plane bed, Permo-Triassic St Bees Sandstone, UK. Low-angle laminae labeled c. Sharp bases to relatively thick laminae labeled d. (C) Planar laminae composed of very fine grainstone (light) and mudstone (dark), Middle Ordovician St. Paul Group, Maryland, USA (photo courtesy of Robert Demicco). (D) Wavy and crinkled parallel laminae (stromatolite) composed of grainstone (dark) and dolomitic limestone (light), Upper Cambrian Conococheague Limestone, Maryland, USA (photo courtesy of Robert Demicco). (E) Planar, parallel laminae in dolomitic mudstone, Lower Proterozoic Wittenoom Dolomite, Western Australia (photo courtesy of Robert Demicco). (F) Parallel laminated calcium carbonate crusts on Pleistocene limestone, Florida Keys, USA (photo courtesy of Robert Demicco).

boundaries, referred to as *primary current lineation* or *parting lineation*. The ridges are a few grains high and have a spacing of about 1 cm.

Laminae commonly occur in sets (*laminasets*) that are recognizable because of changes in texture, composition, or orientation of laminae (Figure P11). Sets of planar and parallel laminae normally have bounding surfaces that are more-or-less parallel to the laminae within them. If the angle between the

laminae and the laminaset boundary exceeds a few degrees, the sedimentary structure is referred to as *cross lamination* or *inclined lamination*. However, some sets of planar lamination do contain low-angle inclined laminae in places.

The term lamina has been used to denote a thin sediment layer produced by momentary fluctuations in current velocity and sediment transport rate (Otto, 1938, and many others). Such genetic implications for the term lamina should be

avoided, as it cannot be known conclusively how all laminae form. Indeed, planar and parallel laminae may form in different ways in different depositional environments. Their origin is also different depending on sediment size. Some examples are given below, but the list is not exhaustive.

Origin of planar laminated sand under unidirectional currents

Upper-stage plane beds occur beneath fast, shallow unidirectional water flows in which there is appreciable transport of bed load and suspended load. Deposition on upper-stage plane beds gives rise to planar lamination (Figure P11(A)). Most early explanations for the formation of planar laminae beneath upper-stage plane beds involved the influence of turbulent variations in bed shear stress and sediment transport (reviewed by Bridge, 1978; Allen, 1982, 1984). Turbulence, and specifically the turbulent bursting process linked to large coherent structures in the flow (Bridge, 1978; Allen, 1984; Cheel and Middleton, 1986), cannot explain the thickness, lateral extent and size grading within planar laminae. However, the migration of low-relief bed waves can (Jopling, 1964, 1967; Bridge and Best, 1988, 1997; Paola *et al.*, 1989; Best and Bridge, 1992). The fine-grained bases of laminae are due to deposition from suspension on the distal lee sides of the bed waves. Most low-relief bed waves do not have avalanche faces, and the grain size of bed load tends to decrease from the crest to the toe of the lee side, resulting in the coarsening upward parts of laminae. However, the largest low-relief bed waves may have a short lee-side avalanche face at the base of which coarse sediment accumulates. This relatively coarse sediment lies with sharp contact on the underlying laminae. A predominance of fining-upward laminae may result from preferential preservation of the lower parts of the largest bed waves that moved over the bed. Low-angle, inclined laminae within the thicker planar laminae are due to turbulent fluctuations in sediment transport on to the depositional lee side of the bed waves (Figure P11(A)). Parting lineation results from the imprint of high-speed and low-speed streaks within the viscous sublayer of hydraulically smooth and transitional turbulent boundary layers (Allen, 1982).

Transcurrent lamination is the name given to sets of more-or-less planar lamination that are produced by the migration of low-relief bed waves and/or those with a very small angle of climb (Allen, 1982). Transcurrent laminae have also been associated with migration of low-relief ripples (in water and air) and dunes, bed-load sheets, and antidunes (Jopling, 1967; Smith, 1971; Reineck and Singh, 1973; McBride *et al.*, 1975; Bennett and Bridge, 1995).

Origin of planar laminated sand under reversing currents

Upper-stage plane sand beds also occur under high-velocity water currents that reverse in direction periodically, particularly associated with gravity waves in shallow water. Deposition under these plane beds also gives rise to planar lamination. However, under these conditions, the deposition of laminae is probably due to the unsteady sediment transport associated with the passing of individual waves. In the surf zone of sandy beaches, the swash and backwash associated with wave breaking gives rise to planar laminae with characteristic concentrations of heavy minerals

(Figure P11(B)). This is the well-known *beach lamination* (Clifton, 1969; Reineck and Singh, 1973; Allen, 1982). The character of sets of these laminae can be influenced by tides, storms or storm seasons. It is uncertain whether low-relief bed waves play any role in the formation of laminae by wave currents.

Origin of planar and parallel laminated mud and sand

Lamination of mud and very fine sand involves episodic deposition from suspension, provided that the mud was not transported as sand-sized pellets (Figure P11(C)). The laminae will be planar if they are deposited on a planar surface, and if deposition rate does not vary appreciably in space. The laminae arise because of temporal changes in the sediment supply or the ability of the flow to suspend sediment of a particular type. For example, changes in the turbulence intensity of water currents may be associated with the passage of individual floods over floodplains and lakes, seasonal variations in sediment supply and transport rate in lakes (e.g., *glacial varves*), passing of gravity waves, periodic storms at sea, and tidal currents that vary over a number of different timescales (reviews in Reineck and Singh, 1973; Smith *et al.*, 1991; Demicco and Hardie, 1994). The general term for these types of laminae is *rhythmite*. Although turbulent fluctuations in suspended sediment transport (time scale of seconds or less) have been invoked to explain planar laminae in muds (review in Bridge, 1978), it is unlikely that a recognizable mud layer could be deposited in such a short period of time.

Parallel, nonplanar lamination in muds and sands occurs where the sediment is periodically draped over a surface with preexisting topography. Carbonate mud laminae deposited on cyanobacterial mats during storms or high tides give rise to parallel, nonplanar laminated *stromatolites* (Figure P11(D)).

Chemically and biologically formed planar laminae

Planar laminae may be formed by seasonal variations in the type and abundance of the tests of microorganisms (e.g., foraminifera, diatoms) that accumulate on the bed of the sea and lakes. Variations in the nature of chemical precipitation of minerals in some depositional environments may also give rise to planar lamination (e.g., laminated calcium carbonate crusts). Some lamination in muds is manifested only by color changes, associated with changes in chemical composition that could be primary or diagenetic (Figure P11(E), (F)).

POREWATERS IN SEDIMENTS

Approximately 20 percent by volume of the sedimentary portion of the earth's crust consists of water that occupies most of the matrix and fracture porosity of sediments and sedimentary rocks. These porewaters are variously called *groundwater* in freshwater aquifer systems, *interstitial water* in marine sediments, and *formation water* or *basinal brines* in deep sedimentary basins. Porewaters as a group range widely in

chemical and isotopic composition and in their physical properties. There has been considerable interest in the origin and migration of porewaters because of the role these fluids play in the geological, geochemical, and economic resource evolution of sediments and sedimentary basins. The presence of porewaters under pressure facilitates or may even induce tectonic deformation of sedimentary basins and continental margins. Porewaters serve as transport agents for heat and reactive solutes in sediments, and variations in the composition of porewaters in space and time yield important information on mechanisms and rates of solute transport and diagenetic reaction. The study of porewaters thus complements the study of diagenesis obtained by the sedimentological, mineralogical, and geochemical study of the solid phases present in a sediment.

Historical development and outline

The origin of waters in the earth's crust has been speculated upon since ancient times (Hanor, 1988). Prior to the 1600s, there was a general belief that fresh groundwaters were formed by the subsurface distillation of seawater which had infiltrated deep into the earth. These freshwaters get discharged at the surface to form rivers and streams. Seawater salt was left behind in the form of subsurface brines. Beginning with the publication of Perrault's mass balance studies in 1674, it was eventually recognized that rivers, streams, and fresh groundwaters are meteoric in origin. Debate on the origin of subsurface brines in sediments, however, has continued up until the present time. With the advent of modern geochemical techniques in the last half of the past century, much has been learned about the chemical and isotopic composition of porewaters in sediments and their origin. Chief sources of information have been the analysis of produced waters from oil and gas fields, the analysis of potable groundwaters, and the extensive body of analyzes of waters in deep sea sediments generated as part of the JOIDES and ODP drilling projects.

This article reviews the types of solutes found in sedimentary porewaters and the general types of processes which control or influence porewater compositions. This background information is then applied to three major types of sedimentary pore waters: (1) shallow continental waters; (2) marine interstitial waters in continental shelf and deep sea sediments; and (3) waters in deep sedimentary basins. The focus is primarily on the geochemistry of porefluids, but it should be recognized that many important physical properties of porewaters and bulk sediments, such as density, viscosity, thermal and electrical conductivity, and sonic transit time, are directly dependent on fluid temperature, pressure, and chemical composition.

General composition of porewaters

Concentration units

A wide variety of units have been used to describe the concentration of solutes in sedimentary porewaters. Concentrations are typically expressed in terms of mass, moles, or equivalents of solute per liter of solution, kilogram of solution, or kilogram of H₂O. Many groundwater analyzes are presented in mg/L or g/L, units which are convenient because of the volumetric methods used in most analytical techniques. Many in the marine geochemistry community, however, use

mass or moles per kg of solution, which are pressure and temperature independent concentration units. The concentration unit molality, mol/kg H₂O, is used in thermodynamic calculations of saturation state. One final unit is the equivalent (eq), where the number of equivalents of a solute is equal to the number of moles of solute times absolute charge of the solute. The units eq/L or meq/L are widely used in making charge balance calculations from water analyzes and in defining hydrochemical facies, as described below.

Salinity and major solutes

The polar nature of the H₂O molecule makes water an excellent solvent for charged ions and other polar molecules. The salinity or total dissolved solute (TDS) concentrations of porewaters varies greatly, even within individual sedimentary units. Salinities of a few hundred mg/L or less are typical of sediments flushed by meteoric waters. The average salinity of seawater is approximately 35,000 mg/L, and the porewaters in many marine sediments have similar salinities. The salinities of waters in the deeper parts of sedimentary basins, however, can reach levels of 350,000 mg/L or more.

Although a wide range of dissolved species exist in natural waters, the greatest proportion of TDS is contributed by a relatively few species, typically Na⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻, HCO₃⁻, and SO₄²⁻. Several factors determine the major solute concentration of a porewater. These include relative abundance of the potential solute, the ease of accommodating the solute into liquid water, and reaction rates and solubility constraints imposed by coexisting mineral phases and reactive mineral and organic surfaces. Cation accommodation in water is determined in part by ionic potential, the ratio of cation charge to ionic radius in Ångströms. Cations of small ionic potential, roughly 3 or less, are readily accommodated in aqueous solution as hydrated cations. These include most of the group IA and IIA cations, including Li⁺, Na⁺, and K⁺, and Mg²⁺, Ca²⁺, Sr²⁺, and Ba²⁺. Small, highly charged cations having an ionic radius of 12 or greater form soluble charged anionic complexes with oxygen. Common examples include the anionic complexes of the oxidized forms of C, N, P, and S, which include HCO₃⁻ and CO₃²⁻, NO₃⁻, PO₄³⁻, and SO₄²⁻. Cations of intermediate ionic potential, however, are accommodated in aqueous solution with much greater difficulty. These include the abundant rock-forming cations Al³⁺, Fe³⁺, and Mn⁴⁺, which tend to react with water to form insoluble hydroxides or to remain bound in silicate or oxide mineral lattices. Silica forms the sparingly soluble complex, silicic acid, H₄SiO₄. Valence state plays a key role in the relative solubility and mobility of a cation. The reduced forms of iron and manganese, Fe²⁺ and Mn²⁺, are far more soluble than the oxidized forms Fe³⁺ and Mn⁴⁺. Halogen elements form soluble, hydrated anions: F⁻, Cl⁻, Br⁻, I⁻.

Minor inorganic species

Sedimentary porewaters as a group contain measurable concentrations of virtually every naturally occurring element in the periodic chart. Some elements, such as Pb, Zn, and Cu, sometimes occur in sufficient concentration to make the porewater in question, generally a basinal brine of high salinity, a potential ore-forming fluid. Others, such as Br, are useful in tracing the origin of high salinity in porewaters. Some minor and trace elements, such as Ba, Ra, and As, pose

potential health problems when they are present in drinking-water supplies.

Gases and dissolved organics

Most gases and nonpolar organic molecules are only sparingly soluble in aqueous solution, but their presence can be of importance in driving diagenetic reactions and in deducing the origin of porewater. The microbial consumption of dissolved oxygen and production of dissolved CO₂ are two important subsurface reactions which influence the dissolved gas composition of natural porewaters (Chapelle, 1993). Groundwaters derived from rainwater typically contain atmospherically derived noble gases, whose concentration can be used to estimate the temperature of the water at the time of recharge. Waters in the deeper parts of sedimentary basins can contain primordial helium, ³He, thought to be derived from the mantle or deep crust. Very shallow groundwaters typically contain minor concentrations of fulvic and humic acids derived from the breakdown of organic matter (Drever, 1997), and basinal waters often contain a variety of low molecular weight organic compounds produced by the thermal maturation of organic matter.

pH and redox state

The pH is defined as minus the log of the activity of the hydrogen ion, $-\log a(\text{H}^+)$ and is routinely determined on porewater samples as a measure of acid-base conditions. The pH of natural porewaters varies from over 9 for some shallow groundwaters to less than 4 for some subsurface brines. Several conventions are in use to describe the redox state of natural waters: Eh, or electrode potential; pe, minus the log of the activity of the electron; and foe, the fugacity of oxygen. Sediments and fluids in close proximity to the atmosphere or to oxygenated seawater are typically oxidized because of the availability of dissolved O₂. In organic-rich sediments, however, conditions generally become progressively reducing with depth or distance from recharge area.

Isotopic composition

Several major isotopic systems have been utilized to deduce the origin of solutes and of H₂O in different types of porewater. Hydrogen-oxygen systematics have been used to distinguish between H₂O derived from meteoric precipitation and H₂O left behind in residual brines during the evaporation of seawater (Hanor, 1988). Chlorine and I isotopic systematics have been used to help constrain the apparent age of groundwaters. Carbon and Sr, and more recently Li and B, isotopic systematics have been used to deduce the sources of these solutes and type and extent of diagenetic reaction between fluids and mineral phases.

Graphical representation of porewater compositions and hydrochemical facies

The composition of shallow fresh groundwaters varies considerably in terms of the relative proportion of major cations and anions, more so than either marine-derived interstitial waters or waters in deep sedimentary basins. It has been a challenge to develop simple graphic approaches to portray the spatial and temporal variations in typical

groundwater composition (Domenico and Schwartz, 1990). A useful convention is the concept of hydrochemical facies (Back, 1961), where the composition of porewater is described in terms of those few cations and anions which contribute the bulk of the ionic charge in equivalents (eq/L) or milliequivalents (meq/L). A Ca-HCO₃ porewater, for example, is one dominated in terms of equivalents of charge by Ca²⁺ and HCO₃⁻, although lesser amounts of many other solutes may be present. Prefixes such as F⁻, B⁻, S⁻, and HS⁻, representing fresh, brackish, saline, and hypersaline, may be added so that some qualitative information on TDS is conveyed as well.

General physical and chemical controls on the composition of porewaters

The general types of chemical reactions and physical processes which control porewater compositions are general to each of the three end-member types of pore waters discussed here. The physical processes include advection, which is the bulk transport of solutes through the pore spaces of a sediment by the fluid flow, and fluid mixing which occurs as a result of molecular diffusion and hydrodynamic dispersion around mineral grains. Advection can be induced by sediment compaction, by differences in topographic elevation, by differences in fluid density, and by fluid pressures in excess of hydrostatic (Domenico and Schwartz, 1990).

The types of chemical reactions which influence porewater composition include: hydrolysis or dissolution-precipitation reactions involving porewater and bulk mineral phases, many of which involve hydrogen ion and are thus acid-base reactions; redox reactions in which there is a transfer of electrons, usually between C, N, Fe, Mn, and S-bearing solutes and solids; and mineral and organic surface reactions involving adsorption and ion exchange. Many reactions involving porewaters and ambient mineral phases occur nearly simultaneously. For example, the production of H⁺ by the oxidation of a sulfide mineral may induce the hydrolysis or dissolution of a silicate mineral. Some of the cations released in the process may be adsorbed onto the surface of newly formed clay minerals produced by the destruction of the silicate precursor.

The combined effects of advection, dispersion, and chemical reaction on the changes in spatial and temporal concentration of a solute with time (dC_i/dt) along a one-dimensional flow path can be described by the following mass balance equation:

$$\left(\frac{\partial \phi C_i}{\partial t}\right) = -v\left(\frac{\partial \phi C_i}{\partial x}\right) + D_i\left(\frac{\partial^2 \phi C_i}{\partial x^2}\right) + \phi \Sigma(R_{ij}) \quad (\text{Eq. 1})$$

where t is time, v is advective fluid velocity, ϕ is porosity, and x is distance. D_i is the coefficient of hydrodynamic dispersion for solute i , and R_{ij} is the net source-sink term for solute i for chemical reaction j (Lichtner *et al.*, 1996).

The first term on the right accounts for the net increase or decrease in C_i as the result of the advection or bulk flow of fluid of varying C_i through the sediment. The second term describes the mass balance resulting from mixing due to molecular or Fickian diffusion and dispersion. The final term is the net sum of the rate of the chemical reactions involving other phases and solute i . Variants on this mass balance equation in one, two, and three dimensions are at the heart of mathematical computations designed to couple the physical and chemical processes which control porewater compositions. These calculations are also used to quantify the mass transfer

which occurs between mineral and fluid phases during diagenesis. In one-dimensional systems, it is sometimes possible to solve the equation analytically (Berner, 1980), but in complex heterogeneous systems numerical techniques are required (Lichtner *et al.*, 1996).

Continental groundwaters

Topographically-driven meteoric groundwater systems

The sources of porewaters found in shallow freshwater aquifers and interbedded aquicludes are meteoric precipitation and recharge by lakes and streams during high surface water levels. That portion of rain or snow melt which does not form runoff infiltrates downward into the unsaturated zone, where it may be returned to the atmosphere via evapotranspiration and/or migrate further downward to recharge an underlying aquifer. The groundwater within an aquifer will then typically migrate both downward and laterally along preferred flow paths and eventually discharge into either another continental surface environment, such as a spring, lake, or stream, or into the offshore submarine environment. Most meteoric groundwater flow is driven by differences in topographic elevation between areas of recharge and discharge (Domenico and Schwartz, 1990).

Rainwater typically contains several mg/L or more of dissolved salts. Diagenetic alteration of meteoric water compositions, however, occurs immediately within the soil environment (Drever, 1997). The carbonic acid and organic acids produced by soil bacteria are important weathering agents, and the consequent dissolution of carbonate and silicate minerals results in the leaching of the more soluble cations, such as Na⁺, K⁺, Mg²⁺, and Ca²⁺, from the soil. Although there is some complexing of Al and Fe by organics, the less soluble cations, such as Al³⁺, Si⁴⁺, and Fe³⁺ are preferentially left behind in residual mineral phases. Oxidation of sulfide minerals produces hydrogen ions, which can induce further weathering, and dissolved sulfate. Cation exchange on newly formed clay minerals favors retention of the divalent cations Mg²⁺ and Ca²⁺ in freshwater environments. High rates of evapotranspiration relative to rainfall in arid climates can serve to increase the TDS of soil waters.

Mineral-fluid and organic reactions continue as groundwater migrates along flow paths within the saturated zone, flow paths which are determined by spatial variations in permeability and hydraulic head. The local presence of evaporite minerals such as halite, anhydrite, and gypsum can add Na, Cl, Ca, and SO₄ to the groundwater. As the groundwater flows down gradient from recharge areas it may encounter progressively reducing conditions as dissolved oxygen is depleted by aerobic respiration. Nitrate, manganese, amino acids, iron, and organic carbon are the typical succession of electron acceptors microbes then use to oxidize organic carbon as subsurface conditions pass progressively from oxidizing to reducing (Chapelle, 1993). When conditions become sufficiently reducing, the reduction and dissolution of Fe and Mn minerals commonly gives rise to significant concentrations of these metals in shallow groundwaters. With a further decrease in redox state, however, sulfate is reduced to sulfide, and Fe may be precipitated out as an Fe-sulfide.

In carbonate aquifers, it is not surprising to find groundwaters dominated by Ca-HCO₃ or Ca-Mg-HCO₃ as the principal solutes. A well-studied example is the Floridian

Aquifer in central Florida (Sprinkle, 1989). In siliciclastic aquifers, however, there is typically a progression from Ca-Na-HCO₃ waters in shallow recharge areas to Na-Ca-HCO₃ and then Na-HCO₃ waters further down dip. Examples include the US. Atlantic and Gulf coastal plain aquifers, where bicarbonate concentrations increase down flow paths from initial values of less than 50 mg/L to over 500 mg/L (Chapelle, 1993). The probable source of CO₂ is bacterially oxidized organic material present in the aquifers and/or the interbedded aquicludes. The origin of high Na-HCO₃ groundwaters in siliciclastic aquifers has been a matter of some debate. One school of thought holds that the removal of Ca is predominantly by ion exchange, the other that Ca is removed as CaCO₃ by the introduction of HCO₃.

Continental brines

In arid continental climates where potential evapotranspiration far exceeds rainfall, circumstances can exist which give rise to the formation of brine lakes. Well-known examples include Lake Magadi, Kenya; Lake Tyrrell, Murray Basin, Australia; and Great Salt Lake, Utah. The composition of the brines produced depends critically on the relative proportions of Ca, HCO₃, SO₄, and Mg in the fluid being evaporated. Documented brine types include Na-Ca-Mg-Cl, Na-Mg-SO₄-Cl, and Na-CO₃-SO₄-Cl saline waters (Eugster and Hardie, 1978). These brines recharge into underlying sediments as a result of density-driven flow, where dissolved Mg is removed by the formation of Mg-rich smectite, sepiolite, Mg-calcite, and/or dolomite, and sulfate can be reduced by reduction to sulfide. In contrast to freshwater conditions where ion exchange favors the adsorption of divalent cations, monovalent cations, particularly K, are preferentially adsorbed on clays in saline conditions and removed from solution.

Porewaters in marine sediments

Fluid flow and solute transport in many marine sediments, particularly in deep sea pelagic and hemipelagic sediments are dominated by compaction-driven advection and molecular diffusion (Berner, 1980). More dynamic fluid environments are found on continental shelves, where topographically driven meteoric fluids can mix with marine porewaters; in accretionary prisms, where there is well-documented seaward expulsion of fluids; and along mid-ocean rises and ridges and other submarine volcanic settings, where thermal convection operates (Hesse, 1990).

Seawater is a Na-Cl dominated fluid with SO₄, Mg, Ca, and K as the other major species. The relative proportion of these solutes is nearly constant throughout the world's oceans, with the exception of SO₄-depleted, anoxic bottom waters in closed submarine basins. Much of the water trapped in pelagic and hemipelagic sediments at the time of deposition is seawater. This water, however, undergoes continuous chemical diagenesis and a change in composition with time and depth of burial (Hesse, 1990; Schulz and Zabel, 2000). There is typically a systematic increase in Ca and systematic decreases in Mg and K with depth. The variations in Ca and Mg are generally thought to be the result of hydrolysis of silicate minerals in underlying oceanic basement basalts. The downward decrease in dissolved K may be related to the formation of the potassium-bearing zeolite, phillipsite, and adsorption by ion exchange on clays. There is often a distinct downward decrease

in $\delta^{18}\text{O}$ values of marine interstitial waters, commonly interpreted as resulting from preferential removal of heavy oxygen by the formation of phyllosilicates in altered igneous rocks and volcanoclastic sediments. Increases in $\delta^{18}\text{O}$ increases, however, have been noted in gas-hydrate bearing sections of DSDP cores. Elevated temperatures and enhanced reaction rates associated with submarine hydrothermal activity, such as in the Guyamas Basin, methane release of Ca and uptake of Mg by hydrothermally altered basalts and volcanoclastic sediments. There are also documented increases in dissolved Li, K, and Rb in these areas.

Silica concentrations are typically highly variable with depth and are dependent on lithology. Elevated silica concentrations, for example, are found in siliceous oozes. Recrystallization of biogenic pelagic carbonates releases substantial amounts of Sr but does not seem to have a significant effect on Ca concentration gradients.

With the exception of dissolution of evaporite minerals, chloride does not participate in mineral-fluid reactions in the subsurface. Its behavior is thus said to be conservative. As a conservative species chloride often does not display vertical concentration gradients in marine sediments. The changes in chloride which have been observed in evaporite-free sections result from mixing with freshwater released from gas hydrates, loss of water in hydration reactions, and possibly slight changes in seawater chlorinity during glacial-interglacial cycles. There is typically a reduction in porewater chloride and salinity in decollments and faults in accretionary wedges as a result of dehydration reactions and large-scale fluid expulsion.

In more organic-rich hemipelagic sediments redox conditions become progressively reducing with depth. As a result of a progression of redox reactions similar to those which characterize continental groundwaters, dissolved ammonia, phosphate, and alkalinity typically increase in the upper part of the sediment column, and dissolved sulfate is reduced (Berner, 1980).

Saline waters in deep sedimentary basins

The hydrogeology of deep sedimentary basins is less well-known quantitatively than that of shallow groundwater systems, but deep basin circulation plays a key role in controlling the salinity and composition of basinal fluids through advection and dispersive mixing of fluids of varying salinity. The deep pore fluids in many sedimentary basins are overpressured, i.e., they exhibit fluid pressures in excess of hydrostatic pressures. There has been considerable debate on the origin of overpressuring (Hanor, 1988), but rapid deposition of fine-grained sediment of low permeability is one likely mechanism. There is evidence from variations in salinity and fluid composition that overpressured fluids can be episodically expelled upward into overlying hydropressured sediments (Roberts and Nunn, 1995). The presence of bedded and diapiric evaporites provide other mechanisms for inducing fluid flow. The dissolution of halite produces dense brines which can convect downward. Salt, however, is also an excellent conductor of heat, and there have been documented examples of upward fluid flow along the flanks of warm salt domes (Hanor, 1994).

Sources of chloride and controls on salinity

Pore waters in the deeper parts of sedimentary basins, including basins now part of the continental crust, and basins

containing tectonically deformed sedimentary sequences, are typically saline. The salinities are commonly higher than that of seawater (35,000 mg/L) and can range from 100,000 mg/L to 150,000 mg/L in basins with salt domes to over 350,000 mg/L in basins with bedded basal evaporites. In some sedimentary basins, such as the Illinois, Alberta, and Michigan basins, there is a progressive increase in salinity with depth. In other sedimentary basins, such as the Gulf of Mexico basins there can be reversals in salinity with depth (Hanor, 1988). In the mid-20th century, much discussion was given to the origin of high salinity by the process of membrane filtration or reverse osmosis. In this process overpressuring forces uncharged water molecules through clay membranes, but the negative charge on the clay particles repels charged ions and produces high concentrations of solutes on the influent side of the membranes. Most workers today, however, consider the chloride in basinal brines to have been introduced by some combination of the subsurface dissolution of halite (Land, 1997) and the infiltration of subaerially evaporated marine waters (Carpenter, 1978). During the evaporation of seawater, Br preferentially remains in solution while Cl is precipitated out, first as halite and then as K and Mg salts (McCaffrey *et al.*, 1987). Brines formed by dissolution of halite thus typically have low Br/Cl ratios, which reflect the low Br/Cl ratio of the parent halite. Brines formed by the subaerial evaporation of seawater, in contrast, typically have elevated Br/Cl ratios.

Major solutes

Most basinal brines of moderate salinity are dominated by dissolved Na and Cl. As salinity increases, however, there is a progression from Na-Cl to Na-Ca-Cl to Ca-Cl brines. The controls on the composition of basinal brines have been discussed and debated for a century and a half (Hanor, 1988). In the mid-1800s it was proposed that the high Ca concentrations were connate or syngenetic in origin and reflected high Ca/Na ratios of ancient seawater, a hypothesis which is no longer accepted. Although most of the chloride in basinal brines is derived from halite dissolution or from marine and evaporated marine waters, basinal brines have neither the composition of a NaCl solution or of evaporated marine waters. Instead, there are systematic increases in Na, K, Mg, Ca, and Sr with increasing salinity. The 1:1 slope of the monovalent cations and 2:1 slope of the divalent cations on log-log plots is consistent with the buffering of brine compositions by multi-phase silicate and carbonate mineral assemblages (Hanor, 1994). The phases involved most likely include minerals such as quartz, K-feldspar, albite, illite, smectite, chlorite, calcite, and dolomite. The general decrease in pH and carbonate alkalinity with increasing salinity is also consistent with rock-buffering of fluid compositions. Sulfate concentrations, in contrast to the other major solutes, do not show any systematic variations with salinity. Sulfate concentrations instead are controlled by anhydrite dissolution and the reduction of sulfate to sulfide. Basinal brines and gases in iron-poor sediments can contain significant concentrations of H₂S.

Organic and heavy metals

Volatile fatty acids (VFAs), such as acetate, propionate, and butyrate, are found in concentrations exceeding 100 or even

1000 mg/L in some basinal waters. These waters tend to be of low salinity and may reflect water released from hydrocarbon source rocks during maturation of organic matter. Under conditions of high fluid pressure, concentrations of dissolved methane exceeding several thousand mg/L can be forced into solution.

Basinal brines have long been considered the fluids involved in the formation of some sediment-hosted ore deposits, including Mississippi Valley Type (MVT) and sedimentary-exhalative (SEDEX) deposits. Although much consideration has been given to the role of organic complexing agents, such as acetate, in solubilizing heavy metals such as Pb and Zn, more recent work has shown that chloride is the key complexing agent (Hanor, 1997). At chloride levels in excess of 100 g/L, the PbCl₄⁻ and ZnCl₄⁻ complexes become effective solubilizing agents for Pb and Zn. Barite (BaSO₄) is also a common mineral phase in MVT and SEDEX deposits. High concentrations of Ba are found in those basinal brines that have low sulfate concentrations.

Isotopic composition

The isotopic composition of basinal brines is significantly influenced by diagenetic reactions. Exchange of oxygen with silicate minerals can increase the δ¹⁸O values of basinal waters and the introduction of H from maturation of organic matter can lower δ²H values. Other changes include the introduction of radiogenic ⁸⁷Sr and changes in the Li and B isotopic compositions from the diagenesis of siliciclastic sediments.

Summary

Even though the salinity and composition of porewaters in sediments and sedimentary rocks varies widely, many of these variations are systematic and can be explained in terms of basic principles of solute transport and chemical reaction. In terms of major solutes, redox reactions involving organic matter are important in influencing the concentrations of SO₄ and HCO₃ in all porewaters. Reactions involving silicates, carbonates, and evaporites, however, are the ultimate controls on the addition and removal of Na, K, Mg, Ca, and Cl.

As a group, meteoric groundwaters have the highest variation in proportions of major solutes, which reflect highly dynamic flow systems and local lithologic control on water compositions. Many interstitial marine waters still retain a strong seawater signature despite on-going organic and mineral diagenesis. Diffusional exchange with overlying seawater and within the sediment column is one factor contributing to the buffering of fluid compositions in these sediments. Saline waters in deep sedimentary basins show systematic changes in the concentrations and relative proportions of most major solutes, reflecting rock buffering involving multiple sediment lithologies.

Much work remains to be done in quantifying our understanding of the controls on the properties of pore fluids, including establishing the driving forces and rates of solute transport and the kinetics of the diagenetic reactions which cause mass transfer to occur between porefluids and their sedimentary matrix.

PRESSURE SOLUTION

A grain-scale mechanism of ductile and water-assisted deformation

The transition from loose sediments to hard rocks arises through physico-chemical processes at the grain scale. Pressure

solution, in addition to cataclasis, grain sliding, and plastic deformation, is one of these processes. Pressure solution takes place when some aqueous fluid coating is present around the grains. It is a water-assisted diffusional mass transfer normally occurring in the top few kilometers of sedimentary basins and in other geological environments such as fault gouges and low-grade metamorphic rocks. This slow mechanism of deformation can induce large amounts of ductile strain over geological times when stress and temperature are not high enough to promote brittle or plastic deformation.

The classical pressure solution structures have been described since the last century, for example by Sorby in 1863. They include grain and pebble indentations, stylolites, partly dissolved voids, dissolution seams, and crenulation cleavage. Since, extensive field evidence has accumulated which confirms the prevalence of this mechanism in nature.

Following Sorby's pioneering observations, Weyl (1959) performed the first quantitative interpretation of pressure solution and proposed that the driving force for the deformation be related to stress concentration at grain or pebble contacts. From natural observations such as those of Figure P12, he deduced that deformation by pressure solution involves several successive steps: dissolution at the grain contacts, transport of the dissolved solutes toward the open pore, precipitation in the pore or transport to other pores. This results in an indentation of the grains into each other and a decrease of rock porosity resulting in a ductile compaction.

Mechano-chemical processes

A crucial parameter for pressure solution is the presence of water in the pores, which acts as a medium of reaction and transport with the minerals. If a porous medium is not saturated with respect to water, pressure solution will be localized in the pores where water is present. This effect can create compacted regions in the sediment whereas the porosity of other regions will not be modified.

At the grain scale, pressure solution deformation occurs through three serial steps, the whole process being driven by stress gradients along the grain surface. First, minerals dissolve at grain contacts because of a concentration of stress. The stress variation between the grain contact and the pore surface can be related to the chemical potential of the dissolving mineral (Paterson, 1973). The result is that the concentration in aqueous species is greater in the contact film and induces a gradient of concentration between the contact film and the pore. The second step involves solutes in the contact film diffusing along the grain boundaries. The nature of the interface between two grains is crucial because it is a medium of dissolution and diffusion of matter. It is assumed that some water is trapped inside this interface. And the third and last step is precipitation on the free face of the grains. Note that solutes can be transported by diffusion in the pore fluid and precipitate at some distance from the dissolution area. This provides an explanation of mass transfer at centimeter scale in sedimentary environments under local gradients of stress.

If one of these three steps is slower than the two others, it will control the kinetics of the overall deformation. For example, diffusion within grain contact films controls the compaction of salt aggregates at room temperature. In sedimentary basins, compaction of quartz-rich sediments is limited by the step of quartz precipitation between 3 km and 5 km and by the diffusion at the grain contact below 5 km.

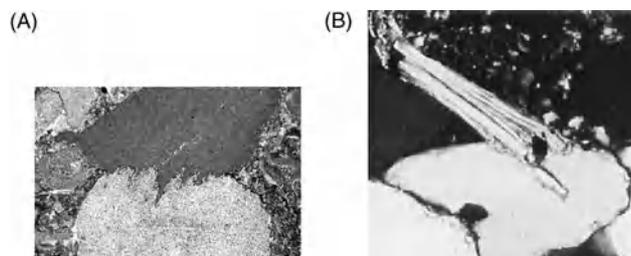

Figure P12 Pressure solution at grain scale: (A) Indentation of two carbonate fossils in a limestone, Mons, Belgium; (B) Indentation of a grain of quartz by a mica flake in a sandstone from the Norwegian shelf.

Above 3 km, pressure solution remains so slow that its rate can be neglected.

Experimental insights

Attempts to reproduce the mechanism and to obtain quantitative information in the laboratory have proved difficult however, owing to incomplete analysis of samples' geometry used in experimental study and to the confounding influence of other deformation mechanisms that can operate concurrently in the experiments. The experiments can be divided in two categories: single contact (Hickman and Evans, 1991) and aggregate compaction (Rutter, 1976; Gratier and Guiguet, 1986) experiments. The former experiments give insights on the mechanism of deformation itself on a single grain whereas the results of the latter are average creep laws. Recent experiments on rock salt, gypsum and quartz aggregates have shown that pressure solution rate increases when: (1) temperature increases (with an activation energy between 15 kJ/mole and 80 kJ/mole); (2) effective stress increases; (3) grain size decreases.

Such experiments indicate that geometrical parameters control the pressure solution rate such as grain size and the geometry of the grain–grain interface. Knowledge of the geometry permits the estimation of the path length for diffusion of the solutes from the contacts to the pore space. Physico-chemical variables of importance include temperature, stress, chemistry of the pore water, mineralogy of the rock, and transport properties of the grain contacts.

Ductility of the upper crust

Pressure solution, as a time-dependent process, is responsible for a slow ductile creep of the rocks. Modeling pressure solution requires taking into account the evolution of the rock texture and grain geometry (Figure P13) during deformation as the contact area and the pore surface vary during deformation. Such models allow investigating the sensitivity to the main input parameters: transport properties at grain contacts, grain size, temperature, and stress. Typical results of these models concern the viscosity of compaction of sedimentary rocks and the time-scale relevant to compaction processes. For example, preliminary results indicate that the viscosity of compaction of silico-clastic sedimentary rocks ranges between 10^{19} and 10^{23} Pa·s depending on temperature, grain size, stress, and mineralogy; values which are similar to what can be deduced from field-based observations.

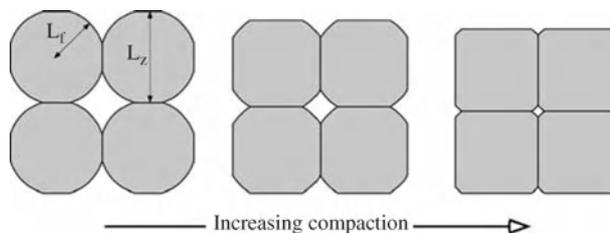

Figure P13 A cross-section view of a cubic packed network of truncated spheres used to model pressure solution. The grain shapes evolve due to pressure solution: the grain radius L_f increases while the grain flattens (L_z decreases) resulting in the porosity and the pore surface decrease. Such models can be applied in sedimentary basin conditions to model compaction.

Still unresolved questions associated with the basic understanding of the process of pressure solution remain. For example, the dominating driving force and mechanism of dissolution, the geometry of the grain boundaries, the structure and transport properties of the aqueous fluid in that grain boundary, and the influence of pore fluid compositions represent challenging issues for actual research.

In the upper crust pressure solution results in a slow process of dissipation of stress energy stored during sedimentation and burial or by tectonic forces. Field observations indicate that pressure solution is intimately associated with brittle processes of deformation, for example on active faults where earthquakes are characteristic of a brittle behavior whereas pressure solution remains the main mechanism of deformation during the interseismic period.

PROVENANCE

Introduction

On Earth, sedimentation is driven principally by tectonic forces, subordinately by climatic and eustatic forces, and to a minor extent in response to impact processes. Detrital sediments retain a record of eroded crustal material. Knowledge of crusts of the past is gleaned from provenance studies. Tracking the immediate and ultimate sources and origins of sediments, principally of siliciclastic sediments, is the domain of provenance studies. In addition, estimating amounts, proportions, and rates of supply of sediments from multiple sources is also within the purview of provenance studies. Contemporary investigations, therefore, focus not only on types, identification, and tectonic settings of source rocks, or the climatic conditions in source areas, or paleogeographic localities of source areas, but also on quantitative distributions of source material and the kinematics of source area tectonics. Approaches, i.e., methodologies of investigations, depend generally on the purpose of the investigators and the scientific questions address by them, but are largely multidisciplinary and diverse (Zuffa, 1985; Morton *et al.*, 1991; Johnsson and Basu, 1993; Bahlbourg and Floyd, 1999; DeCelles *et al.*, 1998). No parent rock or parent rock-assembly is ever fully preserved in any sediment. Because post-derivation weathering, transport, and depositional, and especially diagenetic processes determine the preservation potential of original detrital signatures and lead to disproportionate representation of parent material in sediment, methodologies have to be appropriately adapted in specific cases. We discuss some of the methods before describing the results and the kinds of inferences made in a few recent studies.

The detective work to infer provenance is thus equivalent to restoring a jigsaw puzzle with many missing and damaged pieces.

Historical

Provenance studies have prompted and progressed with newer instrumentation to determine sediment properties. More than 50 years ago color and shapes of heavy minerals were guides to parent rocks; some 25 years ago detrital zircons were separated on the basis of color and shape to obtain U–Pb age-dates to identify sources in the igneous basement of the Potsdam Sandstone; currently, age-dating of and oxygen isotope systematics in single crystals of detrital zircon provides information on the genesis and recycling of crustal rocks. Similarly, optical microscopic observations are now supplemented by backscattered electron image analyzes; chemical compositions of sediments extend beyond major element to trace and rare earth element distribution; and, chemical and isotopic compositions of single detrital grains are determined by using electron and ion microprobes.

Approaches

Methodologies of provenance determination are broadly divisible into three types: petrographic, chemical, and isotopic. All three types are increasingly used in provenance interpretation. Except for the uncommon occurrence of some index mineral (e.g., glaucophane to indicate a blueschist-type source

rock) or an index fossil (e.g., coeval taxa from a disintegrating bank into a deep sea turbidite), most contemporary data are quantitative in nature. Statistical principles of point-counting methods are applied in most measurements.

Petrographic

Mineralogic compositions and classification of sandstones have been linked to source rocks for a long time. For example, arkosic sandstones and conglomerates, many with granitic rock-fragments, have been linked to continental shields, and, lithic graywacke sandstones, many with volcanic and schistose rock fragments, have been linked to orogenic sources. Relative concentrations of detrital quartz (Q), feldspar (F), and rock fragments (R) define sandstone classification. Because the proportion of rock fragments increases with the increasing grain size of sediments, and, because quartz and feldspars also occur in rock fragments, estimating the proportions of QFR is difficult. Results of QFR determination differ depending on the methodology used especially in treating the grain-size effect. Some investigators restrict the grain size range of samples, for example, to medium sand size (0.25–0.50 mm) for sandstones. Others point-count quartz and feldspars in coarse-grained rock fragments as mineral fragments, and restrict the counts of rock fragments, designated as lithics (L), to very fine-grained sedimentary, schistose, and volcanic grains. Composition fields in QFL space (triangular diagrams) are sensitive to detritus from different tectonic regimes (Dickinson, 1985). This is especially true if very fine-grained aggregates of quartz (polycrystalline quartz; chert) are assigned to the L-pole leaving the Q-pole reserved for monocrystalline quartz only. This converts the QFL diagram to a Q_mFL_t diagram. Although the fields in QFL/ Q_mFL_t diagrams are intended to be guides, many sandstone petrologists tend to use a classificatory approach to infer tectonic provenance. The diagram was modified later to erase definitive compositional fields emphasizing the essence of the relationship between sandstone composition and tectonic provenance (Dickinson, 1988: Figure P14).

The QFL approach has two limitations. First, errors associated with the boundaries of compositional fields are large. Second, it ignores the information contained in rock fragments; especially that carbonate grains may be intrabasinal and coeval with the host sediment or extrabasinal and older detritus. Both are useful as provenance indicators. Nevertheless, point counting by the Gazzi–Dickinson method, using QFL/ Q_mFL_t , is the preferred mode for inferring tectonic provenance from petrographic analysis of bulk sediments.

Climate profoundly affects mineralogical and chemical compositions of sediments. Under warm and wet conditions relative to cold and dry conditions, rock-fragments break down to their constituent minerals more rapidly; they become depleted in a sediment while quartz, being the most durable mineral at Earth's surface, is enriched relative to other minerals. Duration of weathering, be it at rock-outcrops or while a body of sediments is parked temporarily (e.g., river valleys, deltas, coastal plains, beaches), contribute to the degree of quartz enrichment. Common upper crustal metamorphic rocks are generally enriched in quartz and are finer grained than common igneous rocks (feldspar-rich and coarser grained). Therefore, it is possible to differentiate between sediments derived principally from metamorphic and igneous rocks under similar climatic conditions; and, to assess relative

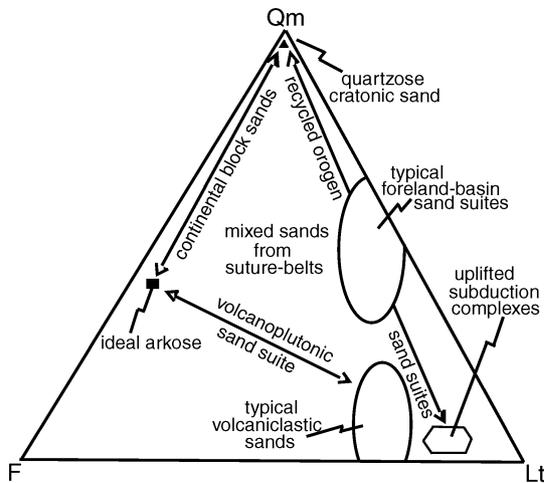

Figure P14 A Q_mFL_t plot of detrital modes (modified after Dickinson, 1988) serves better as a guide to provenance rather than serving as a classification (e.g., as in Dickinson, 1985).

climatic influence on bodies of sediments derived principally from similar source rocks. Point-counting methods in these studies define rock fragments as multi-mineral sand-sized grains in which at least two sub-grains are larger than 0.0625 mm or no single phase constitutes >90 percent of the whole grain.

Properties of rock fragments. Rock fragments, if identifiable despite alteration suffered through weathering and diagenesis, are infallible guides to source rocks. Carbonate rock-fragments may contain identifiable fossils, which may specifically identify and date a source rock. Particularly informative are fossils in coeval carbonate fragments derived from shelfal banks in off-shelf sediments. Overall, the rarity of good preservation and differential preservation of different rock-types lead to incomplete and possibly misleading inferences. For example, quartzite rock fragments are far better preserved than schistose rock fragments. Inference based solely on grain counts of rock fragments derived from a sequence of metamorphosed sedimentary rocks would underestimate the contribution from schistose parent rocks. Based on such arguments, Palomares and Arribas (1993) developed the concept of Sand Generation Index (SGI) quantifying the proportions of schistose, gneissic, and granitoid rock fragments expected to be delivered to daughter sands from identical climatic and geomorphic units. A follow-up study on sedimentary source rocks confirms earlier conclusions.

Properties of minerals. All minerals suffer different degrees of alteration and obliteration through processes of weathering, transportation, deposition, and especially diagenesis. Feldspar, the most abundant mineral in crystalline basement rocks, is subordinate to quartz in most sandstones. If preserved, types of feldspars, their chemical compositions, twinning habits and zoning, and their structural states are useful guides to parent rocks. However, feldspar grains do not survive abrasion and transportation well. Fragmentation along cleavage planes and composition planes (of twinned feldspars) may preserve a biased population in detrital sands. For example, if twinned feldspars from igneous source rocks break along composition planes during transportation, the detrital population may look

like one from metamorphic source rocks that contain, in general, fewer twinned feldspars. Moreover, partial to complete dissolution and albitization render provenance determination from feldspars prone to substantially inadequate interpretation much like that from rock-fragments alone. Hence, degrees of alteration of feldspars cannot be assigned unequivocally to weathering of parent rocks to estimate climatic conditions prevalent in the provenance (e.g., Folk, 1980; after Krynine and the “Dogma of the Immaculate Feldspar”).

Many in search of provenance-related properties have studied quartz because it is the most abundant and the most durable detrital mineral. Additionally, some believe that “quartz is an ideal mineral to study because many of them could be assigned to a definite type of source rock” (Folk, 1980). Properties of quartz are related to its formation and subsequent overprinting by geological events. The genetic classification of quartz types based on optical petrographic properties as taught by Krynine (in 1940s) and later encoded by Folk (p.69 in Folk, 1980) is still valid (but see *Quartz, Detrital*, and caveats below). Principal criteria are extinction types (straight or undulose), inclusions (vacuoles; microlites), idiomorphism and embayment, and nature of sub-grain boundaries (straight; crenulated; wavy) of polycrystalline grains. Based on these criteria six genetic types of quartz are defined: (a) common plutonic quartz, (b) volcanic quartz, (c) vein quartz, and metamorphic quartz of three principal types, i.e., (d) recrystallized, (e) schistose, and (f) stretched. The last three are polycrystalline quartz grains and the first three are presumably all monocrystalline. However, local environment of quartz generation does not necessarily correlate with specific source rock assemblages. For example, vein quartz may come from quartz-bearing veins in several kinds of rocks from several tectonic environments. Additionally, not every detrital quartz grain in a sedimentary rock can be unequivocally assigned to a particular genetic type. Folk devised a pragmatic empirical classification of quartz types for detrital grain generally in the size range between 0.15 mm and 0.35 mm based on the nature and degree of undulose extinction and the nature and abundance of inclusions. An empirical distribution-diagram of detrital quartz-types from different source rocks is constructed to infer the provenance of sand-sized quartz grains in a sedimentary rock (p.67 and p.73 in Folk, 1980). Although neither Krynine nor Folk published data-tables in their summary reports, their observations (published in various journal articles) are based on examining numerous thin sections from numerous rock samples.

Two commentaries on the above remain important. Detailed quantitative optical petrographic studies of quartz in modern sand from known source rocks to test the empiricism of Krynine and Folk showed that: (1) apparent undulosity of any grain depends on the crystallographic orientation of the plane of the thin section and flat-stage estimates may be random, i.e., not significant; and (2) polycrystalline and strained quartz grains (hence undulose) are selectively destroyed in transportation relative to those without strain, i.e., exhibiting straight extinction. This invalidates much of the empirical approach of Krynine and Folk. However, because strain in quartz under natural stress is finite and bending of the c-axis is possibly limited to not more than 30°, one would expect a statistically higher proportion of undulose quartz grains in detritus from metamorphic source rocks. Based on a combination of universal-stage and

flat-stage measurements of undulosity and polycrystallinity in medium sand-sized (0.25–0.50 mm) quartz grains from igneous granitic rocks and various grades of regionally metamorphosed rocks, separate provenance fields can be delineated in a “diamond diagram” that show some overlap between granitic and gneissic source rocks (Basu *et al.*, 1975). In summary, principles espoused by Krynine and Folk are validated although some modification of detail has become necessary. Additionally, post-lithification deformation of a sedimentary unit, for example, such as those involved in tight folding, imparts new strain on detrital quartz grains modifying their original characteristics.

Quartz, feldspar, carbonate, and clay minerals are light constituents ($\rho < 2.89$ g/cc) of detrital sediments and usually add up to about 99 percent of all sedimentary rocks. Heavy minerals are rare because common mafic minerals are weathered easily and because durable heavy minerals (e.g., zircon, tourmaline, rutile) are uncommon in parent rocks. However, minerals characteristic of certain rock types, if preserved, are very useful for provenance determination. For example, the simple presence of detrital glaucophane in a sandstone indicates a high-pressure low-temperature blueschist source that, hardly any property of detrital quartz or feldspar could reveal. Some minerals, such as sillimanite, kyanite, rutile, and most detrital garnet are exclusively metamorphic in origin. Most olivine and pyroxene, especially those rich in Fe, are igneous in origin. Magnetite and ilmenite can be either igneous or metamorphic. However, intergrowth and oxidation-exsolution textures controlled by crystallographic properties and mode of origin (observed with reflected light microscopy or in backscattered electron images) in detrital magnetite–hematite–ilmenite may distinguish igneous and metamorphic source rocks.

A recent and still rudimentary development in provenance studies is to trace the origin of seemingly inorganic material and structures to its biological parent. Unlike permineralized body fossils or impressions, some detrital material may be biogenic but may not have preserved the morphology of its biologic precursor. If and when the biological origin of such grains is proven and accepted by the community, their study would move from the realm of provenance to that of paleontology. For example, Schieber (1996) has discovered remnants of fossilized algal cysts associated with micron-scale detrital oval quartz grains that have generally been considered to be clastic quartz in mudstones, but are possibly silica-replacement of the cysts. A debate rages over a string of nanometer-scale euhedral magnetite crystals of hexaoctahedral prismatic morphology, which if exclusively biogenic, would support the existence of fossils in a Martian meteorite (Thomas-Keprta *et al.*, 2000).

In summary, many properties of minerals are characteristic of their pedigree. In practice, it is not always easy to isolate such properties but may be used in conjunction with other variables for very specific identification of source rocks.

Chemical

Weathering and diagenesis may modify the bulk chemical composition of detrital sediments rather severely even if petrographic identities of constituent grains are preserved. For example, feldspar grains weathered or altered (into clay) may still be recognized petrographically as feldspars, but their chemical composition is close to that of clays. A

quartz-cemented feldspathic sandstone in which detrital feldspars might have been silicified shows an anomalously high SiO₂ content. Albitization of calcic plagioclases changes the CaO/Na₂O ratio of the rock; calcite cementation moves the bulk composition in the opposite direction. K or Ba metasomatism during diagenesis may foster a false sense that the original detritus might have come from a K or Ba-rich source rock. However, not all K, even in shales with known K-metasomatism, results from diagenesis, and it is possible to identify the proportion of detrital and diagenetic K in some shales. There may also be cases where the bulk chemical composition may actually identify the family of a source rock, even though it can not be resolved petrographically. This is more likely in sediment that has lost its porosity very early in diagenesis and in which subsequent chemical diagenesis has been minimal. For example, if a siliciclastic rock has a large proportion of diagenetic matrix (*cf.* pseudomatrix, epimatrix), its chemical composition may tell if the precursor parent grains were volcanic (generally Fe–Mg-rich) or metamorphic (generally Al-rich) rock fragments. Completely argillized rock-fragments may not be readily identifiable in a thin section yet plug porosity and reduce the ease with which diagenetic fluids can permeate a rock. Thus, although weathering, transport, and depositional processes fractionate elemental abundances and ratios between source rocks and detritus in a basin, further fractionation during diagenesis is minimized in material of low porosity.

Bulk rocks. No element is absolutely immobile in the sedimentary system. Some are less mobile than others (e.g., Ta, Th, Zr, Sc, Co, Ti, V, Nb, Y, Th, some REE) and many pairs of these elements (e.g., Th/U, Zr/Y, La/Sm, Ti/Zr) maintain the same ratio relative to other pairs, as parent rocks are converted to sediments and sedimentary rocks. Most of these elements occur in very small quantities in the bulk of sedimentary rocks; most reside in minor and rare minerals, especially in heavy minerals (*q.v.*) and in or on clay minerals (*q.v.*). Because the distribution of heavy minerals, especially those rich in trace elements and rare earth elements, between samples of coarser detrital sediments may not be uniform, most informative data come from siltstones and shales. Provenance interpretation of TE and REE distribution in shales and siltstones is now common.

Mud and mudstones or graywackes comprised of significant argillaceous or argillized rock fragments derived from a large hinterland, transported by large rivers, and deposited on platforms or in large turbidite units, have large-scale provenances, such as the continental shield and the mountain chains beyond. Mudstones and graywackes with such large provenances, representing different time-slices of Earth-history, and collected from around the world, have been analyzed to monitor the temporal changes in the distribution of trace and rare earth elements in Earth's crust (Taylor and McLennan, 1995) and to model the growth of Earth's crust. The ability to infer the “big picture” in space and time through studies of muddy sediments is a consequence of using trace and rare earth elements (TE and REE) as the principal indicators. A pronounced increase in REE content takes place in sediments across the Archean–Proterozoic boundary, indicating a rapid growth of continental crust at that time.

Distribution and partitioning of TE and REE in igneous and metamorphic processes are far better known than in sedimentary processes. Inverse modeling to back-calculate the source composition of sediments is not possible yet.

Additionally, minerals rich in TE and REE (e.g., apatite, monazite, garnet, zircon) may not be homogeneously distributed through different grain size fractions of sediments; some may be susceptible to diagenetic alteration (e.g., apatite) and others may be so durable (e.g., zircon) that they can recycle not only through many sedimentary cycles but also through one or more plutonic cycles. Therefore, application of TE and REE studies to provenance analysis on a regional or a smaller scale is limited. Interpreting of the ultimate origin of the crystalline rocks (e.g., depleted or enriched mantle; crustal melting) from which sediments of a basin have been derived is more readily done than figuring out the nature and the identity of the immediate source rock.

The grain size effect can be offset by analyzing only the $<2\mu\text{m}$ fraction of sediments, which however excludes contribution of minerals that do not normally alter or disintegrate into the $<2\mu\text{m}$ fraction. Diagenetic effects in the distribution of TE and REE in shales, and by extrapolation in the $<2\mu\text{m}$ fraction, are now well documented. Nevertheless, studies at smaller scales and in conjunction with petrographic data are gradually defining and constraining the use of TE and REE as provenance indicators (Cullers, 2000). Because TE and REE analyzes can be made on small samples of $<2\mu\text{m}$ fractions, provenance and sediment dispersal patterns of carbonate sediments may also be traced using the small amounts of detrital clayey material dispersed in such rocks. At present, however, TE and REE characteristics are mostly useful for identifying arc-derived sediments including eolian dust.

Single minerals. Detrital sediments are but a mechanical collection of many single mineral grains each of which may retain a chemical memory of its origin. The more complex the composition of a mineral the higher is the probability of TE and REE substitutions in its crystal structure, which are sensitive to modes of formation of the mineral. Thus low quartz (SiO_2) does not allow much substitution in its lattice, but feldspar ((Ca, Na, K, Ba) $[\text{Al}_{2-x}\text{Si}_{2+x}\text{O}_8]$) provides ample opportunities for substitution. Of particular interest is the easy ability of Eu^{2+} to enter the plagioclase structure relative to other REE. The extent of Eu anomaly in a collection of consanguineous detrital plagioclase determined by instrumental neutron activation analysis (INAA), or determined on individual detrital grains by ion microprobes (SIMS; secondary ion mass spectrometer) indicates if their parental crystalline rock was derived from a source enriched or depleted in REE. Much less abundant detrital minerals, i.e., the heavy minerals, may have definitive chemical signatures of their origin, which can be determined by electron probe microanalysis or using analytical SEMs (scanning electron microscopes).

Luminescence, including *cathodoluminescence* (CL; *q.v.*) and *thermoluminescence* (TL) are physical properties of minerals. Both depend on a combination of the distribution of minor (and trace) elements and crystallographic properties and it is rarely possible to separate the physical from the chemical causes of luminescence. CL depends on the distribution of exciter and inhibitor ions that usually reside in minor to trace quantities in minerals, and on crystal defects such as vacancy in the oxygen site. CL of detrital silicate grains may be diagnostic with some unusual spectrum or fabric and may identify a specific source rock (Seyedolali *et al.*, 1997). More importantly, CL is commonly used to identify populations of zircons for ion microprobe age-dating of single grains. It is

common to find igneous cores (CL-bright) of zircon with metamorphic overgrowths (CL-dull), and to date the core and overgrowths separately. In addition, specific identification of CL spectra of particular source rock, for example, marble with a characteristic stress-history may identify the source-quarry of an ancient statue (e.g., Lapuente *et al.*, 2000); or, identical CL spectra of two diamonds may identify the jewels to be from a single raw stone (Sunagawa *et al.*, 1998). *Thermoluminescence* (TL) can be used, under favorable circumstances to age-date bodies of mostly Holocene sediments. Relative degrees of weathering and exposure to the atmospheres affect TL properties of sediments. Thus, TL is a good guide in identifying the origin and in tracing movements of coastal sands, sand dunes, and loess.

Isotopic

Stable isotopes. Principles and constraints that apply to the use of TE and REE in provenance analysis also apply to ratios of stable isotopes and radioisotopes. Robust stable isotopic signatures of source rocks are commonly preserved in selected mineral and rock fragments. Large sand grains seem to be less affected by diagenetic processes than smaller clay-sized grains and are the preferred material for analyzes. Ratios of $^{18}\text{O}/^{16}\text{O}$ and $^{13}\text{C}/^{12}\text{C}$ in carbonate detritus, such as foraminiferal tests or nodules in siliciclastic sediments, may uniquely identify the source. Isotopic identification of provenance of iceberg-rafted detritus, e.g., for Heinrich events or to track recycling of carbonate dusts is now routine. Isotopic ratios of carbon in organic matter are routinely used to trace the source of petroleum, as are certain organic molecules. Combined molecular-isotopic tracing of organic particles is indeed an extremely discriminating parameter. Oxygen isotopic ratios of detrital quartz and fluid inclusions therein may indicate their temperature of formation. For example, $\delta^{18}\text{O}/^{16}\text{O}$ of quartz from very high temperature rhyolitic tephra and low-temperature authigenic products are different although both types of grains may reside in a single body of sediment. Preservation of high temperature isotopic signature, however, may depend on the degree and selectivity of diagenetic reactions, which in the extreme may homogenize all $\delta^{18}\text{O}/^{16}\text{O}$ values of detrital quartz. The uniformity of oxygen isotopic ratios may also indicate recycling of sedimentary material such as in Vendian and Cambrian shales in Spain.

Radioisotopes. Precise radiometric age-dates perhaps connect detrital grains to source rocks most definitively. For example, from a U–Pb concordia, a 422 million year old granite clast in a Devonian conglomerate is uniquely tied to a specific Silurian granite the original source-terrain of which is identified to be 2445 million years old. Because weathering and diagenetic alterations may disturb the original isotope systematics, the precision in dating is often compromised. If source rocks had suffered retrograde events then some of the isotope systems might have been reset complicating the direct tie-in with daughter sediments. Sedimentary differentiation may preferentially concentrate certain minerals in different size fractions such that analyzes of size separates produce pseudo-isochrons, for example of the Rb–Sr system. Understanding of radioisotope systematics in sedimentary systems has increased substantially in the last 25 years and many of these methodological and natural artifacts have become known.

Determination of radioisotope systematics (mostly Sm–Nd, Rb–Sr, ^{40}Ar – ^{39}Ar , Pb–Pb, and U–Th disequilibria) and

dating Quaternary dust have immensely improved the understanding of its origin, movement, and its relation to geomorphologic changes and climatic conditions through time. For example, Innocent *et al.* (2000) trace the silt fraction in deep-sea sediments to riverine contribution and the movement of the $<2\ \mu\text{m}$ fraction to ocean bottom currents through Nd-isotopic measurements; Grousset *et al.* (1998) and Walter *et al.* (2000) recognize specific dust plumes produced during glacial and interglacial periods and deposited as discrete units from Sr and Nd isotopic studies; and, Aleinikoff *et al.* (1999) trace the sources of loess in Colorado using the Pb isotopic compositions of K-feldspars.

Ancient lithified sediments are commonly far too removed from their sources and their distribution systems (e.g., rivers, wind pattern) are mostly obliterated. Therefore, the origin and modes of movements of ancient sediments are much more difficult to trace than those of their Recent counterparts. If relatively unaltered large polymineralic rock fragments such as pebbles and boulders are present, it is possible to obtain mineral-separates for determining an isochron and estimating the age of the clast for provenance. However, polymineralic pebbles and boulders are not abundant in the sedimentary record nor are they necessarily unaltered. Disaggregation, mineral-separation, and age-dating many pebbles in one conglomerate may be much too time-consuming and perhaps not cost-effective. Populations of a detrital mineral if free from substantial weathering and diagenetic modification of the radioisotope system of interest may produce reliable isochrons and ages (Faure, 1986). Such populations could be separated by grain size (e.g., for feldspars) or color and shape (e.g., for zircon) to obtain appropriate isochrons and concordia for detrital minerals. Improvements in measurement techniques, such as secondary ion mass spectrometry (SIMS), laser ablation microprobe-inductively coupled plasma-mass spectrometry (LAM-ICP-MS), and thermal ionization mass spectrometry (TIMS) now allow age-dating individual detrital grains (especially zircon). The potential of such analyzes in provenance studies is immense. As SIMS becomes more readily available, one may expect to obtain age-dates of several individual grains from all samples of interest and truly collect representative and comprehensive range of ages of source rocks represented in a Formation. Much of current isotopic investigations of bulk sediments and single grains only provide an average provenance age of a sedimentary unit. This is because many detrital grains in clastic sediments are recycled and several source rocks commonly contribute to a single sedimentary unit. However, very ancient age of some detrital zircons indicates the existence of an early crust of the earth and is an important contribution by itself.

Fission tracks in apatite and zircon are robust indicators of ages of thermal events, which are commonly related to unroofing and cooling histories. Thus, apart from identifying source rocks under limited conditions, they provide good evidence for tectonic events especially about the exhumation history of an orogen. Fission track data contribute, albeit somewhat indirectly, to a necessary correction of U–Pb dating of detrital zircons that have endured post-deposition heating and cooling (Carter and Moss, 1999).

Purpose and future

The purpose of any provenance study dictates the choice of methods and the scope of the investigation. For example,

diverse approaches with varied samples are necessary to address a segment of the kinematics of Himalayan orogeny (e.g., DeCelles *et al.*, 1998) whereas a single confirmatory test can identify two fragments of a single diamond (Sunagawa *et al.*, 1998). For most geological problems, application of more than one method decreases the degree of uncertainty in the results. Part of the uncertainty is attributable to not only to the variability inherent in nature but also to the uncertainties associated with the methods themselves. It is necessary to be cognizant of both.

Very few provenance studies have attempted to quantitatively estimate the relative contribution of different rock units or tectonic units to a body of detrital sediments. For a more complete paleogeologic reconstruction of the earth through time, and estimating rates of relevant geologic processes, such quantitative analysis may be the future of provenance studies (Valloni and Basu, 2003).

PSEUDONODULES

Definition and description

Pseudonodules are a soft-sediment deformation structure comprising rounded masses of clastic sediment set in similar or finer-grained matrix. The terminology of pseudonodules

and ball-and-pillow structure (*q.v.*) is highly confusing. It is proposed here that pseudonodules can refer both to individual rounded masses, and to horizons comprising a single row of masses. Pseudonodule horizons can be subdivided into attached pseudonodules, in which the upper surfaces of the pseudonodules are level with the upper surface of the matrix (Figure P15(A),(B)), and detached pseudonodules that are overlain, as well as surrounded by matrix (Figure P15(F),(G)).

Pseudonodules are usually composed of sand or sandstone, or occasionally gravel or clastic limestone. The matrix is usually mud, mudstone or shale, although it may be sandstone, and may differ little in lithology from the pseudonodules (Figure P15(B)), in which case the structure may resemble convolute lamination (*q.v.*). Pseudonodules are usually semi-circular, oval or kidney-shaped, although some are contorted into zigzags or spirals. They range in length from a few centimeters to several meters, and in thickness from a few centimeters to a meter or so. Their outer surfaces may preserve structures such as ripple marks. Lamination within pseudonodules typically conforms to their outer margins, but may become more contorted toward the center. Lamination may be contorted in the matrix. There may be a lateral passage from pseudonodules to “normal” load casts affecting only the base of a bed. Pseudonodules are particularly common in shallow marine and deltaic deposits, but occur in most depositional environments, and similar structures are known from volcanoclastic and intrusive igneous rocks. Some periglacial involutions (cryoturbation structures) resemble pseudonodules.

Although pseudonodules resemble chemically formed diagenetic concretions or the products of spheroidal weathering, the presence of deformed laminae shows that they form by the physical disturbance of unconsolidated sediment. They are a type of load structure (*q.v.*), formed by the foundering of sediment into its substrate, but whereas “normal” load casts affect the base of a laterally continuous bed, pseudonodules seem to represent more extreme loading that led either to the detachment of sinking masses from the base of a bed or to the puncturing of a bed by rising plumes of buoyant sediment.

Historical development

The term pseudonodule (as “pseudo-nodule”) was introduced by Macar (1948), who recognized that contorted laminae within rounded sandstone masses encased in mudstone demonstrated that the structures had formed through deformation prior to lithification. There are few significant differences between the structures described by Macar (1948) and those described by Smith (1916) and Potter and Pettijohn (1963) as ball-and-pillow structure, and most authors have subsequently considered the terms ball structure (Smith, 1916), pillow-form structure (Smith, 1916), pseudonodule or pseudonodule (Macar, 1948) and ball-and-pillow structure (Potter and Pettijohn, 1963) to be synonymous. Other synonyms that have been introduced include: balled-up structure, crumpled ball, droplets, flow-fold, flow layer, flow rolls, flow structure, force-aparts, hassock structure, intra-stratal flowage, kneaded sandstone, mammillary structure, sand rolls, sandstone balls, sandstone flow, slump balls, snowball structure and storm rollers.

Various criteria have been used by other authors to differentiate between pseudonodules and ball-and-pillow structure, including: the recognition of a source layer for ball-and-pillow structure; the occurrence of pseudonodules in

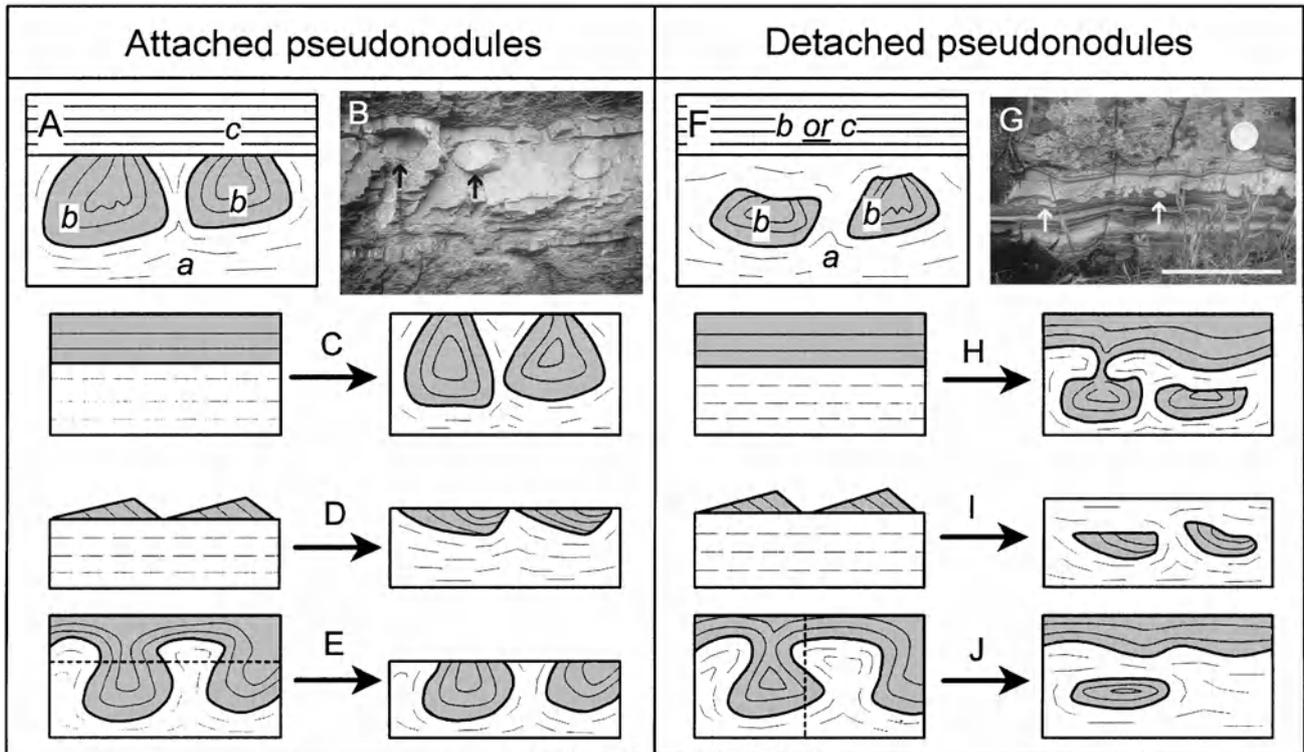

Figure P15 Definition and interpretation of pseudonodules. See text for explanation. B shows attached pseudonodules (arrowed) from Upper Carboniferous delta mouth bar sandstones at Amroth, west Wales, UK. The pseudonodules and their matrix are of similar lithology. The illustrated section is 1.5 m thick. G shows detached pseudonodules (arrowed) and load casts on the base of a tuff bed from the Ordovician of Ramsey Island, west Wales, UK. Scale bar (bottom right) is 10 cm.

a single row, as opposed to vertically stacked masses in ball-and-pillow structure; the use of pseudonodule to describe a single mass and ball-and-pillow structure for a horizon of pseudonodules; or a difference in the inferred origin. What seems clear is that soft-sediment deformation structures comprising rounded masses isolated in matrix are sufficiently distinct from load casts to merit a separate name, and that sufficient variation exists to define several structures in a continuum from load casts to pseudonodules and ball-and-pillow structure. The definitions presented here combine several of the above criteria in an easily applied, objective scheme.

Interpretation

Some early workers interpreted pseudonodules as the products of lateral movements on slopes, but experiments by Kuenen (1958) demonstrated that most pseudonodules are a type of load structure (*q.v.*), in which vertical displacements are driven by variations in gravitational potential energy. Most load structures develop where denser sediment overlies less dense, but similar deformation results from the foundering of an unevenly distributed load (e.g., bedform relief). Deformation can occur in a system in which potential energy is not at a minimum if a lower layer becomes liquidized (i.e., undergoes a

temporary reduction in strength). This allows the upper layer to founder and the lower to rise buoyantly. Several mechanisms of liquidization are associated with the expulsion of excess pore fluid, and some load structures represent a type of fluid escape structure (*q.v.*).

Examples of deformation pathways that can lead to pseudonodules are shown in Figure P15. These can operate in combination, and the end products may be further complicated through the action of lateral forces related to slopes or currents, giving an asymmetry to the pseudonodules. The morphology of pseudonodules is influenced by the relative viscosity of the sediment layers (Anketell *et al.*, 1970), and sinking pseudonodules can deform if they encounter an obstruction, such as non-liquidized sediment.

Methods by which attached pseudonodules can form include: the puncturing of an upper layer by rising buoyant plumes (Figure P15(C); *cf.* experiments described by Owen, 1996); the foundering of an unevenly distributed load (Figure P15(D)); or erosion of load casts (Figure P15(E)). Detached pseudonodules can form by: detachment of masses sinking from the base of an upper layer (Figure P15(H)); complete disruption and foundering of a denser layer (*cf.* experiments by Kuenen, 1958); continued sinking of an unevenly distributed load (particularly if the load is denser than its substrate: e.g., loading of sand ripples into mud as in Figure P15(I)); certain cross-sections of load casts (Figure P15(J)); or isolated slump folds.

Significance of pseudonodules

Pseudonodules record the post-depositional disturbance of sediment by loading processes driven by gravitationally unstable density gradients or by unevenly distributed sediment load. Their presence has implications for the physical state of sediment shortly after deposition, which may relate to depositional processes (Rijsdijk, 2001).

Several factors may favor the formation of pseudonodules over load casts confined to the base of a continuous layer. These include: (a) a driving force of high magnitude (e.g., an unusually large density contrast); (b) a combination of driving forces (e.g., sand bedforms on a mud substrate); (c) a lower layer of very low strength (e.g., deposition of sand onto freshly-deposited mud); or (d) prolonged deformation (e.g., a very thick or fine-grained lower layer, since for some liquidization mechanisms the time needed for strength to be restored is proportional to layer thickness and inversely proportional to grain-size).

Several liquidization mechanisms are initiated by the action of a triggering agent, and pseudonodule horizons have been used as evidence of paleoseismicity, although load structures can readily be triggered by other agents such as the rapid deposition of sediment. The common association of pseudonodules with shallow marine deposits may point to storm activity as a common trigger.

Q

QUARTZ, DETRITAL

Detrital quartz forms about 35 percent of the mineral grains in sedimentary rocks, an amount subequally divided between sandstones and mudrocks. Because of its abundance its internal features, grain size, and shape have been the topic of thousands of journal articles since the 1850s. However, despite this extraordinary effort the amount of information that can be obtained from the mineral is not large.

Internal structure

Many investigations of detrital quartz have concerned its internal structure, particularly the degree of crystal deformation and the character of the crystals in polycrystalline grains (pure quartz rock fragments). Results reveal that nearly all quartz crystals are visibly plastically deformed, a property described in thin section as undulatory extinction. Polycrystalline quartz grains contain crystals that may be elongated or equant, crystallographically aligned or not, unimodal or bimodal in size, and the crystals may have smooth contacts with their neighbors or be interpenetrating (sutured). Elongated and/or aligned crystals and bimodal crystal size distribution indicate recrystallization and, therefore, derivation from a metamorphic rock. Undulatory extinction in crystals and variable types of crystal contacts are common in both metamorphic and igneous rocks.

As the total amount of kinetic energy applied to quartz grains during their sedimentary life increases, polycrystalline grains and grains with undulatory extinction are preferentially destroyed (Figure Q1). Polycrystalline grains fracture along crystal boundaries to produce smaller single crystals of quartz. Crystals with undulatory extinction are destroyed more easily than crystals without undulatory extinction so that pure quartz sandstones are preferentially enriched in nonundulatory grains. The average pure quartz sandstone contains about 40 percent nonundulatory grains, compared to 15 percent to 20

percent in the igneous and metamorphic rocks from which the grains were derived.

Quartz crystals in porphyritic volcanic rocks are generally not plastically deformed and, therefore, are abundant in volcanoclastic sandstones. But in most sandstones quartz grains from porphyritic volcanic rocks are trivial in abundance compared to quartz grains from granites, gneisses, and schists.

Mineral inclusions

Most detrital quartz grains lack mineral inclusions but a wide variety of these inclusions have been described from detrital grains. Commonly the inclusions are too small to be identified with certainty in thin section using only a polarizing microscope. Any mineral found in igneous and metamorphic rocks can be found in detrital quartz. Insofar as the mineral is diagnostic of a specific type of rock it can be useful in provenance determinations. Although there have been numerous studies of mineral inclusions in crystalline rocks, only one investigator (Tyler, 1936) has used inclusions in sandstones for provenance determination. Unfortunately, the sandstone was the St. Peter (Cambrian, Wisconsin), now known to be composed largely of recycled grains from a wide variety of crystalline rocks so that there can be no check on Tyler's conclusions regarding the accuracy of mineral inclusions as an indicator of provenance.

Grain size

Detrital quartz grains vary in size from cobbles to clay. Cobble and pebble size grains are derived largely from either metaquartzites or hydrothermal veins. Those from hydrothermal veins commonly are milky or white in color, an effect produced by inclusions of water bubbles. As grain size decreases into the granule and coarse sand sizes, the proportion of quartz grains derived from granitoid rocks and gneisses increases. In finer sizes the proportion of quartz grains from schists increases. In granule and coarse sand sizes the grains are mostly polycrystalline but in fine sand sizes single crystals dominate. In silt sizes polycrystalline grains are rare.

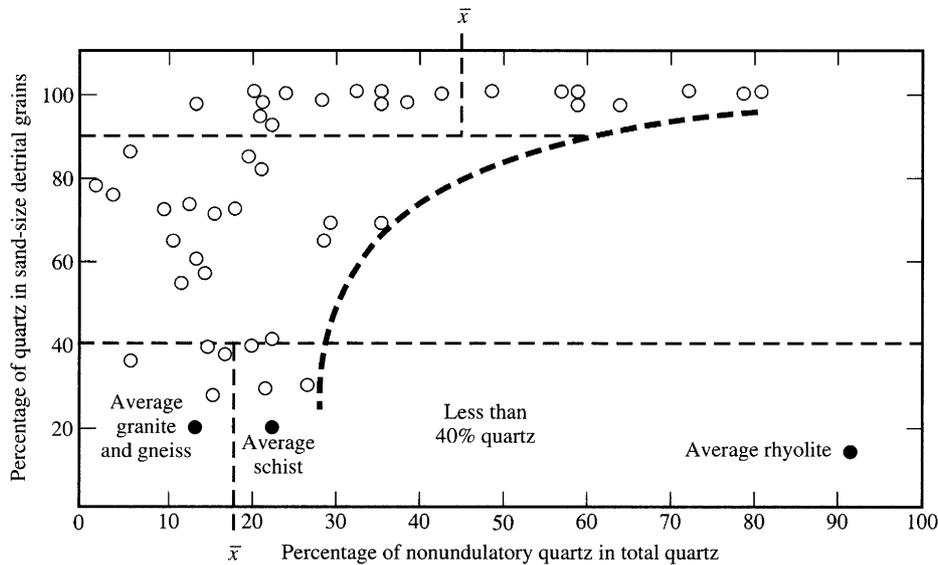

Figure Q1 Relationship between percentage of quartz in crystalline rocks and sandstones and percentage of that quartz that has undulatory extinction (Blatt and Christie, 1963).

This indicates that chert is not an important source of quartz silt.

Part of the change in internal character of quartz with decreasing grain size results from the disintegration of polycrystalline grains during soil formation, impacts during stream transport, and high velocity impacts in environments of deposition such as beaches, marine sand bars, and desert dunes. More important as an explanation, however, is the source rock of most silt size quartz grains. Isotopic evidence indicates that the bulk of detrital silt size quartz grains are generated by disintegration of low-grade metamorphic rocks such as slates, phyllites, and low-grade schists (Figure Q2). These source rocks contain quartz crystals mostly of silt size, which are released into the sedimentary environment as the rocks decay and the grains are eroded. Most silt size detrital quartz grains are not produced by abrasion of coarser quartz particles released from granites and gneisses and coarse grained schists. This fact reflects the hardness of quartz, lack of cleavage, chemical stability, and the fact that quartz sand is transported in streams by saltation, in which impacts with other quartz grains are limited. Apparently, disintegration of polycrystalline quartz grains produces fine quartz sand but little silt.

Detrital quartz is rare in sizes smaller than about two micrometers.

Depositional environment

Detrital quartz tends to be more abundant in some depositional environments than in others. This reflects the fact that feldspars and polymineralic rock fragments are more easily disintegrated than quartz in environments of high kinetic energy. Hence, beaches, marine sand bars, and desert dunes tend to be richer in quartz than are rivers and alluvial fans. But exceptions are common. The amount of quartz in a sedimentary rock is not a reliable environmental indicator.

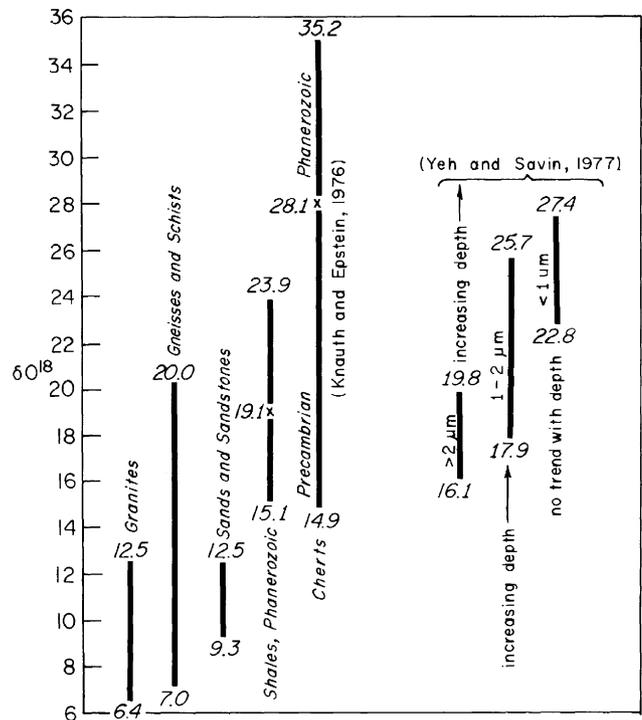

Figure Q2 Range in $\delta^{18}\text{O}$ values in quartz from sedimentary rocks and various types of coarse grained source rocks. Quartz in the few slates and phyllites that have been analyzed (not shown) have $\delta^{18}\text{O}$ values that average 19 (Blatt, 1987).

Quartz cobbles and pebbles travel in streams by rolling and hence are nearly always rounded. The degree of roundness of quartz sand has been used as an indicator of depositional environment but this also is not reliable. Quartz sand grains

can be rounded only in environments of high kinetic energy (not in rivers) but such rounded grains can be subsequently incorporated into environments of low kinetic energy following burial, uplift, and erosion. Recycling is a common phenomenon but the percentage of recycled quartz in sedimentary rocks is unknown. Probably it is quite high.

The percentage and grain size of detrital quartz have been used as an indicator of distance from shore in shallow marine mudrocks. As distance increases, quartz grain size decreases, as does the quartz/clay mineral ratio. Alignment of elongate quartz grains can reveal dominant current directions but directions are more easily deciphered using cross-bedding or other sedimentary structures.

R

RED BEDS

“Red Beds” is the term applied to sedimentary sequences which are predominantly red in color but usually associated with variable proportions of interdigitated drab strata, typically grey, grey-green, brown, or black. They comprise a wide range of facies representing the whole spectrum of non-marine depositional environments from alluvial fans, river floodplains, deserts, lakes, and deltas, and range in age from Early Proterozoic to Cenozoic. Red beds are economically significant; they host a large number of oil and gas reservoirs and are associated with tabular copper and uranium–vanadium deposits (Rose, 1976; Hansley and Spirakis, 1992). Oxidation–reduction reactions play a key role in the formation of red beds in both the depositional and post-depositional settings. The nature and abundance of organic material is thus a key factor in determining the particular characteristics of a red bed sequence.

Red beds are colored by finely disseminated ferric oxides, usually in the form of hematite (α -Fe₂O₃) and generally have a color between 5R and 10R of the rock color chart (Goddard, 1951). Oxidation-reduction (Eh) and pH control hematite formation and the observed minor color variations seen in red beds. In general, the color variations relate to changes in pore water chemistry resulting from fluctuations in depositional or early diagenetic environment. In particular, intercalated marine units are normally non-red because of the reducing conditions generated below the sediment–water interface and such color changes can be a sensitive indicator of base level shifts in marginal marine sequences. The occurrence of ferric oxides in red beds indicates that they formed under oxidizing conditions and that the Earth’s atmosphere was oxidizing. In this context they hold great significance for the evolution of life and much of the key evidence for the evolution of terrestrial faunas and floras including amphibians, reptiles (including dinosaurs) and mammals is found in red bed sequences. However, although it is clear, no particular paleoclimatic significance can be

attached to them, since they are known to form in both arid and moist tropical climates.

In the past the actual mechanisms of red bed formation have been widely debated and we now know that red beds are polygenetic in origin. The conditions for red bed formation necessarily coincide with those that are needed for hematite formation since this mineral causes the red coloration. These include positive Eh and neutral to alkaline pH, conditions which, at the surface at least, are met in hot, continental low latitude areas. Marine red beds are rare because of the abundance of organic material in the marine environment. They do, however, constitute a distinct group of red beds and are included in the classification here. Three principle mechanisms have been proposed to explain the origin of the red color in continental red beds, each relating to a different stage in the depositional and diagenetic history. Four groups of red beds are recognized as follows:

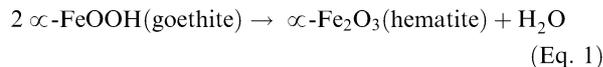

- (1) *Primary red beds*. Deposition and early diagenesis from the erosion of lateritic soils in wet uplands and the aging of ferric hydroxides, especially in the pedogenic environment;
- (2) *Diagenetic red beds*. Burial diagenesis and the intrastratal solution of ferromagnesian silicates;
- (3) *Secondary red beds*. Weathering and ferruginization of non-red strata after uplift;
- (4) *Marine red beds*. Very low organic productivity and slow sedimentation rates resulting in oxic conditions below the sediment–water interface.

Primary red beds

Krynine (1950) suggested that red beds were formed primarily by the erosion and redeposition of red soils or older red beds. A fundamental problem with this hypothesis is the relative scarcity of recent red colored alluvium, and Van Houten (1961) developed the idea to include the *in situ* (early diagenetic) reddening of the sediment by the dehydration of brown or drab colored ferric hydroxides. These ferric hydroxides commonly include goethite (α -FeOOH) and so-called “amorphous ferric hydroxides” or limonite. In fact, much of this material may be the mineral ferrihydrite which has a composition near 2.5 Fe₂O₃ · 4.5 H₂O. This dehydration

or "aging" process is now known to be intimately associated with pedogenesis in alluvial floodplains and desert environments.

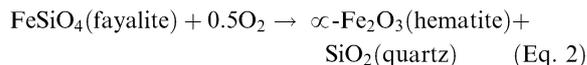

Berner (1969) showed that ferric hydroxide (goethite) is normally unstable relative to hematite and in the absence of water or at elevated temperature will readily dehydrate according to the reaction:

The Gibbs free energy (ΔG_r) for this reaction at 25°C is -2.76 kJ/mol and Langmuir (1971) showed that ΔG_r becomes increasingly negative with smaller particle size. Thus detrital ferric hydroxides including goethite and ferrihydrite will spontaneously transform into red colored hematite pigment with time. This process not only accounts for the progressive reddening of alluvium but also the fact that older desert dune sands are more intensely reddened than their younger equivalents. Folk (1976) showed that the red color of dune sands in the Simpson Desert of Australia was formed during an older period of lateritization and subsequent dehydration of the ferric hydroxides. This paper formed a good model for the reddening process in ancient eolian dune sequences.

Diagenetic red beds

The formation of red beds during burial diagenesis was clearly described by Walker (1967) and Walker *et al.* (1978). The key to this mechanism is the intrastratal alteration of ferromagnesian silicates by oxygenated groundwaters during burial. Walker's studies show that the hydrolysis of hornblende and other iron-bearing detritus follows Goldich's stability series. This is controlled by the Gibbs free energy (ΔG_r) of the particular reaction. For example, the most easily altered material would be olivine:

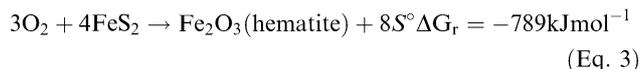

with $\Delta G_r = -27.53 \text{ kJ/mol}$

A key feature of this process, and exemplified by the reaction, is the production of a suite of by-products which are precipitated as authigenic phases. These include mixed layer clays (illite-montmorillonite), quartz, potash feldspars, and carbonates as well as the pigmentary ferric oxides. Reddening progresses as the diagenetic alteration becomes more advanced and is thus a time-dependent mechanism. The other implication is that reddening of this type is not specific to a particular depositional environment. However, the favorable conditions for diagenetic red bed formation, i.e., positive Eh and neutral-alkaline pH are most commonly found in hot, semi-arid areas, and this is why red beds are traditionally associated with such climates.

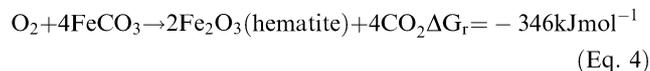

Secondary red beds

Secondary red beds are characterized by irregular color zonation, often related to sub-unconformity weathering profiles. The color boundaries may cross-cut lithological contacts and show more intense reddening adjacent to unconformities. Johnson *et al.* (1997) have also showed how

secondary reddening phases might be superimposed on earlier formed primary red beds in the Carboniferous of the southern North Sea. The general conditions leading to post-diagenetic alteration have been described by Mücke (1994). Important reactions include pyrite oxidation:

and siderite oxidation:

Secondary red beds formed in this way are an excellent example of telodiagenesis. They are linked to the uplift, erosion, and surface weathering of previously deposited sediments and require conditions similar to Primary and Diagenetic red beds for their formation.

Marine red beds

The scarcity of marine red beds is due to the fact that in the marine environment there is abundant organic material and reducing conditions prevail below the sediment-water interface and the stable iron-bearing phase is pyrite (FeS_2). This is a consequence of bacterial activity which results in marine sulfate reduction and the destruction of detrital iron oxides. The process may be summarized using the following equations in which organic material is given the general formula CH_2O . Initially sulfate reduction results in the formation of bicarbonate and hydrogen sulfide:

This followed by the reduction of iron ($\text{Fe}^{3+} \rightarrow \text{Fe}^{2+}$) and the combination of ferrous ion, initially as an intermediate phase such as mackinawite ($\text{FeS}_{0.9}$) or greigite (Fe_3S_4) and subsequently as pyrite as shown in the reaction:

When organic productivity is very low or the rate of sedimentation is very slow the organic material may be completely destroyed and oxidizing conditions (the Eh fence) migrates downward through the sediment column. Under these conditions detrital iron oxides remain stable and further hematite may be produced by equation 1. This is the mechanism by which deep marine red clays and other pelagic red beds form (Froelich *et al.*, 1979; see *Oceanic Sediments*).

Paleomagnetism of red beds

Red beds have long been a source of paleomagnetic data since they have a very stable natural remanent magnetization (NRM). The magnetization is carried by hematite due to its intrinsic spin-canted antiferromagnetism. In some red beds the ferrimagnetic magnetite Fe_3O_4 is also present but typically this is only found in younger (Mesozoic and Tertiary) sections. There has been much debate regarding the validity of paleomagnetic data from red beds; clearly for detailed paleomagnetic analysis the remanence must have been acquired at, or shortly after, deposition. This mechanism is

called depositional (DRM) or post-depositional remanent magnetization (PDRM) and appears to be important in fine grained sediments where magnetic oxides are small enough to rotate into the ambient magnetic field prior to compaction. Magnetizations of this type enable red beds to accurately record the geomagnetic field and there have been many magnetostratigraphic applications, particularly in dating, and correlation of paleontologically-barren sequences (e.g., Baag and Helsley, 1974; Johnson *et al.*, 1982)

The growth of authigenic hematite in red beds results in the formation of chemical remanent magnetization (CRM) and frequently because of the protracted nature of mesodiagenesis such magnetizations are multicomponent and complex (see Turner, 1980 for a detailed discussion). In the future, paleomagnetism will prove to be a valuable technique in dating diagenetic events in red beds and will help resolve the difficulties of distinguishing between different types of red bed sequences.

REEFS

Definitions and classifications

While originally defined by mariners as any shallow and hard submarine structure potentially hazardous to vessels, the term reef is restricted in earth sciences to mean *laterally confined carbonate bodies built by sessile benthic aquatic organisms*. This definition is wide enough to include reef structures of all ages, yet precise enough to identify reefs as a recurring biological phenomenon.

Another common definition restricts reefs to rigid, wave-resistant biogenic structures with a significant syndepositional relief and composed mainly of *in-situ* framework builders. These attributes are often difficult to demonstrate in the fossil record and should not be included in a geologic reef definition. Moreover, even Holocene coral reefs often are internally composed of reworked framework and bioclastic debris (Hubbard *et al.*, 1998) rather than consisting of an *in-situ* framework.

Reefs are unique sedimentary systems because they significantly modify the environment and structure their own habitat. Shallow water reefs are protectors of tropical coasts and stabilize platform margins. Reefs and their sand- to boulder-sized debris form important hydrocarbon reservoirs.

The most widely used reef classifications focus on environment, geometry, and composition. For modern coral reefs, Charles Darwin (1842) recognized fringing reefs, barrier reefs, and atolls. He identified these environmental reef types as belonging to a genetic sequence linked to subsidence history. A fringing reef grows along the shore. With subsidence and continued reef growth, lagoonal sediments fill the space between the former shore and the reef becomes a barrier reef. If all preexisting land is submerged and only the reef and lagoonal sediments remain, the reef will eventually form an atoll. Barrier reefs and atolls exhibit a pronounced facies zonation including (from lagoon to open ocean): back reef, reef flat, reef crest, reef front, and fore reef. Darwin's model, although still valid today and often applicable to the fossil record, must be broadened to include other environmental reef types with or without modern counterparts. Patch reefs (equivalent to platform reefs) were common throughout the geological record. They are isolated reef structures mostly in

lagoonal settings, on carbonate platforms, or in epeiric seaways. Reefs growing on submarine ramps and slopes are rare today but were common in the past.

Geologists traditionally emphasize geometrical reef attributes subdividing bioherms and biostromes. A *bioherm* is a mound-shaped structure, while a *biostrome* is a roughly tabular structure without a significant syndepositional relief. The term *bioherm* is roughly equivalent to ecologic reef or buildup, and *biostrome* roughly agrees with a stratigraphic reef (Dunham, 1970). Other common geometrical terms in reef classification include banks (tabular structures similar to biostromes but mostly micritic in composition) and pinnacle reefs (nearly cylindrical isolated structures often surrounded by basal sediments). Terms such as ball, dish, haystack, kalyptra, mamelon, spread-eagle, and spruce describe the length/width ratio and overall shape of reef bodies in more detail.

A compositional classification of reefs is usually based on three principal components: skeletons, carbonate matrix, and carbonate cement. Framework reefs, reef mounds, and mud mounds are identified. A *framework reef* consists of skeletal organisms in mutual contact. Skeletal organisms range from calcified microbes to complex metazoans and framework. *Reef mounds* consist of approximately equal proportions of skeletal organisms and a matrix of carbonate mud and marine cement; they appear to be matrix-supported. A *mud mound* is dominated by carbonate mud and marine cement, whereas skeletal framework is almost absent. The origin of micrite and marine cement in reefs is continuously disputed and should therefore not be included in the reef definition. If microbes are identified in micrite-rich mounds the term microbial mound can be applied. Evidence for the both active and passive microbial participation in micrite production is increasing, even in mounds without obvious stromatolitic or thrombolitic structures (Riding, 2000). Common features of many ancient reefs are large volumes of marine cement often in the form of *Stromatactis* (*q.v.*). Additional compositional attributes used to classify reefs include the dominant biota (e.g., coral reef or sponge reef), the growth forms and constructional role of reef builders, and the density of framework.

Complex reef classifications combining constructional, compositional, and genetic attributes have been published (Insalaco, 1998), but their utilization is limited because genetic interpretations, often changing with scientific views, are intrinsic to the classification. Descriptive geometrical and compositional classifications should be preferred in the study of ancient reefs.

Reef builders

Reef builders are organisms that contribute to reef growth either directly by the accumulation of their skeletal material or by their metabolic activity. Cyanobacteria and other bacteria, microalgae, and fungi represent the microbial consortium that played a substantial role in reef-building throughout the Proterozoic and Phanerozoic. The functional role of microbes in reef-building is to trap and bind sediment, and to induce carbonate precipitation (Reitner and Neuweiler, 1995). Microbial crusts are often important to provide physical strength to a reef and if possessing external calcified walls microbes could play a substantial role in framework construction. Calcareous algae have been notable reef builders throughout the

Phanerozoic and became especially important when global climate was deteriorating (Kiessling, 2001).

The most important sessile invertebrate animals acting as reef builders are sponges and corals. Although coralline sponges almost exclusively live in reef caves today, where they are reef dwellers rather than builders, various sponge groups such as archaeocyaths, stromatoporoids, pharetronids, chaetetids, and lithistids were very important reef builders in particular Phanerozoic periods (Figure R1). The great dominance of coral reefs in modern tropical seas has led to an almost synonymous treatment of coral reefs and reefs in general. Yet although corals—Tabulata and Rugosa in the Paleozoic, Scleractinia in the Mesozoic and Cenozoic—were important reef builders from the Upper Ordovician until today, it is only in the Mesozoic that coral reefs became predominant (Figure R1). Even in the Mesozoic, bivalves as reef builders, most notably the rudists in the Cretaceous, occasionally outnumbered corals. The great success of scleractinian corals in reef-building is related to the efficient symbiosis with unicellular algae (zooxanthellae), which permit corals to grow rapidly in nutrient-depleted waters. Other Phanerozoic reef builders were bryozoans and occasionally brachiopods, pelmatozoans, and worms.

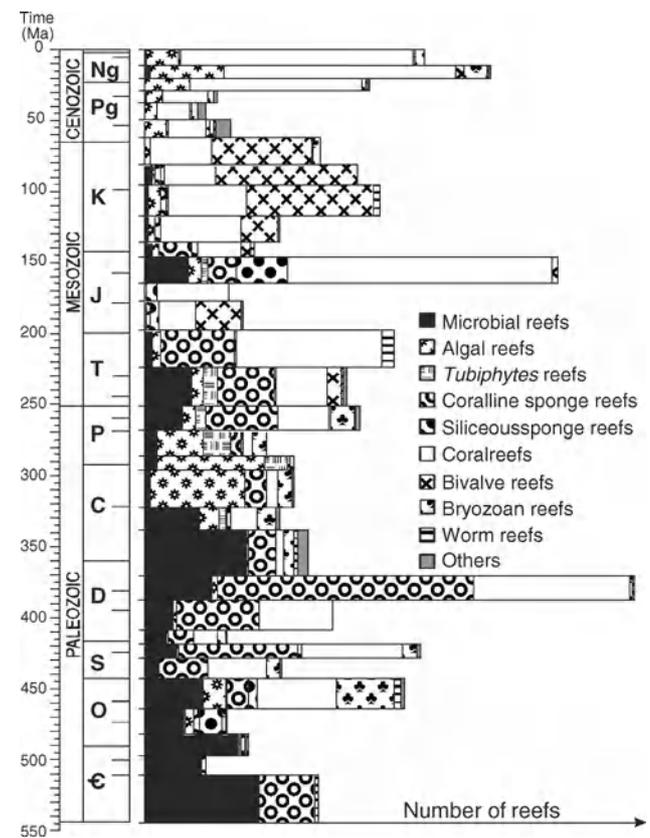

Figure R1 Relative and absolute abundance of Phanerozoic biotic reef types. Time slices represent supersequences as defined in Kiessling *et al.* (1999).

Reef distribution

The reef definition presented in the first paragraph is wide enough to include “tropical” reefs and nontropical or cool-water reefs. Tropical coral reefs, mostly composed of zooxanthellate scleractinian corals and coralline algae are limited today between 35°S and 34°N at western oceanic margins, where warm nutrient-depleted currents reach fairly high latitudes. The tropical reef zone is confined toward the eastern side of oceans where cool nutrient-rich currents reach low latitudes (Figure R2(A)). However, in modern high latitudes (up to more than 70° latitude) reefs are widespread as well. In shallow water, coralline algae may form reefs up to 500 m across (Freiwald and Henrich, 1994), whereas deep water slopes fed by nutrient-rich water sometimes bear impressive reef mounds constructed by azooxanthellate corals (Freiwald *et al.*, 1999). While modern tropical reefs are largely

controlled by temperature and light availability, cool-water reefs require high nutrient concentrations and low terrigenous input. Cool-water reefs differ in biological composition from tropical reefs and are geographically isolated from the tropical reef zone. Applying these criteria to detect cool-water reefs in the fossil record, Kiessling (2001) noted that cool-water reefs have a much less continuous record than tropical reefs. Cool-water reefs apparently only proliferated during icehouse climatic intervals, possibly because only then were high latitudes significantly enriched in nutrients.

A changing ecology of reefs is suggested by variable global reef distribution patterns. For much of the Paleozoic, reefs grew inside vast epeiric seaways and were more common along the eastern margin of oceans than today (Figure R2(B)). Since eastern oceanic margins and shelf seas are usually enriched in nutrients, Paleozoic reefs were apparently more

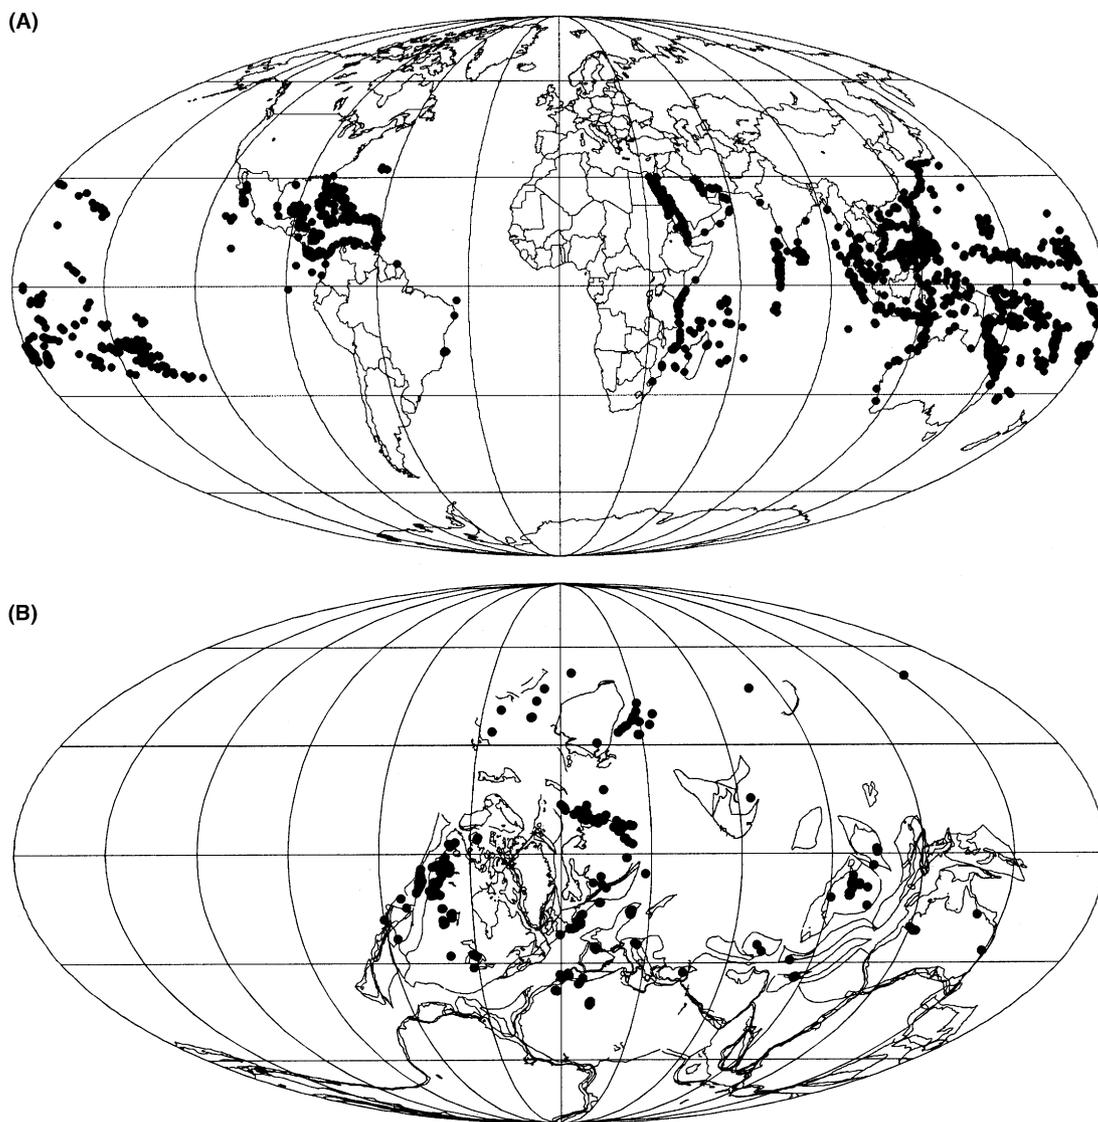

Figure R2 Geographic “tropical” reef distribution pattern today (A) and in the Middle Devonian (B).

nutrient-opportunistic than Mesozoic and Cenozoic reefs, possibly because Paleozoic reef builders did not host photo-autotrophic symbionts or the host-symbiont interactions were not as efficient as today.

Temporal trends and fluctuations in reefs

Whether reefs represent a global evolving ecosystem, or a chance association of species with similar ecological requirements (Wood, 1999, p.9) is still disputed. However, within the wide range of reef structures found in the fossil record, several significant temporal trends are evident in a large database incorporating all Phanerozoic reef types (Kiessling *et al.*, 1999). The most significant trends are related to the declining participation of microbes in reef-building through the Phanerozoic (Figure R1). The number of mud mounds and the relative abundance of both micrite and spar declined, whereas the number of framework reefs increased through time. The number of barrier reefs, the amount of reefal debris, and the intensity of bioerosion apparently also increased during the Phanerozoic. The skeletal mineralogy of reef builders showed a systematic trend from predominantly calcitic reef builders in the Paleozoic to aragonitic reef builders in the Cenozoic. Reef diversity, reef abundance and preserved reef dimensions all vary substantially through time without an underlying trend.

The controls behind these trends and fluctuations are largely unknown. Attempts to correlate long-term changes in reefs with geological changes have so far produced equivocal results. This has three main reasons: (1) different reef types and organisms respond differently to the same climatic or chemical changes (Webb, 1996); (2) intrinsic evolutionary changes in reefs may be more important than extrinsic forcing, and (3) geological as well as reef ecosystem changes are currently insufficiently resolved both temporally and spatially to test rigorously whether they are causally linked.

RELICT AND PALIMPSEST SEDIMENTS

In 1952, K.O., Emery defined relict sediments as “remnant from a earlier and different environment,” and in 1968, expanded the definition to “...sediments that were deposited long ago in equilibrium with their environments; afterward, the environments changed so that the sediments are no longer in equilibrium even though they remain unburied by later sediments.” Although the qualifier does not appear in this extracted definition, both papers applied the term to continental shelf sediments. The term is a codification of earlier thought about the continental shelf, in which the “coastal profile,” a concave-upward exponential curve, was seen as an equilibrium response to the coastal regime of waves and tides (Gulliver, 1899). The response was thought to involve not only the shape of the curve, but the distribution of grain sizes along it. “the subaqueous profile is steepest near the land where the debris is coarsest and most abundant, and progressively more gentle further seaward where the debris has been ground finer and reduced in volume by the removal of part in suspension. At every point, the slope is precisely of the steepness required to enable the amount of wave energy there developed to dispose of the volume and size of debris there is in transit” (Johnson, 1919). Such comments amounted to “thought experiments” on the part of Edwardian geomorphologists such as Douglas Johnson, who had no access to research vessels. Francis Shepard (1932), who did, and who was willing to compile notations from maps in areas which he could not sample, argued to the contrary, “the most outstanding feature on continental shelves is the general scarcity of outward decreasing gradation in texture.” This condition he attributed to lowered sea level during Pleistocene glacial episodes, which exposed the shelf, and subjected it to deposition of till at high latitudes and fluvial sand and gravel at low latitudes. The explanation was given formal expression by Emery (1952, 1968), Francis Shepard’s student. Emery contrasted *relict* sediments with such presently forming (*modern*) classes as *detrital* (water, ice, and wind), *biogenic*, *residual*, *authigenic*, and *volcanic* sediments. The main contrast was that between modern detrital sediments on shorefaces and shelves near river mouths (usually fine-grained, dark, and muddy) and the relict sediment found further seaward usually coarser-grained and iron-stained. Many modern detrital sediments showed seaward-fining grain size gradients, but grain size in the relict sediment, at least at the 10 km or greater sample spacing

characteristic of the early surveys, seemed to vary in a random manner.

During the period of rapid geological exploration of continental shelves in the 1970s and 1980, the concepts of modern, detrital, and relict sediment filled a need, and relict sediments were described from many of the world's shelves (Slatt and Lew, 1973; Herzer, 1981; Barrie *et al.*, 1984; Shen, 1985). More thought was given to the issue. Swift *et al.* (1971) described a *palimpsest* sediment as "one which exhibits petrographic attributes of an earlier depositional environment and in addition of a later [modern] environment." McManus (1975) distinguished between *in situ* relict and palimpsest deposits on one hand, and freshly sedimented materials which might be completely derived from reworking of the bottom (*proteric* sediments), partially so derived (*amphoteric* sediments), or might be entirely new to the environment (*neoteric* sediments). At the same time, advances in automating textural analysis (Ehrlich and Weinberg, 1970) lead to quantitative criteria for applying these terms (Brown *et al.*, 1980; Mazzullo *et al.*, 1983).

A persistent problem in the application of "relict" and related terms to the interpretation of shelf sediment has been the lack of quantitative and analytical understanding of the equilibrium from which the relict sediment is supposed to be a departure. While Ehrlich and Weinberg (1970) and their co-workers achieved considerable success in distinguishing among sources and agents of sediment input on continental shelves by means of grain shape analysis, the progression of the sediment toward textural maturity defined by it is not an equilibrium concept. The equilibrium parameter implicit in the early discussions (Emery, 1952, 1958) is grain size. Grain size frequency distributions have long been seen as equilibrium responses to the hydraulic regime (e.g., Johnson, 1919) however, the problem is a complex one, encompassing aggregate behavior at a range of spatial scales. Not only must grain size frequency distributions of individual bottom samples be understood in terms of boundary layer fluid dynamics (e.g., Sengupta *et al.*, 1991), but regional patterns of grain size must be understood in terms of advective-diffusive grain transport (Clarke *et al.*, 1983; Swift *et al.*, 1986).

RELIEF PEELS

Relief peels are produced by impregnating a thin, surficial layer of unconsolidated, granular sediment. Because of spatial differences in the porosity and permeability, the binding agent penetrates to different depths, producing relief on the peel's surface (Figure R3). The differences in porosity and permeability are themselves determined by subtle differences in grain size, sorting, and packing that are created during deposition of the sediment and/or during any post-depositional bioturbation, deformation, or incipient diagenesis. Such peels have been used extensively since the early 1950s to study the physical and biogenic structures present in modern deposits and unconsolidated older sediments. Commonly, the impregnation process yields a more detailed record of those structures than can be seen in the original core or exposure. The permanence of the peel allows for more thorough study than would be possible otherwise, and photography can be done under controlled lighting conditions, providing better documentation of the structures than might be possible in the field. Relief peels obtained from two or more, mutually

perpendicular surfaces offer the possibility of preparing three-dimensional reconstructions of the structures (*cf.* Bouma, 1969), while multiple contiguous peels can be used to represent large sections. Small samples can be cut from peels, in order to study lamina-specific grain-size distributions, particle orientations, and fabrics. Relief peels make excellent teaching aids in introductory sedimentology courses, as well as in petroleum-geology courses to demonstrate microscale permeability heterogeneity. They also make attractive displays.

Relief peels have been made from both siliciclastic and carbonate sediments with grain sizes ranging from gravel to mud. Many different binding agents and techniques have been used over the years; readers are referred to Bouma (1969) and Klein (1971) for comprehensive reviews. Of the many different binding agents used, epoxy resins, polyester resins, and lacquers are perhaps the most commonly used, although readily available materials such as spray-on photomount adhesive have also been employed (Whyte, 1992). The selection is largely a matter of personal preference and availability, although the binding agent should not react with water if the sediment is wet, and must have a viscosity that is appropriate for the situation. For very coarse sediments (very coarse sands and gravels), high-viscosity agents must be used to avoid excessive penetration, which requires large volumes of the binding agent and creates a heavy peel. On the other hand, muddy sediments are difficult to peel because of their very low permeability (Figure R3(C)); only very low-viscosity binding agents will work. This commonly requires the addition of a thinner and/or heating of the binding agent to lower its viscosity. (Note that all work with such chemicals should be performed in a well ventilated place.) Experimentation is needed to obtain optimal results, especially for heterolithic deposits.

The surface to be peeled must be cleaned to remove any disturbed material and smoothed to remove surface irregularities that would otherwise be visible on the peel. In the case of field exposures, care must be taken to ensure that the face is stable, to avoid collapse and potential injury. In very loose sediments, this may require the introduction of a temporary binding agent. In dry sand, wetting the sediment before excavation may be sufficient; however, in gravels, Hattingh *et al.* (1990) have found it necessary to add wallpaper glue to the water and allow it to set before beginning excavation. Water-saturated sediments, including cores, must be allowed to dry somewhat, in order to permit excavation and/or entry of the binding agent.

The method of application of the binding agent is dependant on the nature of the agent and the situation where the peel is being made. For cores in the laboratory, it is common to pour the agent directly and evenly onto the level surface, taking care to avoid disturbing the surface. A single application is generally sufficient. Strips of plastic film can be inserted around the margins of the core, to prevent the binding agent from adhering to the core box or tube, and to stop the excess material from flowing off the surface. In the case of vertical faces in outcrops or trenches, the binding agent is most commonly brushed or sprayed on gently, usually in several coats to ensure saturation of the surface layer. Spraying is least likely to disturb the surface, but requires more equipment than other approaches (*cf.* Getzen and Levey, 1982). Barr *et al.* (1970) have described a single-application technique that may work in some circumstances.

In order to strengthen peels, some type of backing is typically applied. Loosely woven fabric (e.g., cheesecloth) or wire mesh is sufficient for many situations, and work especially well in cases where the sediment surface cannot be smoothed

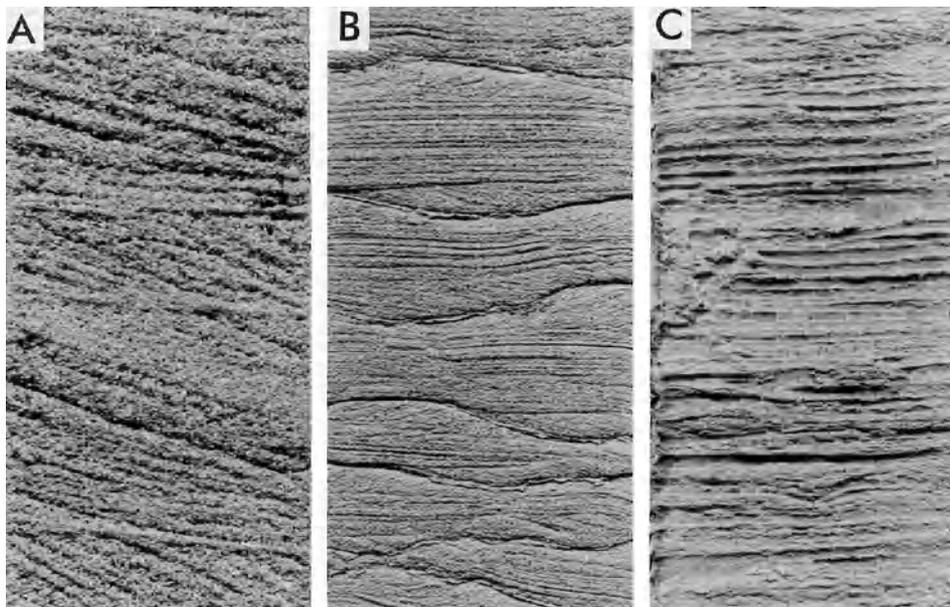

Figure R3 Three 8-cm wide relief peels from modern tidal deposits, Bay of Fundy, prepared from oriented cores using epoxy resin: (A) medium to coarse grained, cross-bedded sand (epoxy penetration 1 cm); (B) interbedded, mud-draped current ripples, and upper-flow-regime parallel lamination in fine-very fine sand (epoxy penetration 2 mm to 2.5 mm); and (C) muddy tidal rhythmmites in which very thin sand layers stand out (epoxy penetration 0–1.5 mm). The mud present in B and C remains on the peel because of cohesion, not because of epoxy penetration.

completely (e.g., in the case of gravels). More rigid backings such as masonite, plexiglass, or stiff card are also used. They may be applied during the peel-making process, or after the peel has been removed. Any backing should be carefully labeled with all relevant sample information, including any orientation data.

The peel must be left in place until the binding agent has set sufficiently that the peel and the surface relief are capable of retaining their integrity. This may take several tens of minutes to many hours depending on the binding agent used and the temperature; heat lamps can be used, with caution, to speed drying. Complete curing may take several days. During this time, it may be necessary to weigh the peel down to prevent warping. Once the binding agent has set completely, loose sediment can be removed by brushing and/or washing (unless the binding agent is soluble in water). A thin, transparent coating may then be applied to protect the surface, if desired. The peel is then ready for study; additional mounting may be required for display purposes.

RESIN AND AMBER IN SEDIMENTS

Many plants produce resinous exudates in response to injury or stress. These exudates, which serve to seal injuries and discourage predators, are organic materials, often composed of mixtures of semi-volatile and volatile organic compounds known as terpenes. After exudation, these mixtures typically harden into solid masses, either by evaporation of volatile components and/or by polymerization. These masses are often highly resistant to biological attack, and hence, tend to resist degradation processes which break down other plant tissues.

For this reason, these materials often accumulate in developing sediments and become part of the sedimentary record.

Resins are fairly common constituents of sediments derived from terrestrial systems. They do not usually occur as massive deposits, although in some cases significant concentrations are known. The most famous of these is the very well-known Eocene “Blue Earth” found in and around the Baltic region, which is the source strata for Baltic ambers, which have been known and collected for millennia. So-called “gem” quality ambers, those that are clear and are most suitable for use in ornamentations or artistic applications are usually less common than opaque samples, but in many instances opaque samples are overlooked or discarded by prospectors and collectors and hence these are not as common in collections as they probably are in sediments. Not surprisingly, resinous materials are commonly found in association with coals and coally shales, although in many of these settings resins may exist only as finely dispersed particles which are identified by microscopy on the basis of their optical properties.

Distribution

Resin-derived materials are both geographically and chronologically widely distributed in the sedimentary record. The oldest confirmed terpenoid ambers have been reported in Triassic sediments, but optically-defined resinites are commonly reported in Carboniferous and Permian coals. The vast majority of well-known ambers are found in sediments of Cretaceous age or younger.

Ambers are known from every continent except Antarctica (and probably exist there but have not been observed). The best known deposits are located in Europe and western Asia, but extensive deposits are also known from the Caribbean Basin (especially the Dominican Republic), South East Asia and North America (Figure R4). Ambers are also known in Africa and South America, but fewer deposits have been described for these locales. This probably does not reflect a greater absence of ambers in these regions, but rather the political realities in many of these regions which tend to discourage prospecting.

Terminology and nomenclature

The nomenclature of ambers is a mess. Historically, because the appearance and to some extent the physical properties of ambers vary significantly, many have been given informal names based on the geographic origins or on the name of the individual who first reported the existence of a particular deposit. Hence, the literature is full of references to burmite, rumanite, beckerite, glessite, etc. In reality, most of these names are not particularly useful since they are not based on any useful objective characteristic of the amber which would allow a user to determine the relationship of samples from different deposits. An exception to this is “succinite,” the term generally applied to ambers from the Baltic region. This term derives from the characteristic presence of succinic acid (also sometimes known as amber acid) in ambers from this region.

Adding to this confusion, use of the term “amber” can itself be controversial when the age of the sample is in question or is known to be modest. Because resins are continuously being produced and deposited, recent, and modern deposits are well-known. In fact in some places, these recent deposits, (which often contain materials on the order of a few thousand years

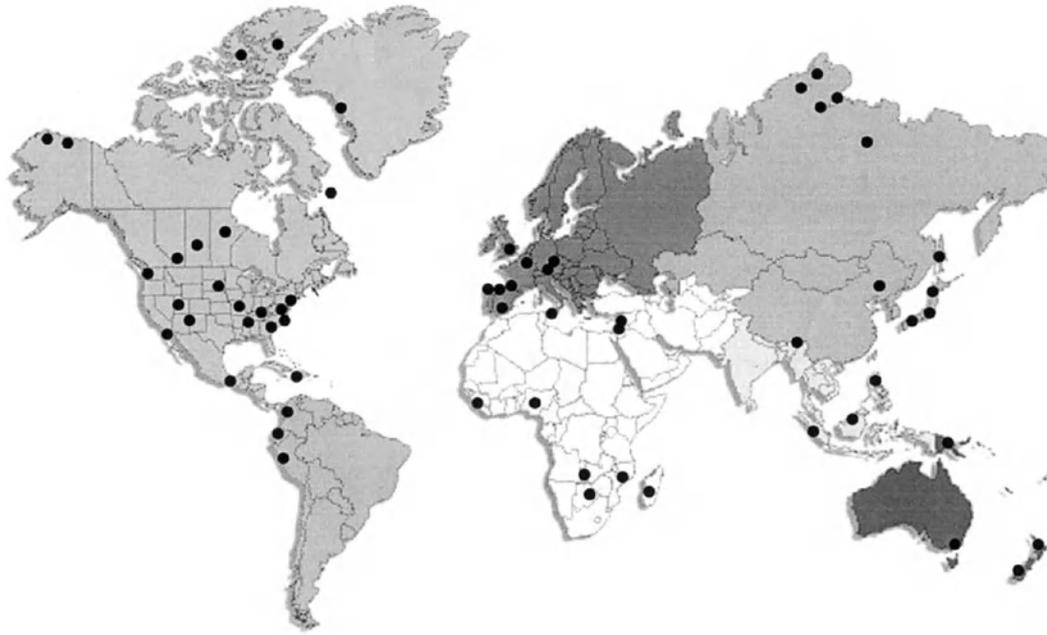

Figure R4 Global distribution of known significant amber deposits. (Many smaller, less well-characterized deposits are also known.)

Table R1 Radiocarbon (^{14}C) scale for definition and description of sedimentary resins. (Modified after Anderson, 1996)

^{14}C Age (years BP)	
0–250	Modern Resin or Recent Resin or Copal (in specific circumstances ^a)
250–5,000	Ancient Resin
5000–40,000	Sub-fossil Resin
>40,000	Amber, Fossil Resin, or Resinite (“resinite” reserved for samples identified by optical microscopic analysis)

^a See Langenheim, 1995 and references cited therein.

old or less), were actively “mined” until quite recent times to provide raw materials for varnishes and polishes. Although often structurally related to much older samples, use of the term “amber” to describe these recent materials is usually considered inappropriate. Loosely (or un-) defined terms such as “copal” or “young amber” are sometimes applied to these materials (See Langenheim, 1995, 2002 for a discussion). However, this raises the (controversial) question of when a sedimentary resin becomes amber. This is often hotly debated since application of the term “amber” increases the value of the material considerably. An objective basis for clarification of the nomenclature of ambers has been proposed (see Table R1 below). This uses objective analyzes (radiocarbon dating) of the amber itself to determine the correct nomenclature, but this has yet to be widely adopted and remains controversial.

Structural characteristics and classification

Unlike many inorganic minerals, ambers do not have a continuous, or repeating structure. In fact, ambers are typically amorphous materials. Most ambers are, however, based on polymeric structures. This is probably due to the fact

that non-polymeric resins are simply softer, more soluble, and volatile and generally less resilient than their polymeric analogues, and hence, are less likely to survive burial and diagenesis in a recognizable form.

Modern analyzes of amber have shown that many ambers share common structural characteristics, and that ambers can be grouped, or classified on this basis. For many purposes, these groupings are more useful than conventional nomenclature (for the reasons set out above) and classification systems based on structural characteristics have been proposed by several authors. The most widely used and accepted of these systems classifies ambers on the basis of the specific structural characteristics of the resin. A summary of this system is illustrated below (Figure R5).

Class I ambers, which are based on polymers of labdanoid diterpenes, are clearly the most common form of amber. Possibly accounting for 80 percent or more of known amber reserves. This class of ambers is further subdivided on the basis of the presence or absence of succinic acid, (butane-1, 4-dioic), and the specific stereochemistry of the labdanoids on which the polymer backbone of the amber is based. *Class II* ambers, which are based on a not yet fully described (Anderson and Muntean, 2000) polysesquiterpenoid structure, are less

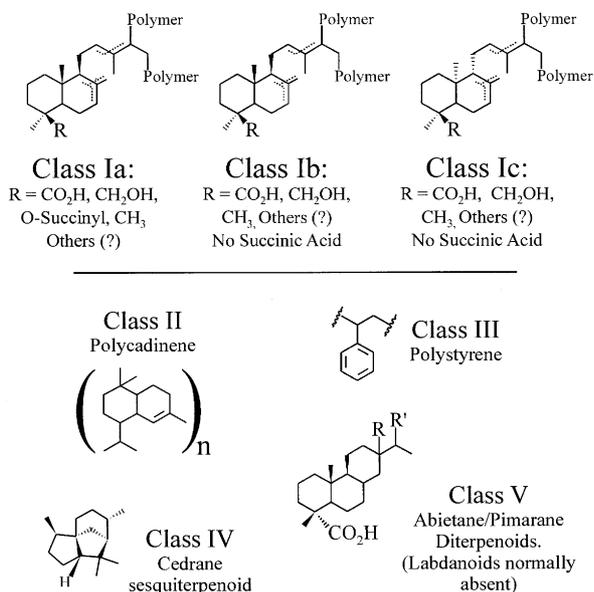

Figure R5 Classification system for sedimentary resins based on structural characteristics of major organic constituents. Modified after Anderson and Crelling, 1995.

common overall than Class I ambers but are nevertheless very abundant in some regions, especially South East Asia and parts of western and southern North America. Class III, Class IV, and Class V ambers are generally rare and represent resins of specific families or non-polymeric resins which are preserved only in unusual sedimentary circumstances.

Class I ambers are by far the best characterized ambers at this time, but even for these materials complete structural characterization remains elusive. It is known, however, that the structures of these materials undergo regular systematic changes over time in response to (primarily) temperature. This raises the possibility that these materials be useful as thermal maturity indicators, and if so these materials would not suffer from complicating factors such as multiple sources, migration, or mixing, which can be problematic in other organic maturity markers. Also, in most cases ambers occlude a variety of terpenes in addition to the common structural components which make up the polymeric backbone. In at least some cases these occluded compounds may be characteristic of the original botanical source, allowing investigators to determine the presence of particular genera or species at a particular location at a particular point in geologic time. Such information is likely to be highly valuable in paleoenvironmental reconstructions.

Inclusions

Finally, it is not possible to conclude this article without some comment about inclusions, which are often found in ambers. Due to their “sticky” nature when first exuded, it is not uncommon for extraneous materials to become embedded within resins. These inclusions often include plant parts, small insects, and (rarely) small vertebrates and other materials such as feathers. Once enveloped, the quality of preservation of

these included materials is unequalled by any other medium. As a result, these types of fossils are highly prized by collectors and paleontologists and are sometimes of considerable value. Insects, for example, are preserved in exquisite detail, often allowing paleo-entomologists to study detailed characteristics. This extraordinary degree of preservation extends to some extent to soft tissues, and even cellular structure (Grimaldi, 1996). Claims of preservation of DNA, and even viable bacterial spores in amber have received considerable press, but for the most part remain controversial at this point.

RIPPLE, RIPPLE MARK, RIPPLE STRUCTURE

Definition

Ripples, ripple marks, or ripple structures can be defined as small-scale, flow-transverse ridges of silt or sand produced by fluid shear at the boundary between moving water or air and an erodible sediment bed. Principal ripple types are *current ripples*, formed by unidirectional water flows, *wave ripples*, generated by oscillatory wave action, and *wind ripples*, formed by eolian currents (see *Desert Sedimentary Environments*). Large-scale equivalents of ripples are *dunes* (see *Surface Forms*).

Basic concepts

Ripple marks are quasi-triangular in vertical cross-section parallel to flow direction (Figures R6(A),(C–E)) or wave propagation (Figure R6b). Current ripples are asymmetric, with gentle upstream face (*stoss side*) and steep downstream face (*lee side*) approaching or at angle-of-repose. Individual current ripples can be up to 60 cm long and 6 cm high, but the mean length and height of a field of current ripples are usually <20 cm and <2 cm, respectively. Wave ripples are symmetric or slightly asymmetric in cross-section (Figure R6(B)). They can be 200 cm long and 23 cm high, but typical dimensions are an order of magnitude less.

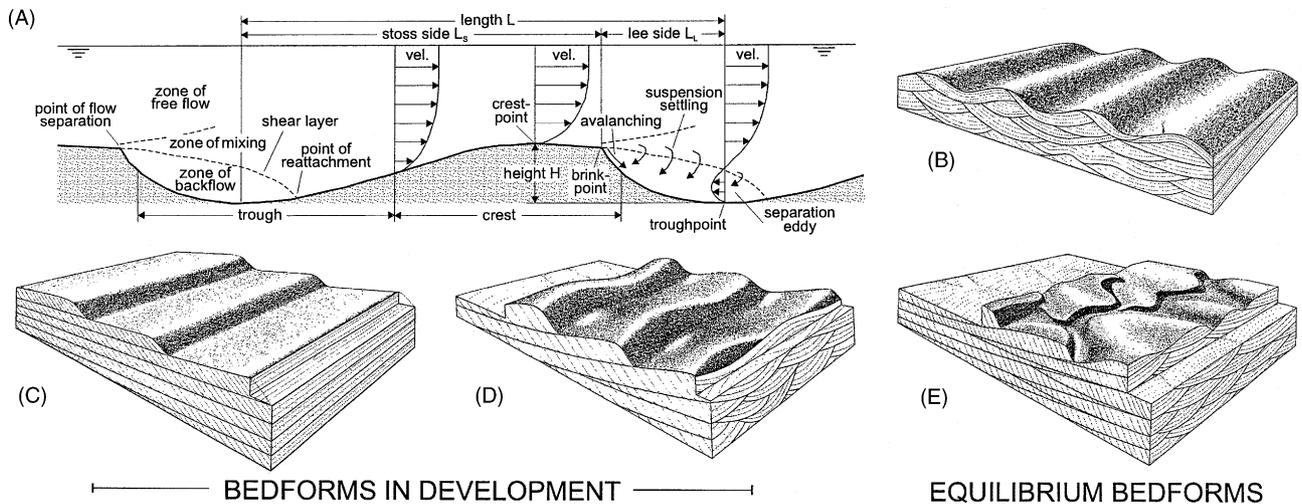

Figure R6 (A) Ripple marks in vertical profile parallel to flow. Terminology is based on Allen (1968) and Reineck and Singh (1980). Note that avalanching and suspension settling generate cross-lamination depicted in (C)–(E). vel. = flow velocity. Water depth note to scale. (B) Plan form and internal structure of symmetrical wave ripples with rounded crests. Wave ripple crests can also be pointed. Wave propagation direction is perpendicular to crest lines. Note bundle-wise arrangement of cross-laminae. (C) Straight-crested, (D) Sinuous-crested, and (E) Linguoid current ripples, with characteristic cross-lamination. Flow is from left to right. Note that current ripples evolve from straight-crested via sinuous-crested to linguoid, independent of flow velocity. Ripples in (C) and (D) are therefore developing, and (E) shows equilibrium forms. Figures (B)–(E) after Reineck and Singh (1980). Copyright © 1980 by Springer-Verlag. All rights reserved.

The geometry of ripples is expressed by the *vertical form index* (or *ripple index*), L/H , the *symmetry index*, L_s/L_L , and the *planform* (Figure R6). Most common vertical form indices are 8–9 for current ripples and 3–8 for wave ripples, although lower indices and indices up to 20 are no exception for both types. The mean symmetry index for a field of current ripples is mostly >2.5 , and dissimilar from typical indices of <2.5 for wave ripples. However, co-existence of oscillatory and unidirectional currents may produce *combined-flow ripples*, whose symmetry index overlaps with current ripples, and thus complicates genetic process reconstruction. Weak cross-sectional asymmetry can also be produced by intrinsic resultant mass transport of water in the direction of wave propagation, mostly in shallow water. Current ripples comprise four common styles of plan form: *incipient*, characterized by mm-high solitary ripples or ripple patches on a flat bed; *straight-crested*, with straight, continuous crest lines (Figure R6(C)); *sinuous-crested*, with sinuous, continuous crestlines (Figure R6(D)); and *linguoid*, with discontinuous, tongue-shaped crestlines (Figure R6(E)). Although wave ripples can have three-dimensional plan form, particularly in the presence of unidirectional currents, wave interference, or under high waves, straight crests with diagnostic bifurcation and abrupt termination of crest lines are most common.

Flow over current ripples separates at the brinkpoint in an upper *zone of free flow* and a *zone of backflow* with *separation eddy* in the lee of the ripple (Figure R6(A)). These zones are divided by a *zone of mixing*, a shear layer along which Kelvin-Helmholtz vortices generate high instantaneous shear. In the ripple trough, the shear layer gradually trends downward until the main flow becomes *reattached* to the bed. Current ripples migrate in the flow direction by erosion of the stoss side and deposition on the lee side. The migration rate is inversely

proportional to ripple size and proportional to local sediment transport rate, which varies with the degree of sheltering by adjacent ripples. Depositional processes associated with ripple migration comprise suspension settling through the zone of mixing and recurrent avalanching of bed load material from the brinkpoint onto the lee slope (Figure R6(A)). Each avalanche-settling cycle produces a *cross lamina*. Sets of cross-laminae are diagnostic of migrating current ripples. Preservation of cross-lamination is enhanced by net deposition in flows that are oversaturated with sediment and produce *climbing ripple cross-lamination* (see *Cross-Stratification*).

Flow over wave ripples comprises three stages: (1) During passage of a water wave crest, flow separation occurs over the ripple crest and a separation eddy and avalanche deposit are produced; (2) During subsequent decelerating flow in the wave cycle, the eddy rises, and may take suspended sediment with it; (3) During passage of the water wave trough (with reversed flow direction), the suspended sediment moves over the ripple crest, a new separation eddy develops and avalanching occurs on the opposite ripple face. Wave ripple cross-lamination produced by net deposition from successive waves is characterized by bundles of oppositely inclined laminae (Figure R6(B)). For combined-flow ripples, the dominant inclination of cross-laminae is parallel to the unidirectional flow component.

Historical development

Ripple marks have been described extensively since the beginning of modern observational geology. Sorby (1859), Darwin (1884), Hunt (1904), Kindle (1917) and Bucher (1919) established the foundations for modern ripple analysis. Allen (1968), Potter and Pettijohn (1977), Reineck and Singh (1980)

and Allen (1984) summarized further benchmark papers, which include studies on ripples in recent and ancient sediments, ripples in experimental flumes, and the theory of ripple formation and stability. In the last two decades, ripple marks have been used primarily in facies analysis. Yet, innovative work continued in experimental flumes and through mathematical modeling (e.g., Miller and Komar, 1980; Diem, 1985; Arnott and Southard, 1990; Gyr and Schmid, 1989; Nelson and Smith, 1989; Best, 1992; Baas, 1994, 1999; Werner and Kocurek, 1999; Baas *et al.*, 2000). Best (1996) and Raudkivi (1997) presented excellent reviews of recent current-ripple literature.

Applications

Ripples and cross-lamination have been used as indicators of stratigraphic younging and to reconstruct (paleo)flow direction or (paleo)wave crest orientation. Moreover, ripples can be used as estimators of local flow properties, notably flow type, flow strength and sediment accumulation rate. Flow strength can be constrained from *bedform stability diagrams* (see *Surface Forms*). Current ripples form at relatively low flow velocities between the threshold for sediment movement and *upper-stage plane bed* (for particles $< \sim 0.12$ mm) or *dunes* (for particles ~ 0.12 – 0.7 mm). They do not form in cohesive clay and in sand coarser than ~ 0.7 mm. Wave ripples exist in all silt- and sand-grades, and between maximum oscillatory velocities for the threshold of sediment movement and upper-stage plane bed.

Unidirectional flows occur in many depositional settings, which renders current ripples of limited use in paleoenvironmental reconstruction. Nevertheless, hydraulic conditions are most favorable in sandy rivers, on intertidal flats, and in turbidites. Wave ripples require relatively weak near-bed oscillatory flow, such as on lake beaches, intertidal flats and the marine shoreface. They are therefore better suited for paleoenvironmental analysis than current ripples. Combined-flow ripples have been found on intertidal flats and in other shallow marine and coastal environments.

Ripple marks provide the sediment bed with form roughness. Form roughness is essential for calculating flow resistance, bed shear stress and velocity distribution in sediment transport analysis.

Current investigations and gaps in knowledge

Refinement of existing models and development of new ideas continually improve our knowledge of ripples. Present-day work on current ripples concentrates on the mechanisms controlling their formation (Best, 1992; Raudkivi, 1963; Williams and Kemp, 1971), their rate of development toward equilibrium morphology (Baas, 1999) and the feedback relationships between ripple geometry and flow conditions (e.g., based on “wave instability” theory by Richards, 1980). A field of current ripples can be generated from a single, artificial, or flow-induced, bed defect if the height of the defect is large enough to induce flow separation at its lee side.

Baas (1994, 1999) demonstrated that current ripples developing on fine- and very fine sand-grade flat beds evolve from incipient, via straight-crested and sinuous-crested, to linguoid equilibrium plan form with constant mean height and length. Contrary to earlier work (e.g., Allen, 1968), the equilibrium dimensions were found to be independent of flow

velocity. Velocity governs merely the time needed to reach equilibrium geometry, which may range from several minutes to hundreds of hours. Baas (1993) proposed relationships between sediment size, D , and equilibrium current ripple height, H_e , and length, L_e (cf. Raudkivi, 1997):

$$\begin{aligned} H_e &= 3.4 \log D + 18 \\ L_e &= 75.4 \log D + 197 \end{aligned} \quad (\text{in mm}) \quad (\text{Eq. 1})$$

Although the above model has been applied successfully to current ripple dynamics in tidal environments (Oost and Baas, 1994) and used to reconstruct sedimentation rates in turbidites (Baas *et al.*, 2000), several gaps in our knowledge remain. First, the role of turbulence in the growth rate of current ripples has never been assessed in detail. Second, aggradation promotes current ripple preservation, but no comprehensive study of its influence on ripple dynamics exists, particularly under conditions of turbulence modulation. This knowledge would strengthen the use of current ripples in (paleo)hydraulic reconstructions, and in the determination of drag coefficients in sediment transport calculations.

The latest studies on wave-induced bedforms concentrate on the sediment entrainment under oscillatory and combined flows, and the dynamics of such flows over wave and combined-flow ripples (e.g., Traykovski *et al.*, 1999; Paphitis *et al.*, 2001). This work will remain important, considering the complexity of the feedback relationships between flows and bedforms. A better process-based distinction between combined-flow and current ripples is needed, as the use of indices is unsatisfactory. This could be achieved by exploring potential differences in grain shape fabric of current, wave, and combined-flow ripples.

channels toward a receiving basin, commonly an ocean or lake. Rivers are open systems in which energy and matter are exchanged with the external environment (Knighton, 1998). They are supplied with water almost entirely from precipitation (meteoric water) routed to the channel via overland flow, groundwater, swamps, lakes, snowfields, and glaciers, and they acquire most of their sediment load by dissecting uplands or by reworking unconsolidated debris from previous erosional events. Sediment deposited by rivers in subaerial settings is called *alluvium*. Consequently, rivers are divisible into *bedrock reaches* with rigid boundaries, and *alluvial reaches* that have a mobile boundary of relatively unconsolidated material, often with vegetation assisting channel stabilization. Rivers drain catchments (drainage basins or watersheds), are organized into complex patterns of trunk, tributary, and distributary channels, and commonly support adjacent floodplains that are inundated when the channels exceed bankfull capacity. Their headwaters are principally in upland areas and they may flow throughout the year (perennial) or cease for part of each year (intermittent if flow is seasonal and ephemeral if flow is irregular). Due largely to tributary contributions, river systems generally increase in discharge and channel dimensions downstream, however, in areas of permeable sediment or aridity, percolation, and evaporation may cause channels to reduce or disappear.

While only about 0.005 percent of continental water is stored in rivers at any one time (Knighton, 1998), rivers transport to depositional sinks the great majority of subaerially weathered and eroded sediment as well as dissolved material. River drainage networks occupy about 69 percent of the land area, transporting an estimated 19 billion tonnes of material annually, about 20 percent of which is in solution. Denudation rates and river load reflect primarily the effects of climate, relief, and tectonic uplift, as well as rock, and soil type, catchment size, vegetation cover, and human influence. Upland rivers are commonly bedrock systems that form a sediment *source zone* (Schumm, 1981). They are typically erosional with very limited sediment storage. Intermediate reaches usually form a *transfer zone* with disjunct areas of bedrock erosion and temporary deposition. Lowland rivers are dominantly alluvial. They lose competence to form a *sink zone*, depositing their load in floodplains, alluvial fans, lakes, desert basins (internal sinks), or in marine deltas, estuaries, lagoons, continental shelves, and ocean basins (external sinks). Many rivers have responded to sea-level fluctuations by cutting and filling their lowermost valleys.

Fluvial strata constitute about 10–20 percent of the Phanerozoic rock record, with many predominantly alluvial deposits in excess of 10 km thick. The oldest known fluvial deposits are in the Archean of southern Africa, where they date back to more than 3.5 Ga and reflect the emergence of continental crust and establishment of subaerial weathering. Alluvial detritus is formed principally of silicate gravel, sand, and mud, with volcanic, carbonate, and evaporite grains, and particles of gold, tin-bearing minerals, and other economic materials (see *Placers, Fluvial*). Some deposits contain huge boulders derived from rock falls and catastrophic floods in steeplands. Rivers that traverse peatlands and densely vegetated regions transport large amounts of plant material and dissolved and colloidal organic matter, and these blackwater streams contribute significantly to the carbon content of sediments in sink zones. Alluvial strata include a wide range of sedimentary structures mostly generated by unidirectional

RIVERS AND ALLUVIAL FANS

Introduction

A river is a natural stream of water that under the influence of gravity flows regularly or intermittently in a channel or

flow. Floodplain deposits are usually associated with soil formation and consequently, in combination, alluvial stratigraphy can reveal a detailed story of variable flow conditions and changing terrestrial environments over space and time.

Historical developments

The importance of river erosion and landscape formation was clearly recognized in classical times. Whereas Thales of Miletus (*b.* ~624 BC) thought that deltas building into the sea were evidence that water could change into sediment, Herodotus (*b.* 484 BC) identified sedimentation and described the alluvial plains of Egypt as the “gift” of the Nile. Plato (*b.* 428 BC) clearly recognized fluvial erosion and transportation. Aristotle (*b.* 384 BC) was the first scholar known to have conceptualized the modern hydrological cycle and he also identified river erosional and depositional processes, particularly those on the Nile and the silting up of river channels entering the Black Sea. Strabo (*b.* 64/63 BC) described floodplains as having been formed of sediment from their adjacent rivers. However, between Roman times and the Renaissance a long scientific interregnum prevailed in Europe, with a widespread belief that the Earth’s surface had been shaped by catastrophic processes associated with the biblical Great Flood (the *Diluvialist* theory).

After the geological importance of hydraulics and river processes was rediscovered by Leonardo da Vinci, Agricola, Bernard Palissy, George Bauer and others in the 15th and 16th Centuries, the importance of fluvial processes through geological time was questioned again in the 18th Century due to a group lead by a German scholar, Abraham Werner. Known as the *Neptunists*, they proposed that the rock record represented deposition in deep oceans where powerful currents had carved valleys and ridges, restricting alluvial influence to modern rivers and their sediments. James Hutton in the 18th Century was the first post-classical scholar to clearly recognize and articulate the importance of modern-day processes to explain features visible in ancient rocks, the basis of his principle of Uniformitarianism. He saw that long-term fluvial erosion was the erosive mechanism active in the repetitive cycles of landscape denudation: *No trace of a beginning, no prospect of an end.* He argued that fluvially eroded debris from the land created most of the detritus appearing in ancient sedimentary strata, and hence he and his followers became known as the *Fluvialists*. Hutton’s concepts were clearly espoused by Charles Lyell in the many editions of his seminal book *The Principles of Geology* (1830–1833).

It was not until the late 19th and early 20th Centuries that modern and ancient river deposits and fluvially eroded landscapes received widespread and detailed investigation, especially from North Americans such as J.W. Powell during exploration and settlement of that continent. G.K. Gilbert (1877) was the first to apply the concept of *dynamic equilibrium* to rivers, and W.M. Davis in the late 1890s proposed the normal or fluvial cycle of erosion and landscape change that, although now not wholly accepted, fostered a widespread interest in modern geology and geomorphology. Davis was probably the first person to recognize braiding as a river pattern distinctly different from meandering. In 1925, J. Barrell demonstrated that sedimentary strata, hitherto widely thought to be deposited in marine environments, were in many cases terrestrial including fluvial. The outstanding study of the Mississippi River by H. Fisk (1944) described the fluvial

geomorphology, sedimentology, and stratigraphy of a very large river system, Miall (1996) regarding this work as the first major advance in modern fluvial sedimentology.

Post-war fluvial facies analysis, strongly linked to drilling and exploitation of hydrocarbon reservoirs, led in the 1960s to J.R.L. Allen’s comprehensive model for meandering-river deposits, the first for any environmental setting. Undoubtedly the most significant modern advances in understanding river form and process originated from research by L.B. Leopold, M.G. Wolman, S.A. Schumm, J. M. Miller and their associates in the 1950s and 1960s. R.A. Bagnold (see *Physics of Sediment Transport: The Contributions of R.A. Bagnold*) greatly advanced sediment transport theory, and A. Sundborg described in detail meandering river processes and floodplain sedimentology, providing important European contributions. Sediment dynamic experiments, following studies in the 19th Century by H.C. Sorby, allowed detailed facies interpretation in hydrodynamic terms (see *Flumes; Sediment Transport by Unidirectional Flows*). With the development of radiocarbon dating in the late 1940s and luminescence dating in the 1970s, the means of dating Quaternary alluvium became available, allowing fluvial sediments and paleoflow regimes to be related more precisely to wider controls, principally tectonic activity, eustasy, and climate change.

Theoretical underpinnings

It has been recognized since the 18th Century that quantitative analysis in fluvial studies has been of necessity a compromise between theory (based on “ideal nonviscous fluids”) and empiricism (based on real viscous fluids), a problem known as the d’Alembert paradox. Despite major advances, the development of unifying theories in fluid mechanics and sediment transport remain elusive. Empirical research into stochastic relationships has shown that, as flows vary, rivers construct highly predictable channel forms and sedimentary structures. However, a truly rational or deterministic explanation for such consistency has not been possible due to a lack of mathematical closure, for while there are four flow variables (width, depth, velocity, and slope) there are only three determining equations (continuity, resistance, and sediment transport). Solutions have been sought by adopting *extremal hypotheses*. If fluvial and thermodynamic systems are compared, rivers may be visualized as adopting a *most probable* state by minimizing both the variance of the system’s flow components and the total work done. More strongly physically-based extremal hypotheses have been proposed by imposing assumed conditions such as maximum sediment transport rate or minimum stream power. In a recent reassessment of some of these approaches, Huang and Nanson (2000) have demonstrated mathematically that straight reaches of alluvial rivers appear to operate at maximum efficiency and illustrate the basic physical *Principle of Least Action*. However, such theoretical analyzes remain contentious.

Drainage networks

Drainage basins are usually characterized by interconnected lengths of river channel that converge from the elevated basin margins toward a trunk stream that exits at the lowest point. The resulting combination of channels forms a *drainage network* (Figure R7). Drainage networks refer to the pattern of the network of stream channels within a basin or sub-basin,

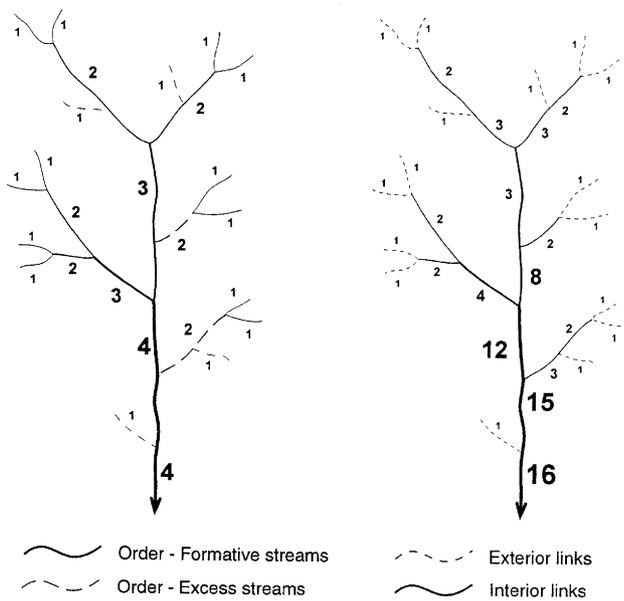

Figure R7 Drainage-basin stream networks with stream ordering: (A) as by Horton (1945) (modified by Strahler); (B) channel links ordered by magnitude (after Knighton, 1998).

and should not be confused with *stream patterns* that refer to the planform appearance of individual reaches of river (e.g., meandering and braiding, see below). They are usually erosional features and have been mapped in the stratigraphic record where unconformable surfaces separate bedrock from overlying alluvium. Headwater streams are normally relatively small, steep, often bedrock controlled with uneven gradients, and the bases of the hillslopes are connected directly to the stream channels such that rates of channel incision and sediment removal relate closely to slope processes. Downstream, the basin channels are of lower and more uniform gradient, and are commonly *self-formed*, being shaped within their own alluvium. Although in places they may connect with the hillslope, it is more common that alluvial terraces and floodplains act as a temporal and spatial buffer between channel and slope processes. Channel links are a length of channel from the source to the first tributary (*external link*) or between two successive tributaries (*internal link*). In 1945, Horton developed a system of ordering channel links within drainage networks in a downstream direction (Figure R7(A)). This provides a useful classification of the position of streams within a network, although link order is not a reliable indicator of channel size or discharge. To determine *link magnitude*, each link is assigned the value of the sum of all the external links supplying it, providing a useful surrogate to link discharge (Figure R7(B)).

In terrain of homogeneous or alternatively highly complex geological structure, drainage networks tend to take on a strongly irregular *dendritic* pattern. However, where well-defined and relatively simple geological structures are present (faults, folds, domes, volcanic cones, rectangular joints etc.), visually distinctive and somewhat regular drainage patterns can form. Drainage networks are highly amenable to numerical analysis and in consequence they have been studied

in great detail in attempts to interpret their controlling variables, internal relationships, sediment yields and their relationship to both catchment and overall landscape evolution. However, because most networks are dendritic, their essentially irregular pattern means that few physically definitive relationships have been identified, except perhaps those from topological studies that have pointed out the spatially nonrandom elements present.

The most widely used and probably useful statistic derived from drainage network analysis is that of *drainage density* (the total length of channels per unit area of the basin). It expresses the degree of basin dissection and sediment production and transport by surface streams, and is influenced by such variables as climate, rock, and soil type, vegetation density, and landuse. Highly impermeable, soft, and poorly vegetated rocks can produce high drainage densities and sediment yields (e.g., badlands). Drainage density is also broadly correlated with precipitation. It is low in very arid areas, greatest in semi-arid areas where there is sufficient rainfall to cause erosion but insufficient vegetation to impede it, and lower again in more humid areas with denser vegetation. It appears to partially rise again in very wet areas where the stabilizing effects of even dense vegetation are overcome.

Stream gradients

Stream gradients are the result of two broad causes. An independent gradient is imposed on the stream by the gross valley form, the product of geological and drainage history. However, an adjustable and therefore dependent component of gradient develops from the interaction of stream discharge, width, depth, velocity, sediment size, sediment load, boundary roughness, and path sinuosity. Mackin (1948) stated that a *graded or equilibrium stream* (see below) is one in which, over a period of years, slope is delicately adjusted to provide, with available discharge and prevailing channel characteristics, just the velocity required for the transportation of the sediment supplied from upstream. Confined upland streams are generally not equilibrium alluvial systems because their gradients are largely imposed by a bedrock valley that is the product of ancient stream erosion or forces such as glaciation and tectonism. It is in the middle or lower reaches where the valley is wider that the stream can more readily adjust its gradient by altering its sinuosity and hence its path length in response to contemporary conditions. Change in channel slope accounts for only part of the adjustment of alluvial rivers to their controlling factors and, more realistically, the channel's various morphological and hydraulic parameters tend to show mutual adjustment.

Over their full distance, the longitudinal profiles of natural rivers show a strong tendency to become concave upward. This concavity is associated with at least three possible causes, although the directions of cause and effect are difficult to resolve. Firstly, there is a tendency in most rivers for discharge to increase downstream but for velocity to remain fairly constant. Discharge (a volume) increases as a cubic function whereas the resisting boundary of the channel (the area of the bed and banks) increases only as a squared function. If the gradient did not decline substantially an imbalance between impelling and resisting forces would result and the flow would accelerate rapidly downstream. Profiles tend to be most concave where discharges increase downstream most rapidly. Secondly, grain size commonly declines downstream due to

clast abrasion (see *Attrition, Fluvial*) and size sorting, so the gradients required for sediment entrainment and transport will decline downstream. Stream profiles are more concave where clast sizes decline in size downstream most rapidly and show little concavity where grain size is constant or increases. Slope decreases most rapidly with a decline in gravel size and least with a decline in sand size. Because of the production of finer clasts, streams over shale tend to have gentler gradients than those over sandstone or limestone, although concavity depends on the combined effects of grain size and discharge. A third possible reason for profile concavity is that antecedent relief and potential energy conditions along a river from headwaters to mouth cause random-walk models to develop concavity as the *most probable* profile. In relation to this proposal it has been found that shorter streams tend to have less concave profiles and streams with greater relief exhibit greater concavity.

Marked changes in river gradient are termed *knickpoints*, and may reflect the presence of more resistant bedrock, changes in sediment load (for example, from tributary streams), tectonic activity, or base-level changes in the past. Eustatic or other base level changes tend not to be propagated over long distances upstream unless the stream is confined and can not readily adjust other parameters such as sinuosity.

Biota and soils

Prior to the mid Paleozoic, subaerial erosion was dominantly physical and produced abundant coarse material, with river forms probably reminiscent of today's active glaciofluvial or volcanic landscapes. In the late Silurian and Devonian the evolution of terrestrial plant communities and associated soils greatly enhanced chemical weathering and the production of clays. The development of cohesive stream banks and stabilizing root systems must have changed rivers dramatically in the late Paleozoic, promoting the accumulation of substantial argillaceous and organic deposits in terrestrial environments and strongly affecting global patterns of carbon production and storage. The development of terrestrial vegetation also reduced runoff and allowed the diversification of a complex array of floodplains and associated soil types in environments ranging from rainforests to grasslands (after the mid Cenozoic) and deserts. The first peats (precursors to coal) were deposited in the Devonian and peat has subsequently been an important component of fluvial strata. The rapid succession of plant communities in response to climate change, termed *floral overturn*, should have exerted an important influence on sediment flux to depositional basins.

There is now appreciation of the importance and complexity of river-vegetation interactions. Particular attention has been given to the effect of vegetation growing within channels on flow resistance, of bankline vegetation and debris dams on bank strength and channel morphology, and of riparian vegetation generally on floodplain and channel sedimentation and erosion. Wildfires destroy vegetation and promote landscape degradation, greatly increasing sediment yield and adding charcoal to the fossil record.

Floodplain soils can be diagnostic of particular environments, containing evidence in the form of pollen and spores, invertebrate remains, burrows, rhizomorphs, evaporites, and desiccation cracks (see *Weathering, Soils, and Paleosols*). For this reason and because soils develop through close interaction

with the atmosphere and the groundwater prism, they are important repositories of information about past climates. Large animals, including hippopotamus, beaver, and perhaps dinosaurs, have affected rivers by trampling sediments, damming channels, and creating paths across banks that can lead to avulsion.

River hydraulics and sediment entrainment

Flow in open channels is subject to two roughly opposing principal forces. Acceleration due to gravity (g) acts to move water and sediment downslope with its effectiveness modified by stream gradient (S), while flow resistance (channel roughness) (see *Flow Resistance*) opposes this downslope motion. The interaction of these two forces ultimately determines the ability of flowing water to erode and transport sediment, and thereby generate landforms. Flow in rivers is almost always turbulent. The flow boundaries including the water surface are deformable, thereby changing the shape, roughness, and energy conditions in the channel as the flow changes. Frictional losses are the product of boundary roughness, internal distortion, and changing flow phases (super- to sub-critical). All these factors make fluid mechanics much more complicated than solid mechanics, however, relatively simple empirical formulas have been developed to obtain approximate relationships suitable for most straightforward analytical procedures.

River discharge (Q):

$$Q = wdv \quad (\text{Eq. 1})$$

where w = channel width; d = mean depth; v = mean velocity. This is known as the *flow continuity equation*.

Mean boundary shear stress (τ):

$$\tau = \gamma R S \quad (\text{Eq. 2})$$

where γ = specific weight of water; R = hydraulic radius $\sim d$, ($\gamma = \rho g$, where ρ is water density). This is known as the *Du Boys equation*.

Channel roughness or flow resistance is commonly obtained from one of two equations:

Manning equation:

$$n = 1/v R^{2/3} S^{1/2} \quad (\text{Eq. 3})$$

Darcy-Weisbach equation:

$$f = 8g RS/v^2 \quad (\text{Eq. 4})$$

The work done by a river can be expressed in terms of stream power in two forms:

Power per unit length of the channel:

$$\Omega = \gamma Q S \quad (\text{Eq. 5})$$

Power per area of the bed:

$$\omega = \gamma Q S/w \quad (\text{Eq. 6})$$

While suspended and dissolved sediment load can be relatively easily measured the more complex problem of determining bed load is usually attempted using one of many available transport equations, none of which are reliable over a wide range of conditions (see *Numerical Models and Simulation of Sediment Transport and Deposition; Sediment Fluxes and Rates of Sedimentation*). These equations can be classified into three

basic types (Knighton, 1998):

Excess shear stress ($r_o - r_{cr}$):

$$q_{sb} = X' r_o (r_o - r_{cr}) \quad \text{Du Boys type} \quad (\text{Eq. 7})$$

Excess discharge ($q - q_{cr}$):

$$q_{sb} = X'' s^k (q - q_{cr}) \quad \text{Schoklitsch type} \quad (\text{Eq. 8})$$

Excess stream power ($\omega - \omega_{cr}$):

$$q_{sb} \approx (\omega - \omega_{cr})^{3/2} d^{2/3} D^{-1/2} \quad \text{Bagnold type} \quad (\text{Eq. 9})$$

In the above, q_{sb} is bed load per unit channel width, X' and X'' are sediment coefficients, D is grain size, q is flow discharge per unit width of channel and the subscript "cr" denotes the critical condition for sediment motion.

In a straight river cross section, the flow velocity is usually fastest at or just below the surface near the center of the channel and declines toward the bed and banks, the flow field deforming through river bends (Figure R8). A narrow deep channel usually directs a relatively gentle velocity gradient to a fine-grained bed that requires low shear stresses for transport, and directs relatively steep gradients to banks that are often cohesive, well vegetated, and erosion resistant. Wide shallow channels tend to exhibit erodible banks and coarse and/or abundant bed load that requires high shear stress for transport, braided rivers being a classic type.

The erosion of cohesive material such as bedrock or partially indurated alluvium occurs in three ways. *Corrosion* is the chemical dissolution of rock in water and can be important where rocks are readily soluble (e.g., limestone) or where water is chemically active. *Corrasion* occurs when rock is mechanically braided by water armed with particles either in transport or stationary but vibrating on the rock surface. *Cavitation* results from the production of shock waves due to the formation and implosion of vapor bubbles on rock surfaces at very high velocities. This is a rare process in most subaerial streams but can be common in subglacial or underground streams where flow is confined.

The entrainment of noncohesive sediment from the boundary is a complex process but largely a function of flow velocity and grain size. In the case of gravels, the sorting, and packing arrangements of the clasts on the bed are also important, for an armored or imbricated bed can be difficult to entrain (see *Armor*). As flow velocity increases two dominant forces act to entrain individual clasts. A *drag force* caused by friction between the flow and the surface of the particle causes it to

move downstream and to slide or roll (or pivot) over any obstructing particle. However, as velocity increases a pressure gradient develops between the top and bottom of the grain setting up a *lift force* that acts to lift the particle out of its recess on the bed. The lift force decreases rapidly away from the bed but once the particle is elevated it is far more susceptible to the drag force and to turbulent eddying within the body of the flow that acts to keep particles in motion. The entrainment of sediment on the boundary can be expressed in terms of mean flow velocity and mean grain size, but the problem is to define the threshold velocity for motion on an imbricated or armored bed, or where grain size is highly variable.

The competence of historic or prehistoric flows is commonly judged from the size of the largest particle in the resulting deposit, although such estimates may suffer from the limited availability of coarse sediment. Fine-grained, cohesive deposits require much higher flow velocity for entrainment and transport than the size of individual grains would suggest. Such materials include bed and bank material, sand-sized mud aggregates reworked from soils, and flocs of aggregated clay, organisms, and detrital organic material in rivers and estuaries (e.g., Gibling *et al.*, 1998). Because aggregates and flocs are commonly destroyed by compaction during burial, flow competence may be difficult to assess for some fine-grained material, which may have originated as sand-sized bed-load rather than from settling of suspended flakes.

Equilibrium and threshold theories

Because alluvial rivers are open systems with mobile and deformable boundaries, they have the ability to self regulate. If perturbed, they will often return to something like their original condition (*homeostasis*), or they will adopt a new form but one that minimizes the effects of the original change. This reflects *dynamic equilibrium*, a condition first described for rivers by Gilbert (1877) and applied widely in science, especially chemistry (Le Chatelier's Principle). Because rivers are relatively slow to adjust and because their morphological parameters adjust at different rates, it can be difficult to determine if a particular reach is in an equilibrium or balanced condition. Nevertheless, the recognition that alluvial rivers adjust toward equilibrium conditions has become a basic tenet, almost a paradigm of modern fluvial research. Richards (1982) has suggested that equilibrium conditions in rivers can be identified on the basis of four criteria: (1) essentially stable relationships between form and process; (2) continuity of sediment transport in a reach over time and space; (3) strong correlations between system variables; (4) an adjustment to maximum operational efficiency. In many studies roughly balanced conditions have been shown to exist over short periods between erosion and deposition in a single reach, or between width, depth, and velocity. If one variable is altered, the others adjust in a way that minimizes the overall change and maintains a balanced condition. Because flow conditions and sedimentary bedforms are usually in dynamic equilibrium, ancient flow structures permit an accurate interpretation of paleoflow conditions.

Most changes in rivers are the result of external factors such as changes in base level, climate, vegetation, or sediment supply, and occur gradually. Rivers in dynamic equilibrium generally resist change, however, Schumm (1973) has shown that an *extrinsic threshold* can be reached when a progressive

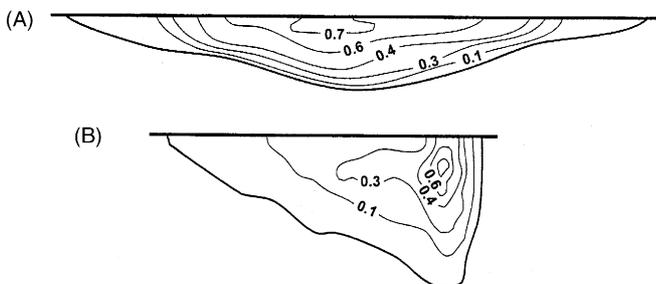

Figure R8 Velocity fields in cross sections of: (A) a wide shallow channel (note the steep velocity gradient to the bed); (B) a narrow deep channel bend viewed downstream and curving to the left (note the steep velocity gradient against the outer cutbank).

change in an external variable triggers a sudden change in the system's response. At an imposed critical change of slope or sediment load, a meandering channel can change abruptly to a braided channel. Similarly, a gradual and progressive increase in the flow velocity will suddenly achieve the threshold for sediment entrainment, after which the whole streambed becomes mobile. There are numerous thresholds above critical entrainment when bedforms change from a motionless bed, to ripples, to dunes, to transitional, and to super-critical flow bedforms (see *Surface Forms*). Schumm (1973) also showed that changes may be initiated intrinsically when, with no external change, one of the variables reaches a critical condition (an *intrinsic threshold*). While operating within its normal range of water discharge and sediment load variation, a river may reach a point of incipient instability when a threshold is crossed and a sudden internal change is initiated. A meander cutoff is an example where gradual, ongoing adjustments to equilibrium conditions prevail until a threshold is reached, with breaching of the meander neck and a dramatic change in local sinuosity and gradient (Knighton, 1998).

Crossing an intrinsic threshold will normally produce only a localized change recognizable in the stratigraphic record as, for example, an avulsion channel or crevasse splay.

Hydraulic geometry, regime theory and dominant discharge

Channel geometry is the cross-sectional form of a stream channel (width, mean, or maximum depth, cross-sectional area) fashioned over a period of time in response to formative discharges (approximately bankfull) and sediment characteristics (Figure R9). Because the above three geometric parameters and the additional four flow parameters (velocity, water-surface slope, flow resistance, and sediment concentration) vary with discharge, the term *hydraulic geometry* is used to describe the relationships of all seven parameters to discharge as the independent variable. Discharge changes can be measured at-a-station as the channel fills during a flood, or at bankfull in the downstream direction. There are significantly different relationships for *at-a-station* and *downstream*

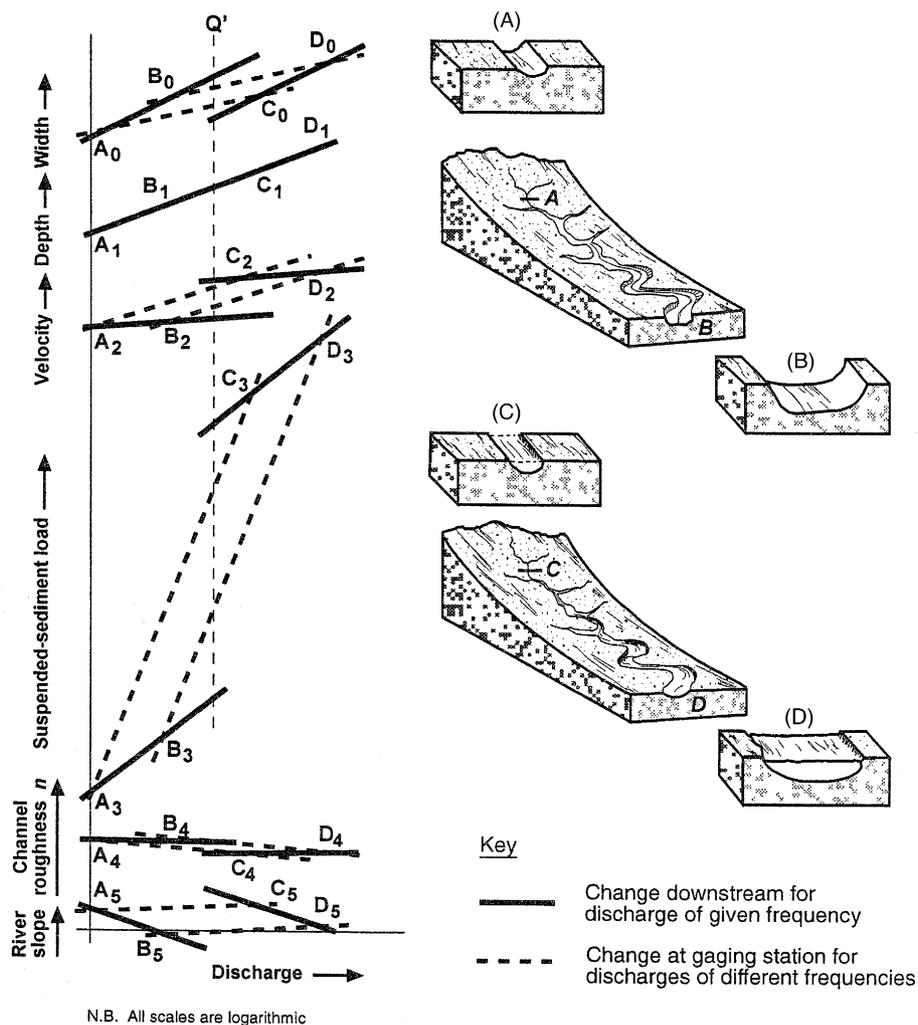

Figure R9 Hydraulic geometry relationships of river channels, comparing variations in width, depth, velocity, suspended load, toughness, and slope to variations in discharge, both at-a-station and downstream (after Leopold and Maddock, 1953).

hydraulic geometry (Figure R9). Holding discharge constant, at-a-station hydraulic geometry is largely controlled by variations in bank strength and available sediment load. Streams with low sediment loads and cohesive or well-vegetated banks tend to be relatively narrow and deep whereas those with abundant loads and weak banks tend to be wide and shallow. However, because bank strength has only a moderate range but river discharges vary by many orders of magnitude, hydraulic geometry is remarkably consistent across the full range of river discharges (Figure R9). Because channel depth is greatly restricted by limited bank strengths, rivers increase in width relative to their depth as their size and discharge increases—a prominent downstream tendency (Church, 1992).

Research during the construction and maintenance of irrigation canals with near-constant discharge in India and Pakistan in the late 19th and early 20th Centuries independently determined very similar hydraulic geometry relationships to those in natural rivers, engineering findings that have been termed *regime theory*. Consequently, stable alluvial rivers exhibiting consistent and predictable hydraulic geometries are said to be *in equilibrium* or *in regime*.

Hydraulic geometry shows that river channel dimensions are closely adjusted to water discharge. However, discharge varies from perhaps no flow in droughts through to catastrophic flood events: so which discharge(s) define the channel's characteristics? Wolman and Leopold (1957) showed that in the USA, bankfull flows occur with the surprising regularity of about once every 1–2 years across a diverse range of rivers, something that would be an extraordinary coincidence if bankfull flows did not in themselves play a large part in determining channel dimensions. It has also been shown that with increasing at-a-station discharge, flow velocity tends to increase until near bankfull flow conditions and then stabilizes at higher discharges because of a marked increase in roughness near the bank crests and over the floodplains. In other words, most flows beyond bankfull are not notably more effective in altering the channel and transporting sediment than is bankfull flow. Furthermore, while in some cases exceptional floods may undertake significant work in the form of sediment transport and channel reconstruction, they are sufficiently rare that on an average annual basis, they usually achieve far less than do smaller but more frequent events of about bankfull (Figure R10). However, there is evidence that in a limited number of environments (e.g., pro-glacial streams, confined gorges, and some dryland rivers), catastrophic events can achieve substantial and long-lasting changes. In other words, here these become the dominant discharge. Extreme, high-velocity events cause considerable channel enlargement, followed by a long period of “recovery” from smaller flows. Thus, channel dimensions at a given time in such an environment may reflect the period that has elapsed since the last extreme event, which also terminated “memory” of the pre-existing channel geometry.

Sediment transport

As discharge increases, detrital sediment transport in alluvial channels mostly occurs when the flow conditions (largely velocity) exceed the critical condition for entrainment of sediment at rest on the bed and banks (see *Numerical Models and Simulation of Sediment Transport and Deposition*). The flow conditions required to entrain stationary sediment are greater

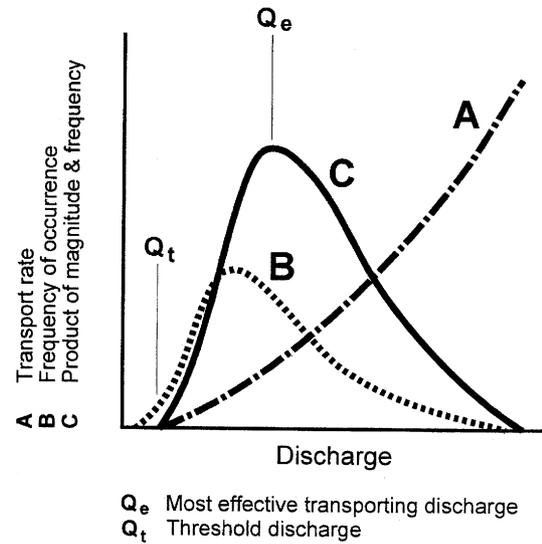

Figure R10 Dominant discharge. Curve A is the transport rate of suspended load rising with discharge. Curve B is the frequency of the full range of possible discharges. Curve C is the product of curves A and B and shows that the most effective discharges for transporting a river's load are moderate floods, generally occurring about once every 1 to 5 years.

than those required to keep sediment moving. Rivers transport their sediment load in essentially four ways. *Bed load* or *traction load* is almost constantly in contact with the bed, *saltating load* bounces or skips over the bed (effectively intermediate between bed load and suspended load), *suspended load* is held in the water column by turbulence and *dissolved load* is transported in solution. The first three are composed of detrital sediment, and the concentrations and relative proportions of the first two are highly dependent on the energy of the flow, which increases with water discharge. Suspended load is energy dependent but can also be strongly influenced by the rate of sediment supply to the river. The concentration of dissolved material depends largely on water temperature, catchment geology, groundwater chemistry, and vegetation. In contrast to detrital load, dissolved load commonly decreases in concentration due to dilution effects with increasing flood discharge. The three detrital types are the primary constituents of alluvial strata, with bed, and saltating load commonly forming sedimentary flow structures diagnostic of variable flow conditions. Soluble matter, once in solution, is mostly flushed from the catchment, being precipitated only under unusual geochemical conditions. Because of the difficulty of separating different sediment types on the basis of transport, another commonly used classification defines the detrital sediment load in terms of the bed composition prior to entrainment. *Bed-material load* is that which is contained largely within the bed material at rest, whereas *wash load* is the muddy suspended component not found in significant quantities in the bed (it is derived largely from fines in the stream banks, floodplains, and valley side-slopes).

Yields of suspended sediment and dissolved material are usually closely related to water discharge and are therefore relatively easily measured. In contrast, bed load (especially coarse bed load) is transported in a highly variably fashion,

both spatially, and temporally, and is therefore extremely difficult to measure accurately, especially in large rivers. Bed-load is mostly (but certainly not entirely) a function of the highly variable shear stresses acting on the bed, and is often estimated from average flow and sediment characteristics. Because bed load is the coarsest fraction and moves mostly short distances during relatively infrequent, high magnitude flows, it is commonly the smallest proportion of transported sediment (often <10 percent of the total load). It is therefore sometimes ignored, however, this overlooks the importance of bed-load in determining river form, as well as its contribution to the stratigraphic record—in laterally migrating and accreting systems sediment deposited within channels has an especially high probability of being preserved. The *capacity* of a river to transport bed-load is usually limited, but few flows reach their limit for transport of suspended load, the concentration of which is largely controlled by the rate of supply.

Reliable relationships have been determined between sedimentary structures, sediment size, and flow velocity (or shear stress) (see *Surface Forms; Sediment Fluxes and Rates of Sedimentation*). Bed roughness changes in a complex but predictable fashion with increasing velocity and sediment transport. It reaches a maximum with dune formation under lower regime flow and antidune formation under upper regime flow.

Sediment character has a profound influence on river style. As a consequence, Schumm (1960) developed a classification of rivers based on bed load, mixed load and suspended load systems, with width:depth ratios of >40, 10–40, and <10, respectively. His approach has influenced later classifications of rivers, floodplains, and stratigraphic sequences.

Sediment deposition

Alluvium results from fluvial sedimentation. This takes place for suspended or saltating sediment when the flow velocity drops below that of the settling velocity (the velocity of a particle falling through a column of still water), and for bed load when flow velocity drops below that maintaining sliding or rolling of particles over the bed. When velocity wanes or decreases locally within the channel or on the floodplain surface, the coarsest fractions are deposited first. As a result, sediment sizes are sorted vertically, and laterally within the total alluvial system. On laterally migrating meandering rivers, upward fining successions within point bar and floodplain deposits result from flow velocities that decline from near the deepest part of channel (the thalweg) and adjacent point bar (depositing gravel or coarse sand), to the upper point bar, convex bank, and floodplain surface (depositing fine sand and mud). In braided rivers, coarse braid bars characterize the lowermost deposits, and with braid-channel, and braid-bar migration or abandonment, overbank fines, and channel fills characterize the uppermost deposits. Adjacent to laterally stable channels, or on floodplains away from the zone of active channels, floodplain strata broadly fine upward as each successive stratum makes the surface higher and less accessible to overbank flooding. However, in detail such upward fining successions are usually complex, exhibiting numerous size variations, and reversals resulting from temporal and spatial variations in flow conditions within individual floods and between successive floods. Secondary currents are known to play a major role in producing the broad spatial variations in

sedimentation in bends, bars, and floodplain scrolls, as well as in innumerable smaller flow structures.

In a genetic classification of different floodplain types, Nanson and Croke (1992) identified six floodplain-forming processes: lateral point-bar accretion, overbank vertical accretion, braid-channel accretion, oblique accretion, counterpoint accretion, and abandoned channel accretion. Both geomorphologically and sedimentologically, the major distinction is between coarser bar deposits laid down by the lateral shifting of channels, and fine-grained vertical accretion deposits resulting from overbank sedimentation, but there are many varied combinations of all six. Based largely on the interrelated properties of stream power and sediment character, Nanson, and Croke identified three floodplain classes: (1) high-energy noncohesive; (2) medium-energy noncohesive; and (3) low-energy cohesive (Figure R11). To these they added 13 derivative orders and suborders that are based largely on the floodplain forming processes. Miall (1996) incorporated this essentially geomorphic model with his 1985 architectural element analysis to develop a detailed system of fluvial sedimentary facies and styles (see *Floodplain Sediments*). Although generally viewed as depositional elements, floodplains can also be subject to periods of intense erosion during flood episodes, resulting in *catastrophic stripping*.

River deposits include a wide range of sediment types, but a distinctive suite of facies is common to many channel and floodplain settings. The reader is referred to Miall (1996) for a detailed description of fluvial facies.

Channel patterns: their geomorphology and sedimentary facies

Rivers respond to imposed discharges and sediment conditions by adjusting their channel pattern or planform in conjunction with their hydraulic geometry. Because river patterns are so easily recognized on air photos and maps they have become a primary basis for river classification (Figure R12). Generalizations from planform can be made in terms of lateral stability, sediment load, sediment size, bed/suspended load ratio, width/depth ratio, floodplain type, and stratigraphy.

Leopold and Wolman (1957) proposed the first widely adopted geomorphological classification with their concept of a continuum of river patterns between end-members of *straight*, *meandering*, and *braided*. A significant problem is that these are not mutually exclusive; for example, many braided channels have a sinuous (meandering) planform. Nevertheless, in an effort to retain the continuum approach, more recent classifications have essentially adopted the original tripartite system but with additional types added, the most distinctive being low energy, fine-grained multiple-channel rivers termed *anastomosing*. The existence of a broad continuum of river patterns is evidenced in slope-discharge plots that, in order of declining stream power and grain size, separate rivers into braided, meandering, straight, and anastomosing (Figure R13). However, to date there is insufficient evidence to determine whether straight and anastomosing channels can be separated from each other on this basis alone. The concept that stream power and sediment-caliber control the continuum has led some to argue that the relative ease of eroding and transporting bank material determines channel patterns (Brotherton, 1979). Both meandering and braiding patterns appear to reflect a need to consume excess energy were the valley slope is greater than

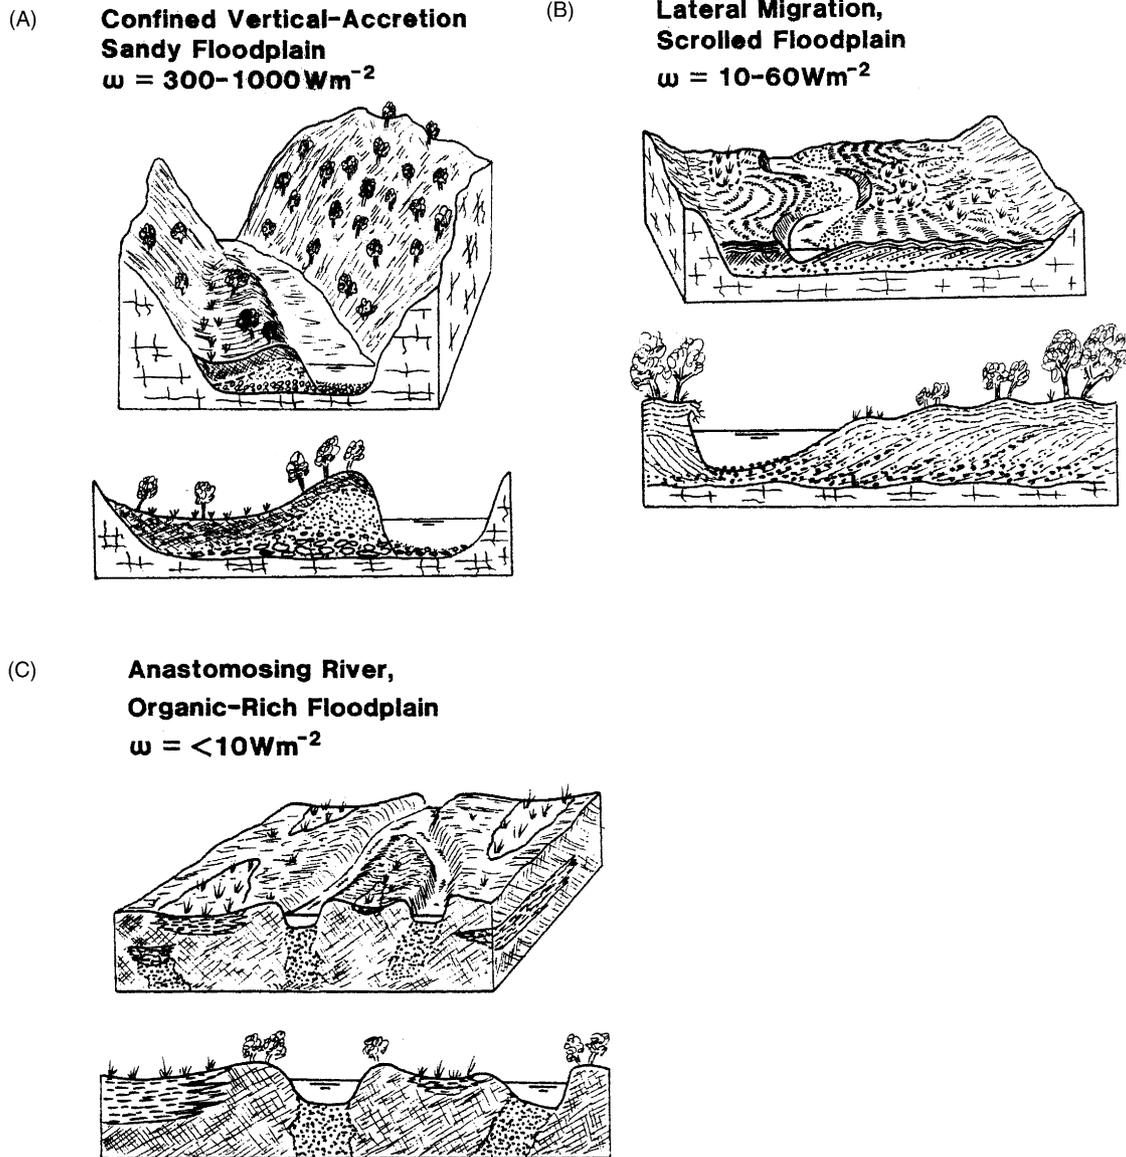

Figure R11 Examples of Nanson and Croke's (1992) three main floodplain classes: (A) A High-energy noncohesive floodplain; (B) A medium-energy noncohesive floodplain; (C) A low-energy cohesive floodplain.

that required for an equilibrium channel slope (Bettes and White, 1983), but the issue remains unresolved.

The term *anabranching* describes rivers that flow in multiple channels separated by stable, vegetated, alluvial islands that divide flows up to bankfull regardless of their energy or sediment size, with anastomosing rivers simply a low-energy fine-grained type (Nanson and Knighton, 1996) (see *Anabranching Rivers and Anastomosing Rivers*). Importantly, neither term is now used as a synonym for braided rivers in which the flow is divided by braid bars overtopped below bankfull. Individual anabranches can be straight, meandering, or braided. The term *wandering* river has become popular to describe anabranching rivers intermediate between meandering

and braided. It is important to recognize that the association between river planform and sedimentology is not always clear, especially in transitional zones (Brierley and Hickin, 1991).

These classifications apply mainly to self-formed, alluvial channels. Church (1992) noted the problem of including rivers from mountains to basins within one classification scheme. Taking this problem into account, he divided channels into small, intermediate, and large categories based not on channel dimensions but on the relationship between grain diameter (D) and depth (d). In *small channels* ($D/d > 1.0$), individual boulders are significant form elements, leading to irregular steps and pools. In *intermediate channels* (D/d 0.1–1.0), flows are often wake-dominated, with a variety of

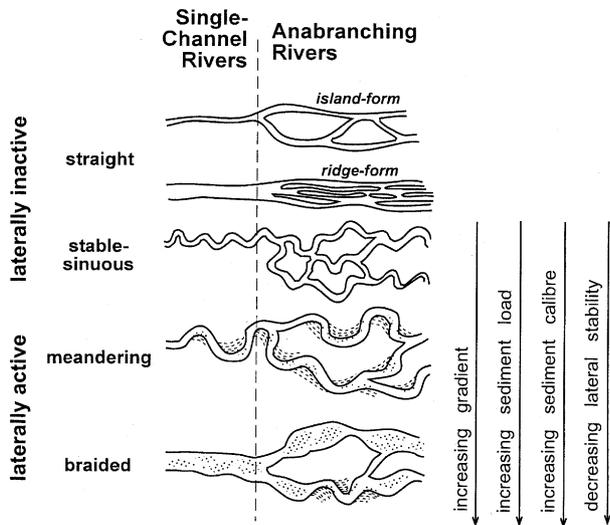

Figure R12 The common range of river patterns in single-channel and anabranching rivers. There is a trend of increasing gradient and sediment calibre and load from laterally inactive, to meandering, to braided (modified from Nanson and Knighton, 1996).

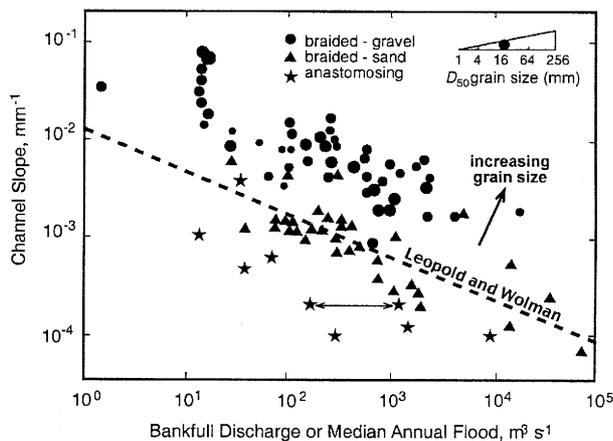

Figure R13 Gravel braided, sand braided, and anastomosing channels differentiated on slope-discharge, with median grain size (D_{50}) (after Knighton, 1998).

pools, riffles, rapids, and bars, as well as steps, and jams caused by logs and branches. *Large channels* ($D/d < 0.1$) are dominated by the water-flow regime, and exhibit deep shear flow, and a well-defined velocity profile, with bedforms that dissipate energy. The channel types described in the previous paragraphs are typically large channels following this scheme, and their fills predominate in the fluvial record. Small and intermediate channel fills are probably important in the rock record where unconformities include bedrock valleys with very coarse sediment.

Braided Rivers are relatively high-energy systems with large width-depth ratios and at low stage have multiple channels that divide and rejoin around alluvial bars (see *Braided*

Channels). They tend to occur in settings with steep gradients, weakly cohesive banks, abundant coarse sediment, and variable discharge (Leopold and Wolman, 1957; Knighton, 1998). Sediments are typically dominated by gravel and sand, but silt-dominated systems are also known. Braided rivers are prominent near mountain and glacial fronts, range from humid to arid regions, and commonly change downvalley into finer grained, single-channel systems, although some feed directly into oceans, and lakes as *braidedeltas*. The Brahmaputra River, one of the world's largest braided systems, has a channel-belt width of up to 20 km, with individual channels several kilometers wide and maximum scour depths of up to 50 m, however, braiding can also occur in small streams crossing a sandy beach.

While processes and relationships between variables can be described, a widely accepted *rational* explanation for braiding has been elusive. Leopold and Wolman (1957) argued that braiding is an equilibrium adjustment to erodible banks and a debris load excessive for a single channel. Some workers have differentiated between braiding caused by the above, and that designed to consume energy in less-efficient multiple channels as a result of excessively steep valley gradients, following observations that degree of braiding may increase as slope steepens (Bettess and White, 1983).

In a detailed flume study, Ashmore (1991) found that braiding can develop in four ways: (1) growth of a central bar without avalanche faces, commonly linked to stalling of coarse bed-load in the channel center (Leopold and Wolman, 1957); (2) scour at pools leading to deposition of a downchannel lobe, with stalling of bed-load sheets on the lobe top and subsequent development of a mid-channel bar with avalanche faces; (3) chute cut-off of mid-channel and point (bank-attached) bars, with the formation of a new, discrete channel; and (4) dissection of lobate bars by multiple channels. Others cite avulsion within the channel belt as a bar-forming process (Kraus and Wells, 1999). Repetition of these dynamic processes along the river produces a complex array of interacting channels and bars. In different environments, channels can be aggradational, vertically stable, and incisional but all situations are characterized by frequent shifts in channel position. Many changes in braided river morphology occur episodically, even at constant discharge, as a result of short-term fluctuations in the transport rate related in particular to bed-load pulses.

Friend and Sinha (1993) defined the intensity of braiding using a *braid-channel ratio*, B , which measures the tendency of a channel reach to develop multiple channels. $B = L_{ctot}/L_{cmax}$, where L_{ctot} is the sum of the mid-channel lengths of all primary channel segments in a reach, and L_{cmax} is the mid-channel length of the widest channel in the reach.

Braided river deposits in the rock record are typically composed of suites of channel fills or stories that are stacked to form complex (multistory) bodies dominated by sandstone and conglomerate. Bar deposits are identified as large-scale sets of inclined strata that tend to dip downstream and oblique to flow, although lateral accretion is common. The channel bodies range from a few meters to hundreds of meters thick, with some especially thick occurrences exceeding 1 km of coarse-grained strata, and they vary from small bodies embedded in floodplain mudstones to extensive, basin-scale sheets.

Meandering Rivers are usually moderate-energy, single-channeled, and sinuous rivers with moderate width-depth ratios

and gradients (see *Meandering Channels*). Their planforms can be described precisely in terms of wavelength, amplitude, and radius of curvature, although in reality their planform can be irregular. Included within the group are sinuous channels, with point bars developed at convex bends, and relatively straight channels within which the thalweg winds between alternate bars. Channel sinuosity is measured as the ratio of channel length to valley length with the term “meandering” applied when this ratio is greater than about 1.3. Such rivers contain relatively few bars that are not bank attached, thus having braid-bar ratios close to 1.0. Meanders are self-similar over a wide range of scales and their planform (especially width and wavelength) can be related to channel discharge (see Knighton, 1998, table 5.9), and these relationships have been used to determine paleodischarges from ancient meander traces (e.g., Smith, 1987).

“There is no general agreement as to how or why streams meander.” (Knighton, 1998, p. 225). The regularity and widespread occurrence of meanders shows they are not simply the product of random disturbance. The “bar theory” proposes that periodic deformation of the bed is the fundamental cause of meandering, especially through the development of alternate bars that deflect flow into the banks. However, this does not explain the initiation of the alternate bars. Furthermore, meanders occur without sediment deposition in supraglacial streams cut into ice and in ocean currents. Using “probability theory” Langbein and Leopold (1966) proposed that meanders reduce stream gradients to an equilibrium slope for the transport of an imposed sediment load, producing a longer path length with minimum variance and minimum total work. This approach suggests that alternate bars and point bars are a response to controlling factors, not themselves the prime cause of meandering.

Meandering rivers tend to occur in settings with moderate gradients, cohesive and/or well-vegetated banks, mixed loads of sand (sometimes gravel) and mud, and commonly perennial flow. The concave banks in bends are typically erosional and adjacent to pools. The locus of the lowest point in the channel (the thalweg) changes to the opposite side of the channel at the riffle (sometimes called the crossover), a shallow zone in the long profile between each bend (pool). The convex side of each bend usually has a point bar with surfaces that slope gently into the adjacent pool. Point-bar surfaces generally dip at low angles ($\sim 4^\circ$) but locally exceed 12° , and their width is about two-thirds that of the channel. Meandering rivers are especially common in downvalley, lower-gradient reaches of rivers, and in estuaries they support bi-directional, tidal flow, and more complex bars.

As the outer bank of each bend erodes, the point bar migrates systematically laterally and downstream, usually balanced by erosional retreat of the concave bank. Lateral migration rates are most rapid where bends have radius of curvature to channel width ratios of about 2 to 3 (Hickin and Nanson, 1975). Where a meander tightens through time, the point bar may be partially truncated by erosion along chute channels (chute cutoff) or completely truncated with full isolation of the bend (neck cutoff), resulting in an oxbow lake. Repeated cutoffs and local channel-migration result in a meander belt composed of many laterally juxtaposed channel segments (Fisk, 1944).

Meandering-river facies and grain size distribution primarily reflect the pattern of helicoidal flow that develops around each bend (see *Meandering Channels*). As the channel migrates,

sediment eroded from the concave bank is transported obliquely across the channel and up the opposing point bar, with flow waning progressively toward the bar top. Sediments grade and bedform scale decrease systematically up the bar surface (Allen, 1970). These lateral-accretion deposits are termed *inclined stratification*, or in mixed load streams, *inclined heterolithic stratification*. Point-bar accretion is commonly linked to scroll bars which can develop as a within-channel bar on the point bar platform, and through vertical and up- and downstream growth become effectively a levee bank around the convex bank of a meander bend. With lateral accretion, repeated scroll bar, and associated levee bank growth generate a distinctive ridge-and-swale or scroll topography on the floodplain surface.

Meandering rivers on the scale of the lower Mississippi may be expected to generate moderately wide (e.g., 10 km) and relatively thick (e.g., 10–30 m) meander-belt deposits (Fisk, 1944). These broad bodies (an order of magnitude wider than the parent channel) form by a combination of progressive lateral accretion, meander cutoff, and channel avulsion, and they consist of juxtaposed channel segments that can be identified by abrupt changes in accretion direction and paleoflow. Such bodies with a set of discrete segments or stories can be termed multilateral; however, stories within many channel bodies are stacked both vertically and laterally, and the bodies are best described as “multistory”. Exhumed meander belts with mappable segments and cutoffs have been documented from well-exposed terrains (Smith, 1987). The majority of meandering-fluvial bodies documented in the geological record are less than 30 m thick and 6 km wide, with width:thickness ratios that commonly exceed 100 and rarely approach 1,000. In some instances, channel fills with point-bar deposits form components of much thicker, complex fluvial bodies, and valley fills.

Straight rivers rarely persist in an alluvial setting for a distance of more than 7–10 channel widths. While many rivers contain straight reaches, for the purpose of definition straight rivers are classed as those without significant bends for more than this distance (sinuosity of <1.1). Where compared to other patterns they are argued to be at the low end of the flow-strength to bank-strength ratio, so are usually fine grained. Flume experiments suggest that straight channels develop at very low gradients, an inference supported by the relatively straight channels (even prior to canalization) in the lower Mississippi River and Delta. Where naturally sinuous channels in readily erodible material have been artificially straightened, alternate bars usually form rapidly and subsequent bank erosion leads to the development of a meandering pattern. Some straight reaches reflect incision along tectonic lineaments which controlled the channel orientation.

Surprisingly, straight channels have never been specifically studied as a pattern type so very little is known about their geomorphology or stratigraphy, and there is no proposed facies model for straight rivers. Because of the relative absence of lateral activity, the predominant mechanism for alluvial sedimentation along straight reaches of river is likely to be vertical aggradation of both channel and overbank deposits, and a fixed-channel model (Friend, 1983) may be appropriate (see below).

Anabranching rivers are a system of multiple channels characterized by vegetated or otherwise stable alluvial islands which are either excised by avulsion (see *Avulsion*) from a previously continuous floodplain, or formed by the accretion

of sediment in a previously wide channel. The islands divide flow up to bankfull (Nanson and Knighton, 1996). Anastomosing channels are low gradient, laterally stable, straight (most common) to highly sinuous, with low width-depth ratio and well-vegetated or highly cohesive banks.

Anabranching rivers include a wide range of settings and facies which greatly complicate attempts to explain the form and origin of these unusual rivers (see *Anabranching Rivers*). Because of their propensity in certain environments to accumulate sandy channels and fine-grained overbank muds and organics, anastomosing rivers can be important locations for the preservation of coal and hydrocarbons. An anastomosing reach of the valley-bound Columbia River of western Canada comprises a suite of mixed-load channels that avulse frequently through rapidly accreting organo-detrital wetlands, with prominent levees through which crevasse splays feed into floodbasins (Smith and Smith, 1980). Anastomosing systems of the Okavango Delta in Botswana are sandy bed-load channels with very subdued levees that transport low suspended loads through nonaccreting to very slowly accreting reed-swamps and lakes (e.g., McCarthy *et al.*, 1988). In stark contrast, rivers of the semi-arid Australian Channel Country are entirely detrital, mud-dominated systems, with high suspended load, subdued levees and insignificant floodbasins. They traverse broad alluvial plains that are accreting very slowly in a cratonic setting, and exhibit infrequent avulsions (Gibling *et al.*, 1998). On the Ganges plains in the Himalayan Foreland Basin, a rapidly accreting anastomosing reach of the Bagmati River experiences avulsion on a decadal scale, with frequent crevassing through levees onto monsoonally flooded plains. Anastomosing rivers were also prominent during the early Holocene history of the Rhine-Meuse and Mississippi deltas. However, in a detailed review, Makaske (2001) found no standard sedimentary succession for anastomosing rivers.

As a group, anastomosing rivers are not diagnostic of climatic conditions, ranging as they do through sub-arctic, alpine, temperate, wet tropical, and semi-arid settings (Makaske, 2001). However, individual types may well be diagnostic of certain climatic conditions. Because most rivers are single thread, the question arises as to why multi-thread anabranching rivers form at all. They appear to develop under conditions where there is insufficient gradient to move water and particularly bed-load through a single channel system (deltas are classically anabranching). However, as with other river patterns, a truly rational explanation is still sought.

Alluvial fans

Alluvial fans are fluvial depositional zones that are essentially fan-shaped in planview, convex upward in transverse section, and occur at the exit of a confining basin. Their location reflects a sudden decline in flow competence due to valley widening, a reduction in gradient, and a loss of water due to infiltration. Fans vary greatly in size but exhibit well defined relationships between their area and slope and the size and lithology of their catchments. They may exist as single features or coalesce to form a piedmont or *bajada* many kilometers in lateral extent where closely spaced rivers exit a mountain front. They typically extend for a few kilometers to tens of kilometers basinward, but some volcanoclastic fans and aprons that border active volcanic arcs extend for more than 100 km, on account of their huge yields

of unconsolidated material, enormous discharge and long runout distances for debris and stream flows. Fans that debouch into an ocean or lake are termed *fandelas*, with good examples in the Red Sea, Gulf of Suez, and East African rifts. In relatively arid environments, flow volume declines basinward, and the size, and proportion of channels decreases, with a concomitant increase in sheetfloods (sheets of unconfined water moving rapidly downslope).

Talus or *scree cones* are steep accumulations of debris at an abrupt break of gradient such as at the base of a cliff or at the exit of a small hanging gully. Although also fan-shaped, they are not alluvial, formed instead of loose, highly angular clasts transported subaerially by gravity, sometimes aided by snow avalanches. They are distinguishable from fans by being much steeper (26° – 36°) and with sediment that *increases* in size down slope.

Large rivers such as the Gandak and Kosi that enter the Gangetic Basin from the Himalayan Front in India and the Okavango River in Botswana deposit sediment cones that extend hundreds of kilometers from the mountains. However, such low-gradient features are not considered by some to be alluvial fans. Blair and McPherson (1994) argued that there is a hiatus in the range of longitudinal slopes of alluvial distributary systems, with few fluvial depositional systems having slopes in the range 0.007–0.026. Most meandering and braided systems have gradients of <0.007 , and they recommended restricting the term alluvial fan to systems with gradients of 0.026–0.466, as such fans are characterized by viscous debris flows and sheet floods. Stanistreet and McCarthy (1993) proposed a tripartite classification with end-members of *debris-flow dominated fans* with gradients of 0.1 to 0.001, *braided fluvial fans* such as the Kosi system with gradients of 0.001 to 0.0003 and *low sinuosity/meandering fluvial fans* such as the Okavango system with gradients of <0.0003 . In an earlier classification, Schumm (1977) called debris-flow dominated fans *dry fans* and did not differentiate between the two types of fluvial fan that were called collectively *wet fans*. Low gradient coalescing alluvial surfaces have been termed *riverine plains*, as for example the Canterbury Plains of New Zealand and the Riverine Plain in the Murray basin of Australia.

The main advantage of the more prescriptive approach of Blair and McPherson (1994) is that fan deposits are potentially recognizable in the rock record through the predominance of debris-flow deposits with matrix-supported fabrics (dry fans). However, the Stanistreet and McCarthy (1993) approach more readily incorporates what have been widely regarded to date geomorphically as alluvial fans, while still retaining the debris-flow category as their steepest type. An additional problem with the Blair and McPherson approach of linking fans with debris flows is the strong overlap of mechanisms between end-members of debris and stream flows and the difficulty of distinguishing true debris-flow deposits in some cases. In some debris flows, larger clasts are not suspended but remain in contact during motion, generating deposits with clast-supported textures and low clay content. There has also been widespread recognition of hyperconcentrated flood flows, intermediate between debris and stream flows in hydraulic behavior and sediment properties (commonly clast-supported) and representing extraordinary floods with unusually large sediment volumes. As Miall (1996) noted, it remains to be seen which approach proves to be the most useful and widely adopted.

Dry fan development is known to be prevalent today, especially in arid upland regions with sparsely vegetated slopes subject to infrequent flash flooding. Wet fans were predominant in the geologic past, especially in glacial periods with abundant seasonal snowmelt, and are still active today in some humid upland regions with frequent runoff (Schumm, 1977). Because of the limited travel-distance and viscosity of debris flows, dry fans tend to be small, and relatively steep. Debris flow deposits in the near-source part of the fan are poorly sorted and often matrix-supported with angular clasts and outsize boulders. Running water reworks them through sheet and channel flow into a downslope progression of gravel and sand, with mud predominant near the fan toe. The lower fan can be characterized by braided stream deposition. Debris flows aggrade the upper fan, but fluvial action can periodically cause entrenchment, producing a complex topography. "Sieve deposits" of well-sorted gravel without matrix, identified as a distinctive sediment type on some fans, may be debris-flow deposits from which fines have largely been winnowed at the surface.

Wet fans can be small or large and show pronounced sediment-size sorting, clast rounding and traction-current deposition. Alternating aggradation and incision near the fan head produces coarse overbank sheetflow deposits and splays as well as trenched channels with longitudinal gravel bars. The mid fan consists of typically braided channels that switch back and forth depositing longitudinal gravel and transverse sand bars. The lower fan is characterized by transverse bars or dunes with overbank mud and the channels meander in places, as in the Kosi Fan of northern India. Experimental work by Schumm (1977) and Schumm *et al.* (1987) identify two main autogenic processes in the upper to middle part of braided wet fans: the avulsive shifting of distributary channels and a cyclic trenching and backfilling of channels. These alternations can be controlled entirely by intrinsic thresholds relating to sediment supply from the basin and deposition on the fan. During the trenching phases, coarse sediment is moved more effectively down the fan whereas with backfilling the fan aggrades and sediment is distributed across the surface by sheet flow. With fan building, segmentation can produce individual depositional zones or lobes, each associated with an individual distributary channel (Schumm *et al.*, 1987). In combination they build to form the fan as a whole. Climate undoubtedly affects fan development. During wet periods wet fans are usually strongly aggradational whereas extensive trenching can occur in dry periods.

Coarse-grained, permeable fan sediment promotes groundwater recharge, resulting in strong transmission losses and the demise of perennial rivers over the fan surface. In arid regions the groundwater may discharge beyond the fan margin, resulting in evaporitic playa lakes in arid regions such as Death Valley, California, as well as promoting enhanced vegetation growth in some areas. Large groundwater resources are associated with many fans. Some interfan areas have little fluvial activity, and arid-zone fans may interfinger with eolian deposits. However, very active rivers can be present between large cones, for example the Baghmata River that lies between the Gandak and Kosi cones in northern India. Channel switching on fans results in inactive areas where soil formation and chemical effects, such as formation of desert varnish, are enhanced.

Alluvial fan deposits in the rock record may be hundreds of meters thick and commonly occupy rapidly subsiding

extensional and foreland basins where faults controlled basin-margin relief. Most are a few tens of square kilometers in area, but some large, wedge-shaped volcanoclastic aprons cover areas of 10^3 km² and are up to 1 km thick. Fan deposits are typically poorly channelized and comprise amalgamated narrow channel (ribbon) bodies and broad (sheet) bodies of conglomerate and sandstone. Downflow, ribbons, and narrow sheets of conglomerate and sandstone are interbedded with mudstones, and mark the positions of major distributaries and fan lobes in more basinward settings, sometimes passing distally into sheetflow deposits.

DeCelles *et al.* (1991) documented wet fan deposits in the Cenozoic of the western US with cycles of aggradation and degradation. Periods of aggradation and flow expansion near the fan apex generated broad sheets which were subsequently incised, allowing sediment to bypass the upper fan through deep channels. The cycle was completed with channel backfilling and renewed dispersal over the fan surface. The resulting lithosomes are 10 m to 50 m thick and up to several kilometers wide, and are composed of smaller channel bodies in the form of scour-based sheets up to 10 m thick and hundreds of meters wide. Similar episodes of sheet aggradation under conditions of high supply, followed by incision as supply waned are also prominent in volcanoclastic fan and apron deposits. Other fan deposits consist of overlapping lobes of gravel separated by thin paleosols. These studies underline the importance of sediment supply in controlling fan architecture, commonly linked to climatic change or volcanism. Trenching may also have extrinsic causes, such as tilting or base-level rise in fan deltas, and extensional basins have complex fault systems where rapid shifts of activity and sediment supply along fault segments can result in complex sedimentation patterns in fans and bajadas.

Many fan deposits consist of cycles or megasequences, tens to hundreds to meters thick, that coarsen or fine upward. Coarsening upward cycles represent the basinward advance of fan lobes or entire fans, bringing coarse sediment over basal fines. In contrast, fining upward cycles reflect declining sediment supply due to scarp retreat, fault-block evolution, denudation of topography, or gradual abandonment of fan segments. In strike-slip basins, entire fan bodies may represent the lateral migration of the depocenter past the fan entry point, so that the fan is progressively detached from its feeder channel. The presence of fan wedges in basal fills may imply tectonic activity and uplift of a nearby source area, or may imply periods of tectonic quiescence followed by trenching and dispersal of fan sediment farther out into the basin. Fan and other fluvial deposits may also build basinward as thrusts advance, with deformation and cannibalization of fan sediments below the thrust mass. The location of fans close to tectonically active areas can cause early tectonic deformation, including the development of unconformities.

Deltas and estuaries

Rivers of all types are influenced by coastal processes. Most large rivers with high sediment loads terminate in delta distributary systems on open marine shelves (shelf-phase deltas) or on the shelf margin at lowstand or where the shelf is unusually narrow (shelf-margin deltas) (see *Deltas*). They may also terminate as bayhead deltas in restricted embayments, in back-barrier lagoons or in freshwater lakes. Under the low gradients typical of rivers approaching the coast,

distributaries tend to have low sinuosities and many are essentially straight, commonly forming anastomosing and distributary networks.

Other rivers enter the sea through estuaries which are the drowned seaward parts of river valleys (see *Estuaries*). Estuarine facies commonly have a tripartite nature, passing landward from sandy wave-influenced facies at the estuary mouth to muddy central-basin facies, to sandy river-dominated facies (Dalrymple *et al.*, 1992). Although flocs of clay and organic material are widespread in inland rivers, fluvial deposition is especially enhanced by flocculation of clay where the suspended load encounters saline water, with preferential settling of mud during low-velocity turnaround points in the tidal cycle. Where sea-level rise inundated low-gradient plains, such as on the North American craton during the Late Paleozoic and Cretaceous, tidally influenced channel and valley fills are prominent. Important depositional zones on many modern river systems, deltas, and estuaries are described in detail elsewhere in this volume.

Major controls on accumulation of alluvial deposits

Tectonism, eustasy, and climate are key factors that govern the nature and accumulation of alluvial sediments. The effects of tectonism and eustasy are mediated principally through the creation and loss of accommodation, the space available for sediment to accumulate. Because insufficient sediment may be available to fill all the space generated in a basin, it is important in stratigraphic analysis to distinguish the thickness of strata preserved at a given place and time (*accommodation*) from the maximum possible space available which corresponds closely to the height of a water column at a given place and time (*potential accommodation*).

Tectonism operates through basin-scale subsidence and local fault activity, over timescales of years to millions of years in orogenic belts, and locally over just a few decades within sedimentary basins. Gravelly alluvial fan wedges accumulate where faults create strong basin-margin relief, and unusually thick alluvium, including peat, accumulates in rapidly subsiding parts of foreland and extensional basins. Such deposits commonly contain cycles and megasequences that may reflect tectonic events. Asymmetric subsidence in half grabens leads to drawdown of axially supplied sediment into the most rapidly subsiding zones, strongly influencing the proportion and connectedness of channel bodies in the succession.

Eustasy operates principally through glacioeustatic change in sea-level, related to systematic variation in the amount of insolation received as the earth orbits the sun (the Milankovitch effect). Sea level may vary by >100 m on timescales of tens of thousands to a few hundred thousand years. Such high-frequency and high-amplitude changes generate prominent sequences in coastal alluvium. Sea-level fall and lowstand are marked by widespread erosion, valley formation, and paleosol development on interfluves, whereas transgression and highstand are marked by flooding surfaces, backfilling of valleys with alluvium, and peat accumulation in coastal wetlands (Posamentier and Allen, 1999). On geological timescales, sea-level change typically affects fluvial facies and accumulation rates for only a few hundred kilometers inland. During periods of earth history when continental ice-sheets were lacking, sea-level changes of low amplitude may have been mediated by other factors, including buildup of valley

glaciers, methane hydrates, and groundwater storage. Lake-level change affects fluvialacustrine systems and, due to the confined nature of lakes, can produce unusually large changes in level over short periods, with profound effects on fluvial architecture, as in the Volga River where it enters the Caspian Sea. Groundwater level acts as base level for some fluvio-colian systems.

Climate change involves many parameters, including total precipitation, temperature, and nature and degree of seasonality (Blum and Tornqvist, 2000). Such change operates on timescales of years to millions of years, and is mediated to alluvial systems through changes in discharge, sediment flux, sediment type and soil type. Basinwide changes in fluvial style and sediment grade in the Channel Country of Australia have been linked to climatic and discharge changes that correlate with glacial cycles (Gibling *et al.*, 1998). Discharge variation may be especially important in monsoonal areas, such as southern Asia, where the intensity of monsoon circulation and precipitation is closely linked to the glacial-interglacial cycle. In such areas, precipitation may increase at least twofold over periods of a few thousand years, causing basinwide changes in fluvial style and vegetation and strong incision of drainage networks. The type and density of vegetation in riparian and upland regions is especially sensitive to climate and strongly influences sediment flux because of the crucial role that vegetation plays in stabilizing soils. Thus, floral overturn in response to climatic variation may have had a strong influence on sediment supply to basins, as may vegetation destruction by wildfire.

A key effect of the three major controls is the creation of river valleys, as outlined in earlier paragraphs. Valleys are linear troughs with dimensions much larger than those of the channels they contain (Schumm and Ethridge, 1994). Valley fills are most commonly recognized in the bedrock record where prominent unconformities represent long gaps in time, whereas valleys incised into alluvium and marine sediments may represent short-term effects, and are more difficult to recognize. Although many coastal valleys reflect sea-level lowering, valley formation may also reflect discharge variation, uplift, and localization of incision along faults.

River terraces are paleo-floodplains, abandoned usually as a result of climate change, eustasy, or tectonism. They are normally elevated above the floodplain along the valley margins but can dip below the floodplain surface, and below sea level off shore as a result of sea-level rise. Their sedimentology is diagnostic of the environmental and associated flow conditions that prevailed at the time of their formation.

Geometry of fluvial bodies in the ancient record

The three-dimensional geometry, permeability framework, and degree of connection (connectedness) of fluvial deposits have considerable practical importance for aquifers, hydrocarbon reservoirs, and mining of coal and economic minerals that are hosted by fluvial strata. Important studies of channel-body geometry were published by Krynine (1948) and Friend (1983). Channel and floodplain sediment bodies in preserved strata can be divided on the basis of width: thickness ratio (measured normal to the flow direction) into ribbons (<15:1), narrow sheets (<100:1) and broad sheets (>100:1). As noted earlier, a link between channel proportions and sediment load was noted by Schumm (1960), and these arbitrary divisions have

counterparts in modern channel dimensions, for many self-formed single channels have width:mean depth ratios of less than 20, with progressively fewer with ratios up to 100 and above. Large braided rivers and braidplains may have width:depth ratios of several hundred and upward. Krynine also suggested divisions in terms of stratal area. No upper limit has been placed on sheets which, in the case of widespread flood layers and braided-fluvial sheets, can have very high aspect ratios, as noted earlier. This geometric classification is independent of scale, and can apply equally to scour fills a few decimeters and valley fills that are several kilometers thick. Dimensional divisions become more difficult to apply where fluvial bodies are stacked to great thicknesses without intervening extra-channel strata, as in some alluvial fan deposits localized at basin margins and basinwide braided-fluvial formations. Sediment accumulation as levees and crevasse splays on channel margins can result in channel fills with *central bodies* and marginal *wings*.

As noted by Friend (1983), braided and meandering rivers tend to have *mobile channel belts* that migrate laterally, and generate widespread sheets of gravel and sand. The sheets may contain discrete channel fills of ribbon form that represent the fills of confluences, anabranches, and localized scours that were cut and filled rapidly. In contrast, channels in cohesive fine-grained material can be categorized as *fixed channels* that are laterally stable between episodes of abrupt switching and generate bodies in the form of ribbons and narrow sheets. These represent an initial channel form, perhaps widened slightly through time by bank migration. A third category is *sheetflood deposits* with very extensive sediment sheets that represent poorly channelised settings.

Where floodplains aggrade rapidly, typically due to rapid subsidence or sea-level rise, channel bodies tend to form ribbons or narrow sheets that are encased in floodplain fines and poorly connected. In contrast, where floodplains aggrade slowly, rivers tend to migrate laterally and rework their alluvium, resulting in sheets of well connected channel bodies. Growth of peat domes can restrict channel migration and promote thick ribbon bodies. Thus, channel-body geometry commonly represents an interplay between initial channel form, aggradation rates of channel and floodplain sediments, and the rate of lateral channel expansion through sediment of varied consistency. Avulsion patterns have an important influence on channel body form, as avulsing channels can create new courses or can reoccupy pre-existing courses, thus promoting the generation of stacked, multistory bodies (Jones and Schumm, 1999; Kraus and Wells, 1999). There is no unique relationship between channel planform and 3D channel-body form, because the final form usually represents the evolution of one or more channels over a prolonged period, during which the channels migrate and avulse laterally and aggrade vertically. Commonly, however, fluvial processes and alluvial facies are related to the four dominant river patterns of straight, meandering, braided, and anabranching, and to the two dominant terminal depositional systems, fans, and deltas.

A descriptive framework for studying the geometry of alluvial bodies was outlined by Miall (1996). This framework involves the use of facies codes for sediment types, recognition of bounding surfaces with a hierarchical order (from bed boundaries to major valley bases), and the identification of architectural elements that are characteristic of many fluvial systems. The latter include sediment gravity sheets, sandy

bedform sheets, downstream, and laterally accreting elements, laminated sand sheets, and overbank fines, as well as bodies with distinctive channel form. The combination of these elements and bounding surfaces can be used to present an objective view of the channel body.

SABKHA, SALT FLAT, SALINA

The term *sabkha* (Arabian for *salt flat*) is used by sedimentologists to designate an arid, subaerially exposed environment (typically a salt-encrusted mudflat). The term came into wide use among sedimentologists following the pioneering studies of the modern carbonate tidal flat deposits of the arid Trucial Coast, Persian Gulf (now the Arabian Gulf) by D.J. Shearman's Imperial College group (Curtis *et al.*, 1963; Kinsman, 1969; Butler, 1970). The term *continental sabkha* has been used for the arid mudflat of a non-marine closed basin, better known to students of the closed basins of the western US as a saline *playa* (Spanish for "shore" or "beach"). In South America the term *salina* is used for a salt-encrusted mudflat. The factors common to both marine and non-marine sabkhas are (1) an arid climate, (2) the dominance of subaerial exposure of the mudflats, punctuated by occasional flooding (seawater on marine sabkhas and meteoric waters on playas), and (3) deposition of evaporite minerals (such as gypsum and halite), subaqueously in ephemeral "lakes" but in the vadose zone and as efflorescent surface crusts during periods of subaerial exposure.

The existing studies of the Holocene Arabian Gulf marine sabkhas have focused on vadose zone gypsum and anhydrite in the sabkha environment. Warren (1989, p.38) defines sabkhas "as marine and continental mudflats where displacive and replacive evaporite minerals are forming in the capillary zone above a saline water table". All the spectacularly deformed layers of nodular anhydrite (enterolithic folds, overthrust and underthrust ridges, diapiric structures, etc.; see Butler, 1970; Demicco and Hardie, 1994, figures 160(A–C)) in the Arabian Gulf are attributed to intrasediment growth of gypsum and anhydrite (e.g., Warren, 1989, figure 2.5). While saline mineralization in the vadose zone is a most significant and characteristic process in any ephemeral evaporite environment, the Arabian Gulf sabkha "model", based on vadose processes, does not include a most important stage in the marginal marine sabkha depositional cycle, the "gypsum pan" stage.

This pivotal step in evaporite mineral formation in the "sabkha cycle" is outlined below.

The following description of the formation of *bedded gypsum* in a modern marine sabkha environment is based on observations made on the large (80–100 km²) "ephemeral gypsum pan" of the extensive arid supratidal flat at the southwest margin of the Colorado River delta, Baja California, Mexico (Castens-Seidell, 1984; Hardie and Shinn, 1986, pp. 46–49 and table 1; Demicco and Hardie, 1994, p.197). This active gypsum pan cycles through the following sequence of stages: a seawater flood stage → an evaporative concentration stage (ephemeral shallow saline lake) → a desiccation stage (dry gypsum pan) → a halite pan stage, and back to a flood stage. The length of each cycle is a function of the interval between storms (months to a few years). After a major seawater flooding event the supratidal flat is covered with a sheet of mud-laden seawater (<1–2 m deep). As the flood finally subsides, most of the seawater drains back to the sea leaving an isolated sheet of seawater ponded in the shallow depression (the "evaporating pan") on the supratidal flat. Deposition begins with a cm-scale layer of siliciclastic mud that settles out over the gypsum bed formed during the last gypsum pan cycle. This mud layer is soon covered by a cyanobacterial mat that develops low-amplitude polygonal undulations as the mat grows. Evaporative concentration eventually leads to shrinking of the "lake" and the nucleation of very small aragonite needles and gypsum euhedra at the brine-air interface, held there by surface tension. As these surface-nucleated crystals grow, their increasing weight eventually leads to their settling to the bottom of the shallow "lake" where they act as nuclei for syntaxial bottom growth. Competitive growth and space constraints favor the vertically-oriented nuclei, resulting in a subaqueous gypsum layer composed of an upward radiating array of blade-shaped and "swallow-tail twin" crystals (e.g., Demicco and Hardie, 1994, figure 154A). With progressive evaporative concentration, the saline lake progressively shrinks, exposing the newly-formed subaqueous gypsum layer to the hot, dry air. The gypsum of this subaerially-exposed layer then undergoes diagenetic modification as evaporative pumping draws brine from the shallow subsurface brine table (<1 m) up through the vadose

zone. This brine pumping process promotes the precipitation of gypsum in the intercrystalline cavities in the gypsum bed as vadose cement, which in turn causes the bed to expand laterally. This generates small-scale buckles in the gypsum crust and leads to the formation of larger antiform polygonal ridges (several cms. in height) spaced approximately 2 m apart ("tepees", see Demicco and Hardie, 1994, figure 161). Ultimately, the continued lateral expansion of the gypsum layer gives rise to fracturing at the polygon boundaries and the development of overthrusting and underthrusting at the ridges. In turn, these thrust fracture zones act as localized high permeability conduits for enhanced evaporative pumping of brine up through the vadose zone. When these brines emerge at the surface, they evaporate rapidly to dryness and deposit finely crystalline gypsum beneath the fractured ridges, adding to their volume and height, a process that produces diapir-like masses of gypsum beneath the ridges. This tepee-forming process is only halted by the next flooding event when a new gypsum pan cycle begins. The cycle starts again as seawater, undersaturated with respect to gypsum, floods over the dry gypsum pan partially dissolving the buckled gypsum surface layer, enlarging existing intercrystalline cavities and rounding the margins of exposed euhedral gypsum crystals. This dissolution phase soon results in the floodwaters becoming almost saturated with respect to gypsum. This allows erosion, transportation and redeposition on the pan of loose gypsum crystals and cleavage fragments as sand and gravel sheets. Isolated patches of gypsum sands may be sculptured into classic unidirectional bedforms and wave ripples. Ultimately, as the flood waters subside, seawater left ponded on the gypsum pan evaporates to the point of gypsum saturation and a new gypsum bed is formed. During this stage of this new gypsum precipitation cycle, the dissolution features of the underlying gypsum bed are "repaired" by syntaxial overgrowth (Demicco and Hardie, 1994, figure 154C) and by cementation on the walls of intercrystalline cavities.

Most significantly, the layered gypsum of the Baja California supratidal flats *has not been converted to nodular anhydrite*, yet it has all the basic morphological features found in the Persian Gulf layered nodular anhydrite, that is, cm-scale layers of detrital sediment alternating with cm-scale layers of gypsum displaying enterolithic folding, diapiric structures, and polygonal tepees with overthrust and underthrust "faults" located at the buckled tepee ridges. At the landward margin of the sabkha, gypsum crystals are in the early stages of dehydration to anhydrite (Castens-Seidell, 1984). It is easy to imagine that with time, as the Baja California tidal flats continue to prograde seaward, complete conversion of these gypsum layers to anhydrite will mimic the spectacular evaporite features observed in trenches cut into the landward regions of the Persian Gulf sabkha. By analogy, then, *the Persian Gulf layered nodular anhydrite would have been formed by dehydration of layered gypsum that crystallized subaqueously in shallow ephemeral gypsum pans*, inheriting the principal deformation structures from the parent gypsum bed. The Persian Gulf "gypsum pan" deposits, converted completely to anhydrite, are now defunct. They have been eroded by deflation and covered by windblown sands as the tidal flats have prograded seaward over the past 5000 years. This same model could apply to other, more ancient, layered nodular anhydrite deposits in the geological record.

For each flood event, as evaporative concentration proceeds and the shallow saline "lake" shrinks, the surface brine body may reach saturation with respect to halite, forming an *ephemeral halite pan* at the center (the "bullseye") of the gypsum pan. All the essential characteristics outlined above for ephemeral gypsum pan deposition have been documented and described by Lowenstein and Hardie (1985) for bedded halite in the ephemeral salt pan that lies in the center of the Baja California gypsum pan (see also pioneering study of Shearman, 1970). Significantly, however, the halite of the salt pan on this arid tidal flat is short-lived because, typically, the subaerially-exposed, highly soluble halite crusts of the salt pan are completely dissolved by large inundations of seawater driven onshore by strong storms. When the onshore winds subside, most of the floodwaters drain off the tidal flats carrying dissolved NaCl back to the sea, leaving the relatively insoluble gypsum crusts essentially intact. This observation suggests that we should not expect to find thick accumulations of salt pan halite capping arid tidal flat cycles. Instead, such depositional cycles would be capped by ephemeral gypsum pan deposits (see *Anhydrite and Gypsum*, figure A8).

Analogous processes and products can occur in nonmarine closed basins on ephemeral playas. The main difference would be that the floodwaters would be relatively dilute meteoric waters with a much greater potential for widespread dissolution during the initial flooding stage. In addition, for gypsum to be a significant precipitate, the inflow waters must be of the "neutral" Na-K-Ca-Mg-SO₄-Cl chemical group (see *Evaporites*). In modern ephemeral playa settings in arid closed basins, halite pans are far more abundant than gypsum pans because in such basins there are no outlets that would allow flushing away of the halite formed in the "bullseye" of the pan, as occurs on marine supratidal flats as described above for the Baja California sabkha.

SALT MARSHES

Marshes are wetland environments dominated by herbaceous plants. Sea-coast tidal salt marshes are a specific type found in sheltered back-barrier, estuarine and deltaic settings where they form important environments and ecosystems. They contain halophytic (salt tolerant) grasses, rushes, sedges and forbes that are able to survive in intertidal and fringing environments hostile to upland vegetation. Mature marshes are dominated by living plants and are usually constructed on peats, the partially preserved remnants of former marsh plants. Marshes usually stand higher than flats, from mid-tide to highest spring tides, and are often best developed as a broad flat within a few decimeters of mean high water (MHW). Marsh sediments have been used as tools for stratigraphic reconstruction of coastal evolution (Kraft, 1971) and bases for interpretation of Holocene sea-level change (Redfield and Rubin, 1962; Kraft and Belknap, 1977; van de Plasche, 1986; Gehrels *et al.*, 1996) using radiocarbon dating of peats built from plants that grow near mean high sea level.

Morphology

The morphology of salt marshes depends on tidal range, slope of substrate, and geometry of the enclosing embayment (Kelley *et al.*, 1988). The simplest salt marsh, often an early or ephemeral phase, is created through the colonization of tidal flats with halophytes. Later successional phases create more complex morphology, to a large degree controlled by the ecology of the vegetation. Fringing marshes occur adjacent to uplands. They may occupy relatively steep margins in tidal rivers and estuaries, particularly in rocky or paraglacial regions such as New England. More widespread are those on the landward edge of lagoons, on low-angle coasts. Estuarine and Fluvial salt marshes are elongated in a marginal fringe parallel to the channel and the upland. They may vary from fringing to broad types. Back-barrier marshes are broad and may fill the majority of backbarrier systems (South Carolina tide-dominated mesotidal barrier systems, many New England marshes), or may occur as a relatively narrow band on the lagoon side of wave-dominated microtidal barriers (Long Island, New Jersey, Delaware). Broad, well-developed marshes are generally flat, graded to near mean high water (± 30 cm or less), with the majority of their area in the high marsh zone. Fringing marshes are steeper, because they compress all the marsh zones, controlled by frequency of flooding, into a narrower band.

Ecosystems

Within a marsh there are commonly: (1) a low marsh, colonizing zone; (2) a broad high marsh; (3) tidal creeks; (4) creek levees or margins; (5) salt pannes; (6) higher-high marsh; and (7) upland fringe. Marshes are generally zoned by the

ecology of the plants (Niering and Warren, 1980). Primarily tolerance of the halophytes is to frequency of tidal inundation. Some plants have specialized structures in subsurface rhizomes and roots for gas transport, and glands for excreting excess salt. In some fringing marshes with high tidal ranges, the zonation can be very sharp. In broad marshes or in lower tidal ranges, the zonation tends to be more mosaic in nature, and controlled by proximity to tidal creeks.

Low salt marsh has a very restricted diversity, dominated by salt marsh cord grass *Spartina alterniflora* in much of North America and other areas. Low salt marsh occurs from Mean Sea Level (MSL) to MHW, and is flooded by most tides. High salt marsh is more diverse, generally from MHW to SHW, flooded every fortnight. High salt marsh is more diverse, and varies by climate zone. In New England high marsh is dominated by *Spartina patens* grass, in the mid-Atlantic by *S. patens* and *Distichlis spicata*, in Georgia and Florida by the rush *Juncus roemarianus*. On the Pacific coast of the US, it is dominated by *Salicornia pacifica*, while *Puccinellia maritima* is common in the British Isles.

Higher high marsh is flooded a few times per month, occurring above MHW to Spring High Water. The ecology also varies by latitude. In Maine the dominant plant is generally *Juncus gerardii*, while the Mid-Atlantic is less distinct, with *Distichlis spicata* and shrubs *Iva frutescens* and *Baccharus halimifolia* important.

Upland Fringe is primarily a freshwater system, flooded only during storms or astronomical highest tides, several times per year. Cattails (*Typha angustifolia*) predominate in the Upland Fringe in Maine, while in the mid-Atlantic *Phragmites australis* is dominant. *P. australis* is an aggressive colonizer of disturbed lands, and in the last few decades has expanded greatly in mid-Atlantic marshes, on dredge spoil islands, and is being carried to marshes in northern New England, particularly near major roads.

Marshes may also grade from primarily saline systems, as described above, to more brackish and freshwater systems along an estuary. Many species of sedges such as *Scirpus* and *Carex* characterize these transitional brackish marshes. Salt pannes are flooded low areas in high marsh, with variable salinities that vary from fresh to hypersaline. Their origins are controversial, but usually ascribed to "rotten spots" or ice plucking. They are dominated by cyanobacterial mats, and fringed by *Salicornia* spp., and are a critical ecosystem for larval and juvenile fish.

Processes

Marshes grow through *in situ* primary production, from roots, rhizomes, and stems of living plants, but also build up through accumulation of organic detritus. Most salt marshes are composed not of pure organic peat, but have a majority of inorganic sediment that is carried into the marsh in suspension (or by ice rafting). "Peat" is a field term for fibrous organic rich sediments found in marshes, but its true definition (>50 dry weight percent organic carbon) is found mainly in freshwater bogs. Highly fibrous New England marsh peats often contain less than 10 percent organics by dry weight (although 90 percent water and organics by volume). New England marshes are very firm and fibrous, Georgia and Florida marshes are muddy or sandy, while mid-Atlantic marshes are intermediate in composition.

Tidal currents predominate in channels. Flow is progressively channelized during late ebb through early flood tides, whereas sluggish sheet flow predominates at high water over broad marshes. Blocks constantly slump from margins of creeks, particularly in New England type marshes (due to high tidal range ice effects). However, rapid growth and sediment accumulation in the low marsh environment builds up and heals the slump, resulting in only slow channel migration.

Clastic sediments in fringing or narrow marshes often fine seaward, with lesser influence of runoff from upland sources. This inorganic sediment is extracted from suspension by: (1) direct settling from suspension—enhanced by a quiet water baffling effect, increased boundary layer thickness caused by the plants; (2) pelletization by organisms (mollusks, decapods, worms) and trapping in organic films; (3) adhering to grass stems, washed off by rain or accumulated as the plant dies; and (4) ice rafting in colder climates.

Broad marshes receive sediment from tidal creeks and may have coarser-grained levees, fining toward their interiors. Sedimentation rates in high marshes are an order of magnitude higher at the creek margin than the interior, due to supply. Sedimentation rates on low marsh are another order of magnitude higher (e.g., Wood *et al.* (1989) found sediment accumulation rates up to 8 cm per year in low marsh-tidal flat colonization zone, 0.5 cm per year in fringing marshes, and 2 mm/yr or less in broad marshes). Thus, broad marsh accumulates in equilibrium with sea-level rise and local compaction of marsh, while low marsh can colonize and accumulate much more rapidly.

Autocompaction occurs as a marsh compresses under the weight of accumulating sediment and through decay. Organic structures rot to some degree, but cellulose is preserved in saturated, anoxic, and lowered pH conditions. Kaye and Barghoorn (1964) demonstrated autocompaction to 40 percent of original cross-sections in predominantly freshwater marsh sediments, while Belknap and Kraft (1977) showed compaction-displacement of stratigraphic surfaces related to overall thickness of peats in paleovalleys.

Subfossil plant remains (roots, rhizomes, seeds) are commonly preserved well enough to identify species (Kraft *et al.*, 1979). Insect parts, diatoms, and pollen are also preserved and identifiable. Calcareous shells are not commonly preserved, because of the acidic conditions. Agglutinated foraminifera fossils are often well preserved, and have become critical tools in identification of marsh paleoenvironments and as sea-level indicators (Scott and Medioli, 1978; Gehrels *et al.*, 1996), providing more precise levels than the plants can.

Environmental evolution and stratigraphy

Frey and Basan (1985) suggest that marshes pass through stages. They identify: (1) a Youthful stage with mostly *S. alterniflora*, extensive lagoons, and a high accumulation rate; (2) a Mature stage with approximately equal proportions of high marsh and low marsh, less lagoon area, and the overall accumulation rate decreasing; and (3) Old Age, which consists of almost all high marsh, with poor drainage, and essentially no lagoon.

Salt marsh stratigraphic evolution depends on creation of new accommodation space for peat accumulation through autocompaction and sea-level rise. Rising sea level also allows transgression of the marsh's leading edge over upland surfaces. In a classic model of development of New England-type

marshes Mudge (1858) considered upbuilding and encroachment on the land (transgressive stratigraphy) in an environment of subsidence. Conversely, Shaler (1885) emphasized the progradation of marshes through colonization of flats and lagoons (regressive stratigraphy). Redfield (1972) investigated Barnstable marsh, behind the Sandy Neck spit on Cape Cod, Massachusetts, and found stratigraphy supporting both the Shaler and Mudge models, in a setting of relative sea-level rise, with expansion over mudflat and encroachment onto the upland. Recent work supports this conclusion, but it is clear that there are more complex relationships to rates of sea-level change and sediment introduction in New England salt marshes (Gehrels *et al.*, 1996).

Conclusions

Present knowledge of marsh environments provides a solid basis for facies models in estuarine, deltaic, and barrier settings. Sea-level change analysis is firmly established for general trends. Current research is focused on extracting the most details and establishing the greatest accuracy possible for addressing climate change on the millennial to decadal scale. Debates continue over limits of accuracy and precision of plant, foraminiferal and other indicators (Kelley *et al.*, 2001; van de Plassche, 2001), but it is clear that salt marshes contain a rich record of climate proxies.

SANDS, GRAVELS, AND THEIR LITHIFIED EQUIVALENTS

Introduction

Sand is defined petrographically as detrital particles between 1/16th and 2mm in diameter. Geologically, sand and its lithified equivalent, sandstone, are defined as deposits consisting of 75 percent or more of sand particles, the remainder typically being silt or mud. Gravel is the general term applied to detrital particles larger than 2mm, with such terms as pebbles, cobbles and boulders defined by specific size limits (see below). A lithified gravel is termed a breccia if the gravel fragments are angular, and conglomerate if they have been rounded by attrition. Very few sandstones and conglomerates consist entirely of sand- or gravel-sized particles, respectively. Most conglomerates include a matrix of sand and finer particles, and many sandstones are, to a greater or lesser degree, muddy, silty, or conglomeratic. The third component in many sandstones and conglomerates comprises one or more cements of silica, calcium carbonate or other, less common minerals. In most sandstones and conglomerates there are remaining pore spaces (up to 40 percent but typically <25 percent by volume) that are filled with pore fluids.

Sandstones and conglomerates typically preserve considerable internal evidence of their origins. The mineralogical composition of the detrital particles reflects their lithologic source, and may be studied to yield evidence of sedimentary provenance and unroofing history of uplifted areas surrounding a sedimentary basin. Textures and structures of a deposit provide evidence of the sedimentary processes involved in its transport and deposition.

Sands and gravels constitute about 25 percent of sedimentary rocks, by volume. They have economic importance as hosts for about one third of the world's conventional oil and gas and most of the heavy oil, plus several important economic minerals mined for such commodities as copper and uranium.

Grain size

Grain-size limits for sand and gravel, in mm and in ϕ (phi) units ($-\log_2$ of the grain diameter) are given below. The subdivision is logarithmic. That is, from very-fine sand to pebble grade, each grade size limit is double its predecessor. Similar grade-size subdivisions are used for gravel-size particles but are not shown.

	boulder	
256 mm		-8ϕ
	cobble	
64		-6ϕ
	pebble	
2		-1ϕ
	very coarse sand	
0.5		1ϕ
	medium sand	
0.25		2ϕ
	fine sand	
0.125		3ϕ
	very fine sand	
0.0625		4ϕ

Modifiers may be used to indicate minor components, for example, silty, very fine-grained sandstone, pebbly sandstone, muddy pebble-conglomerate.

For most practical purposes, for example for regional basin analysis or petroleum exploration, grain size may be estimated from hand specimens using a grain-size comparison chart (Miall, 1999, p.26). Vertical stratigraphic changes in grain size of several classes, for example, from coarse-grained sandstone upward to fine-grained sandstone, are significant in terms of changes in transport processes and depositional environments, and are obvious enough to not require confirmation by extensive laboratory analysis. For example, graded bedding is a common result of transport by sediment gravity flow processes, including turbidity currents and debris flows, while a cruder upward decrease in grain size in successive beds is a common result of the gradual filling of channels in fluvial, deltaic, and tidal settings.

Regional variations in sand or gravel grain size may yield information on proximity to sediment sources and on transport directions. Measurements of the largest particles in a gravel (or conglomerate) are particularly useful for such purposes, because gravel clast size decreases rapidly with distance of transport. For example, the downstream diminution of clast size on an alluvial fan at the margins of a basin (as a result of attrition and sorting), and the transition from a fan environment into a larger river may be readily seen from a map of clast-size variations. Mapping such variations may be particularly useful in lithified and deformed rocks where the paleogeography may not be readily apparent from basic stratigraphic data. Grain size changes resulting from attrition or sorting during transport are much less marked in sands, and may require detailed study if regional changes are to be examined.

For more detailed work, laboratory procedures and statistical data analysis methods are available. Use of these methods has declined in recent years because they do not yield additional information that is significant in most basin analysis applications. However, studies of sediment transport and bedform generation may require more precise and detailed information.

The grain size of loose sand may be measured by the use of sieves, settling tubes or electronic grain counting methods. Lithified sandstones may be analyzed in thin section, using a moveable stage to count a set number of grains (typically several hundred). When logarithmic grain-size classes are used, as in the table above, size distributions approximate that of the normal (Gaussian) curve. Cumulative distributions, plotted on a probability ordinate, approximate a straight line. The steepness of the line (the narrowness of the peak about the mean in a histogram) indicates the degree of "sorting" of the sand. Wind transport and wave sorting tend to generate well-sorted sands, that is, sand with the greater bulk of the sand concentrated over a limited size range, while fluvial transport generates more poorly sorted sands. Many attempts have been made to use various statistical measures of the grain-size distribution to identify sediment transport processes, in order to facilitate sedimentological work on very small samples, such as drill cuttings. However, none of these methods is very reliable, especially in lithified sediments, for a variety of reasons. For example, grain-size distribution may be affected by the size distribution of grains in the source rock, and may be modified by diagenesis. Facies analysis methods are quicker to apply and more reliable.

Grain shape

Shape may be defined in terms of three different parameters, roundness, sphericity, and form. Roundness may be measured following a detailed laboratory procedure, but is more commonly estimated by comparison with sets of images of known roundness. These show variations from very angular, through angular, sub-angular, sub-rounded, rounded to well rounded. Fragments are typically angular immediately following breakage from a parent rock, and acquire roundness through attrition during transportation. High degrees of roundness usually are displayed only by particles that have undergone intense wind abrasion, or are multicycle grains.

Sphericity may be defined as the ratio between the diameter of the sphere with the same volume as the particle, and the diameter of the sphere circumscribed around the grain. A more significant measure in terms of its hydraulic significance is the "maximum projection sphericity", which depends on the maximum projection area, and is a better indicator of the fluid resistance of the particle.

Detrital particles may be characterized as three-dimensional ellipsoids with three measurable axes, a short axis, an intermediate axis, and a long axis. Form is defined by the use of two shape indices, the ratio of the intermediate to long axis and the ratio of the short to intermediate axis. The relationships between these two indices define four form classes: oblate (flattened sphere), bladed, prolate (rod-shaped) and equant (round disk).

Studies of these three parameters have some limited usefulness in investigations of sediment transport. Roundness and sphericity increase with distance of transport, while form affects efficiency of transport. Rod-shaped particles are more

easily transported in rivers; disks are more common on wave-formed beaches.

Grain orientation

Traction-current transport tends to align sand and gravel grains such that elongate (rod-shaped) particles commonly align themselves either parallel or perpendicular to the direction of movement. Flat, disk-shaped clasts tend to assume a position on the bed with their maximum projection plane dipping toward the direction of flow—upstream in fluvial environments, facing the sea in wave-formed beaches. This is referred to as an imbricated fabric. Particles transported by sediment gravity flow may also assume preferred orientations. In debris flows, clasts may be rotated by internal shear immediately prior to the cessation of flow, with imbricated, flat (bedding-plane-parallel) or vertical orientations common. Observation and measurement of these fabrics may provide useful information on paleoflow directions (Martini, 1971; Schaefer and Teysen, 1987).

Composition

Sand and gravel represent the detrital products of weathering. Most detrital particles are generated by mechanical weathering, with subsequent fragmentation and rounding of grains taking place by attrition during downslope movement and during movement by wind and water. Chemical weathering typically removes much of the source materials in solution, but may leave sand- and gravel-sized particles as a residue.

The composition of sand and gravel deposits reflects that of the source materials, as modified by weathering and transportation (Blatt, 1992). Some types of detrital particle are much more resistant to weathering and erosion than others. Quartz, an abundant mineral in igneous and metamorphic sources, is highly resistant to mechanical and chemical weathering processes, and is by far the most common detrital sand particle. Minerals such as zircon, rutile, tourmaline and garnet, which occur as accessories in igneous and metamorphic sources, are also resistant and constitute minor components of many sandstones. Grains of this resistant group may be recycled through more than one episode of sandstone formation and erosion, preserving evidence of their lengthy history as detrital particles in the form of well-rounded shapes, and remnants of earlier grain outlines preserved beneath fragments of cement.

After quartz, the next most common detrital particles are feldspars, although these tend to weather readily. After this come a wide range of rock fragments. Most types of igneous, metamorphic and sedimentary rocks occur as fragments in sand and gravel deposits. The smaller, sand-sized particles may consist of single mineral crystals of the source rock, such as rounded fragments of quartz or feldspar, or more or less homogeneous pieces of fine-grained rocks such as shale or slate. Larger fragments, including many gravel particles, may consist of recognizable rock types, such as rounded pieces of an earlier sandstone, or a cobble of a coarse-grained plutonic rock.

Sands and gravels derived by erosion of older rocks, as described in the previous paragraphs, are classified, together with mudrocks and silts, as siliciclastic sediments, indicating the predominance of silica-rich detrital particles in their composition.

By contrast, in temperate to tropical marine settings, sands composed entirely of calcium carbonate may accumulate in shelf and shoreline environments from the fragments of carbonate-secreting organisms such as invertebrate shells and corals. The seawater in such places is commonly saturated with the calcium and carbonate ions, and lime precipitation is common. A particularly distinctive carbonate sand is one composed of oolites, which are particles consisting of concentric laminae of lime crystallized around a small nucleus, such as a tiny shell fragment or a wind-blown quartz particle. In contrast to siliciclastic sediments, carbonate sands are rarely transported far, typically being confined to the shoreline or shelf environment in which they are formed.

In rare instances sands may be composed of evaporite particles. Evaporite deposits, such as halite and gypsum, may form by evaporation of water bodies in hot, enclosed basins. Erosion and resedimentation of this material may take place during flash flood events, during which evaporite bodies may be fragmented, and the clasts redistributed as a form of sand.

Siliciclastic sandstones may be classified according to their detrital composition. Many different classification schemes have been devised. That shown in Figure S1 is one of the more popular. In most sandstones, each detrital particle is composed of a single mineral species, such as a crystal or crystal cluster of quartz, feldspar, calcium carbonate, etc. Arenites are distinguished from wackes by the proportion of detrital matrix (grains <30 microns in diameter). Arenites are defined as

sandstones containing less than 15 percent matrix, wackes as those with 15–75 percent matrix, while rocks consisting of more than 75 percent fine-grained particles are termed mudrocks. Particles larger than 30 microns are grouped into three categories that define the corners of the triangular classification. Sandstones are classified according to the proportions of the various detrital particles, summed to 100 percent. Determinations of these proportions are typically carried out by thin-section analysis using a movable stage. Except in cases of unusually pure (monomineralic) sands, counts of 300–400 grains are typically required to obtain reliable (stable) compositional data.

Sand-sized quartz grains, consisting of a few intergrown crystals of silica, are derived from coarse-grained granitic igneous or metamorphic rocks. Sand-sized quartz grains consisting of numerous small intergrown crystals may have been derived from finer grained igneous or metamorphic sources. A metamorphic origin is commonly revealed by a “strained” crystal fabric—individual crystals go into extinction under cross polarizers under lightly different positions as the microscope stage is rotated, indicating slight distortions of the crystals lattice. Silica grains of sedimentary origin may also be present in the form of chert, which occurs as mosaics of tiny interlocking grains, commonly preserving replaced fossil structures. Chert is normally counted as a rock fragment for the purpose of sandstone classification. Feldspathic sandstones typically are derived from granites or granite gneisses. Lithic sandstones may come from a variety of sources, and are

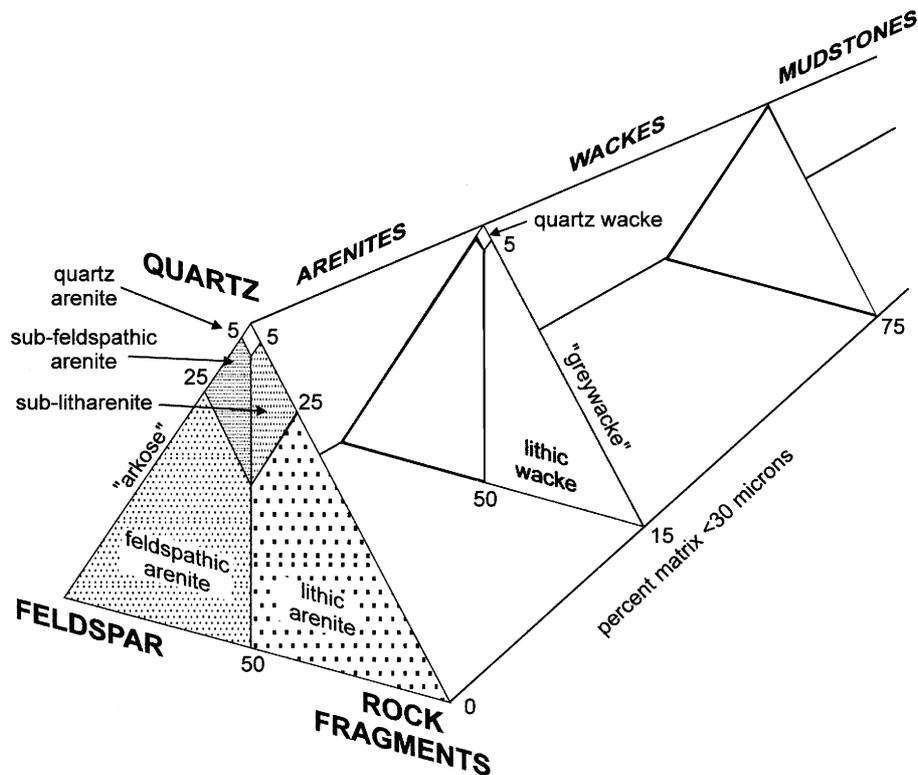

Figure S1 Classification of sand and sandstone according to composition. Sand is classified according to the relative proportion of three major classes of detrital composition. Separation of the three triangles is on the basis of the proportion of detrital matrix (modified from Dott, 1964).

characterized by the predominance of recognizable rock fragments. For example, modern “black-sand beaches” in Hawaii are composed of basalt fragments derived from wave erosion of fresh lava flows. Green beaches are composed largely of olivine grains, accumulated by selective wave sorting from the same volcanic sources. Sands with such unusual compositions are rare in the rock record because of the chemical and mechanical instability of basalt grains under normal weathering conditions. Quartz arenites typically represent recycled deposits from which other minerals have been removed by mechanical or chemical destruction. It is likely that many pure quartz arenites contain grains that were originally derived from a primary igneous or metamorphic source hundreds of millions of years before ending up in the rock in which they are found today. Some rock fragments may oxidize or otherwise decompose in place, and may be represented by clots of clay, that can be mistaken for detrital matrix. This has been called “pseudomatrix.”

Figure S1 includes two old petrographic terms that are not recommended, but are still in use. “Arkose” is an old term for feldspathic arenites, and “greywacke” is an old term for lithic wackes.

Variations in detrital composition areally across a basin or vertically, through a stratigraphic section, can yield much useful information about the paleogeography of a basin and the uplift history of surrounding source terranes, especially if such studies are carried out in concert with analysis of grain-size variations, as noted in the previous section. Given the varying resistance of detrital species to destruction by the processes of transportation, areal variations in composition may yield information about the location of specific sediment sources, and distances of sediment transport away from them. Certain components, particularly distinctive rock fragments, may be capable of being traced back to specific source rocks exposed in a source terrane. Direction and distance of transport may be indicated qualitatively by a decrease in the proportion and grain size of such distinctive components, with a concomitant increase in the proportion of stable grains, particularly quartz. For example, a localized carbonate reef deposit or a small igneous intrusion may yield floods of cobbles or boulders of a distinctive composition to an alluvial fan deposit banked against the adjacent basin margin, with the size and abundance of such grains decreasing toward the basin center as the particles are destroyed by attrition and

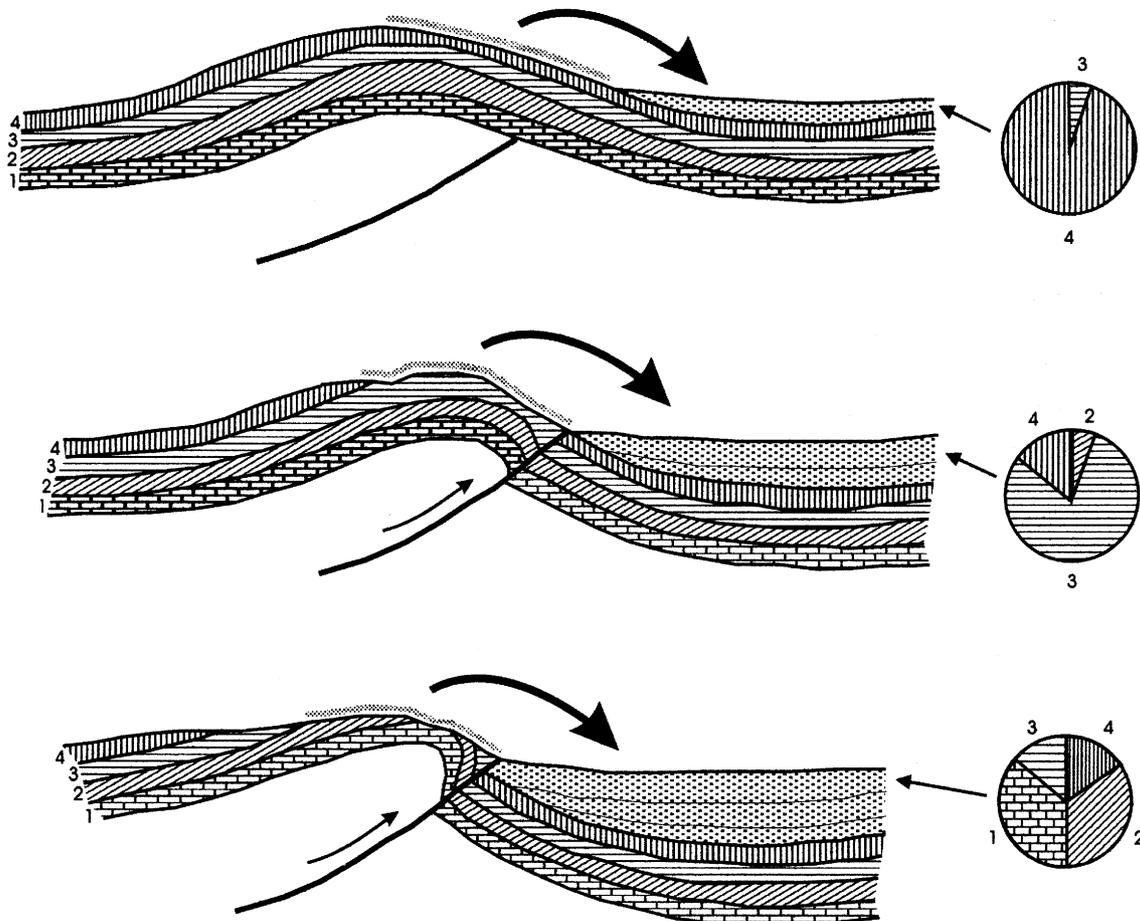

Figure S2 Three successive cross-sections illustrating the erosional unroofing of an uplifted fault block. Detritus from successive stratigraphic units 1, 2, 3, and 4 appear in inverse order in the sand detritus transported to the basin at right, as shown in the pie diagrams (after Graham *et al.*, 1986).

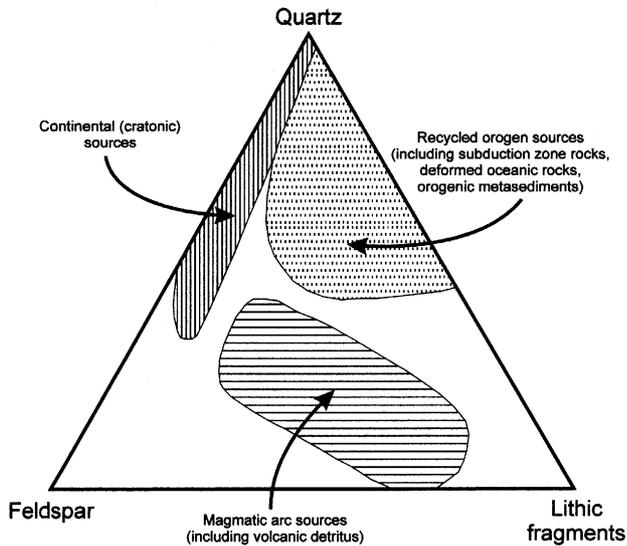

Figure S3 An example of a detrital sand composition plot showing the fields representing derivation from three broad classes of plate-tectonic setting (after Dickinson and Suczek, 1979).

weathering and are diluted by intermingling with other species from other sediment sources.

Vertical variations in detrital composition through a stratigraphic succession may yield invaluable information about the tectonic evolution of a source terrane. For example, proximal sand and gravel deposits in fault-bounded basins commonly display an “inverted stratigraphy” effect, in which younger strata are composed of fragments of successively older source rocks, that are exposed to erosion by gradual unroofing and exposure of deeper levels to surface weathering. Careful analysis of such detrital sequences may provide much information about the tectonic events involved in the building of a source terrane, for example, the emplacement of particular thrust plates or the unroofing of certain igneous bodies (e.g., Graham *et al.*, 1986; see Figure S2). Suturing and uplift of terranes on convergent continental margins may yield “overlap assemblages” of detrital particles derived from one terrane but transported onto and deposited on the adjacent terrane. Such occurrences can help in the dating of the amalgamation events.

Siliciclastic rocks may be characterized by their petrofacies, which is the term used to encompass stratigraphic variations in their detrital composition. Petrofacies characteristics may comprise a useful mapping tool, and may convey valuable information about regional controls on sediment sources (Dickinson and Rich, 1972).

In broad terms, detrital composition reflects the plate-tectonic setting of the source terranes (Potter, 1978, 1984; Dickinson and Suczek, 1979), a relationship that may be useful in the analysis of ancient and deformed rocks, where the plate-tectonic evolution of the area may be one of the problems to be investigated. For example, crystalline cratonic rocks tend to yield quartz- and feldspar-rich detritus; sands derived from magmatic arcs are commonly rich in lithic fragments, particularly volcanic detritus, and so on (Figure S3). Interpretations need to be made with caution, however, because of the many local factors that affect petrographic composition,

including weathering, transport history, depositional environment, and diagenesis (Miall, 1999, p.564).

SAPROPEL

An unlithified, fine-grained, often laminated, black organic-rich deposit containing mainly macrophytic (benthic) plant remains that have been decomposed anaerobically. The original definition (Wasmund, 1930) refers to lacustrine environments where the bottom water contains dissolved H₂S and a benthic fauna is consequently absent. The term has subsequently been extended to include marine deposits that are olive-green, gray or brown in color and contain both planktonic as well as macrophytic organic material. Examples of such sediments occur in the Holocene–Pleistocene sediments of the Black Sea (Strakhov, 1971) and the Holocene–Pliocene section of the Mediterranean Sea (Kullenberg, 1952;

Kidd *et al.*, 1978), including poorly-lithified rocks outcropping in the northern borderlands of the Mediterranean (van Os *et al.*, 1994).

Composition

According to the definition of Kidd *et al.* (1978), sapropels contain more than 2 wt. percent organic carbon and are at least 1 cm thick; sapropelic sediments are similarly defined but contain 0.5–2 wt. percent carbon. Organic carbon contents in Black Sea and Mediterranean sapropels can range up to 16 wt. percent and 30 wt. percent, respectively. The sapropels of the Black Sea contain both terrestrial and marine organic material (Wakeham *et al.*, 1991), whereas in the Mediterranean examples the organic fraction is overwhelmingly marine (ten Haven *et al.*, 1987). Sapropels also contain variable amounts of biogenous carbonate and silica together with fine-grained aluminosilicates. In common with other organic-rich marine sediments, sapropels have high concentrations of pyrite and a suite of minor and trace metals that often include Ba, Cu, Mo, Ni, U, V, and Zn (Calvert, 1983).

Black Sea sapropels

A black, very fine-grained sapropel has accumulated in the deep basin of the Black Sea over the last 7,500 years (Degens and Ross, 1972; Jones and Gagnon, 1994). The lower part of this deposit is especially organic rich (up to 20 wt. percent organic C), whereas the modern section contains 5 wt. percent organic C. A benthic fauna is absent in this permanently anoxic basin. The black coloration is caused by the presence of iron monosulfide, which readily oxidizes when it is exposed to the atmosphere, causing the color of the sediment to fade to dark grey (Berner, 1974). Sapropel formation began when saline Mediterranean waters entered the Black Sea basin via the Bosphorus Strait as a result of post-glacial sea level rise. This changed the Pleistocene Black Lake into the modern brackish (salinity 11^a), anoxic basin (Middelburg *et al.*, 1991). The accumulation rate of organic material increased markedly at this transition, and the accumulation rate of coccolith calcite increased about 2,700 years ago (Jones and Gagnon, 1994), thereby diluting the organic flux and initiating the formation of the modern laminated calcareous marls (Calvert *et al.*, 1991). Sapropels are also known to occur in the Pleistocene section of the deep Black Sea (Calvert, 1983).

Mediterranean sapropels

Multiple horizons of discrete centimeter- to decimeter-thick olive green to brown sapropels are found intercalated in the normal nanofossil marls of the Mediterranean Sea. They were discovered in the eastern basin during the Swedish Deep-Sea Expedition in 1947 (Kullenberg, 1952) confirming a prediction of Bradley (1938) that laminated, organic-rich glacial sediments should have formed when lowered sea level caused stagnation of the partially restricted eastern basin. Drilling in the Mediterranean over the last 25 years has extended the occurrence of these deposits throughout the eastern and western basins back to the Early Pliocene (Murat, 1999; Emeis *et al.*, 2000). The sapropels (>2 percent C_{organic}) are up to 70 cm thick and contain up to 30 wt. percent organic carbon. They may be faintly laminated, and either contain an impoverished benthic microfauna or are barren (Jorissen,

1999). They contain relatively high concentrations of pyrite but only trace amounts of iron monosulfide (Passier *et al.*, 1997); consequently their color does not change on exposure to the atmosphere. They are restricted to periods of climatic amelioration in the Mediterranean when the monsoon-driven freshwater balance changed drastically, and bottom water oxygen levels decreased leading to dysoxic or anoxic conditions on the seafloor.

Formation of sapropels

Sapropels are considered to form by one or a combination of the following processes: (1) increased preservation of organic matter in the bottom sediments; (2) high rates of supply of organic matter to the seafloor; (3) decreased dilution of the organic fraction by other sediment components. The preservation hypothesis focuses on the lower rate of decomposition of deposited organic matter under anoxic or dysoxic conditions because of the lower energy yield of microbially-driven degradation of organic matter using oxidants other than oxygen (nitrate, Mn and Fe oxides and sulfate). Thus, the factors that promote the establishment of bottom water anoxia (or dysoxia) regardless of organic matter supply ultimately drive sapropel formation (Ryan and Cita, 1977). An alternative view centers on situations where the supply of organic matter relative to that of other sediment components increases, either by higher planktonic production in the overlying waters or by higher rates of supply of terrestrial organic matter (Calvert, 1987). Under these circumstances, lower bottom water oxygen levels are due to the consumption of dissolved oxygen by the degradation of settling organic matter and not necessarily by basin restriction, sea level change, etc.; anoxia is a consequence of higher production. Decreased dilution of the organic fraction of a sediment would amplify the effects of anoxia or organic supply emphasized in the other two mechanisms of sapropel formation.

The balance of evidence suggests that the Black Sea sapropel began to form when anoxic conditions were established in the basin following the influx of saline waters from the Mediterranean when sea level reached the Bosphorus sill (Degens and Ross, 1974). Whether the anoxic conditions promoted the preferential preservation of organic matter or production in the basin increased markedly following the transformation of the basin from the lake to the modern marine phase are still matters of dispute. Nevertheless, the bulk accumulation rate of organic matter in the modern facies is similar to rates determined in oxygenated settings at similar water depths and sedimentation rates in the open ocean (Calvert *et al.*, 1991). In the Mediterranean, detailed studies of the geochemistry and micropalaontology of the sapropels and associated sediments (Wehausen and Brumsack, 1999; Calvert and Fontugne, 2001; Mercone *et al.*, 2001) show that bottom waters ranged between full anoxia and dysoxia, reflected in the high redox-sensitive trace metal (Cu, Mo, Ni, U, V) contents, and that planktonic production was significantly higher (high Ba) during their formation. They formed during periods of higher fresh water input to the eastern basin, driven by more intense monsoonal rainfall over northern Africa and the northern Mediterranean borderlands at the precessional frequency (Rossignol-Strick *et al.*, 1982; Rohling, 1994), which probably led to increased stratification and more restricted vertical circulation. The evidence for higher production requires that nutrient supply was higher, and this has been

ascribed to a reversal in circulation (Berger, 1976) such that an estuarine circulation regime (surface water outflow and subsurface water inflow) replaced the modern anti-estuarine circulation (deep water outflow and surface water inflow).

Summary

Sapropel is an organic-rich sediment or sedimentary rock that may be finely laminated; it lacks, or has a depauperate, benthic fauna and high concentrations of redox-sensitive trace metals. Holocene and Pleistocene examples of this facies evidently formed by high organic matter supply and/or preferential preservation of deposited organic matter under anoxic/dysoxic bottom water or sediment conditions in partially restricted environments.

Oceanic Sediments

SCOUR, SCOUR MARKS

Scour is a general sedimentary process which brings about the sustained lowering of a surface by the direct or indirect action upon it of a current of water or air. The process normally acts differentially, resulting in a range of distinctive forms, called scour or erosional marks. Differential solution, as of limestone surfaces or beds of halite or gypsum, gives rise to structures resembling some kinds of scour mark, but the concept of scour excludes this particular mechanism. Scour has been much studied by engineers in connection with the stability of bridge piers and the control of drifting snow along highways.

The mechanisms of scour (Allen, 1982a) are: (1) entrainment; (2) stripping; and (3) corrasion. *Entrainment* affects surfaces composed of sand or gravel, and sees particles removed one by one as the result of the direct action of the shear and pressure forces exerted by the moving fluid, to which may be added impacts due to particles already in transport as

they return toward and strike the bed. Particles become entrained when friction and their immersed weight are insufficient to retain them on the bed. *Stripping* is restricted to surfaces of soft mud in aqueous environments. It involves the tearing of clumps of mud from the bed by the direct action of the current. Depending on the consistency of the bed and the magnitude of the stress, these clumps range in size from tenuous wisps a few millimeters across to plumose-marked plastic lumps measured in decimeters. *Corrasion* sees the removal of material from the surface by the action of fluid-driven debris, which either pounds the bed or chisels fragments from it, depending on its size and the strength of the bed. Generally speaking, corrasion affects materials—stiff or dried muds and rocks—which are too strong to be removed by stripping. The tools available to currents are various: sand grains, gravel, shells and even pieces of ice.

From a genetic standpoint, scour marks may for convenience be grouped into two largely distinct classes, termed current-excited and defect-excited. *Current-excited scour marks* are those which result when a bed is affected by an imposed, stationary pattern of currents, for example, a secondary flow, which create over the bed a corresponding variation in the value of the shear stress or the concentration plus effectiveness of any transported tools. There is no requirement for any significant inhomogeneity in the consistency of the bed. *Defect-excited scour marks* are those which arise when a current flows over a bed containing some gross, localized irregularity or defect. Some defects stand bluff to the current, for example, an upright plant stem, a pebble or shell, a block of stranded ice, or a half-emergent concretion. Others are negative features that reach down from the surface, for example, an open invertebrate burrow on the sea bed, or shrinkage cracks on a surface of dried mud awaiting the next river flood. In all of these cases, the defect creates around itself a pattern of currents which lead to differential scour. Of course, no real surface acted on by a current can be perfectly homogeneous, and it is therefore possible for an unstable interaction between the surface and the current to arise which, in the long term, creates a pattern of scour and a corresponding set of apparently organized forms. Strictly, such scour marks are defect-excited, but the defects in such cases were never gross and remain unseen.

Scour marks are a diverse group and have been reported and discussed from many different environments in a very considerable literature (Allen, 1982b). The main types are as follows:

Current-excited scour marks

- gutters and gutter casts
- ridges-and-furrows (wind)
- yardangs
- furrows-and-ridges (wave-related)

Defect-excited scour marks

- current crescents
- flute marks
- potholes and pothole casts

Gutters, fossilized as gutter casts, are sets of long, occasionally branching, flow-parallel furrows, and ridges found where eroding river and tidal currents drive coarse debris over surfaces of mud and occasionally gravel or rock. Typically, in fluvial, intertidal and shallow subtidal depths, their transverse spacing ranges between a few decimeters and a few meters, and

the sides may overhang. There is evidence that they are localized by secondary currents (paired corkscrew vortices) which concentrate the bed-material in transport into flow-parallel bands, but single gutters could be defect-related. Depositional events, mainly on the ridges, commonly make a modest contribution to the relief of the intertidal forms. In subtidal environments such as the English Channel, where depths measure tens of meters, the grooves occur in sandy-shelly gravels. They have a characteristic transverse spacing of the order of 100 m, and may be many hundreds of meters long. Entrainment is probably the chief mechanism involved in their formation.

Sets of flow-parallel ridges-and-furrows occur in deserts, chiefly the Sahara, where vigorous, sand-laden winds of roughly constant direction are able to corrade comparatively level and uniform rock surfaces. They are probably related to the sets of corkscrew vortices that form in the thick atmospheric boundary-layer when thermal instability occurs. Ridges-and-furrows are huge structures found over vast areas. In depth they range from a few to many meters, lie hundreds of meters apart parallel with the wind, and take extreme lengths of tens of kilometers. As their length shortens, ridges-and-furrows grade into the desert landforms known as yardangs. These are comparatively short ridges of lemniscate plan, the bluff end facing the wind, which arise where comparatively soft materials, such as mudstone, diatomite or friable sandstone, are subject to corrasion. Erosional forms similar to yardangs have been shaped by extreme floods, on both the Earth when ice-dams have broken and, apparently, in the past on other planetary bodies.

Wave-related furrows-and-ridges are found on muddy shores in erosional retreat, such as some saltmarsh edges, and on intertidal rock platforms at the feet of cliffs. In the first of these contexts, where the term mud mound is often applied, they appear as sets of furrows and commonly overhanging ridges arranged at right-angles to the shore. Typically, the sides of the ridges are striated, and the tools responsible for the corrasion, chiefly pebbles and shells, are visible on the floors of the furrows. The transverse spacing of the structures, ranging from a decimeter or so to a few meters, appears to increase with the degree of exposure of the shore to wave activity, supporting the idea that furrows-and-ridges reflect the complex current patterns due to edge waves. Also oriented at right-angles to shore are the furrows-and-ridges that can occur at the feet of cliffs. Less is known about them, but they are similar to the structures developed in mud and may have the same origin.

Current crescents are defect-related scour marks that form because of stripping and/or corrasion around bluff bodies in fluvial and tidal environments and, occasionally, in deep water where turbidity currents operate. The body has a number of effects (Paola *et al.*, 1986). Firstly, it compresses the current around the sides, enhancing its erosive powers. Secondly, the flow decelerates ahead of the body, resulting in the separation of the flow from the bed and the creation of a vigorous, corkscrewing vortex which curves around the front and sides of the body. Thirdly, on the downstream side a sluggish wake is formed in which the rate of erosion is much reduced. The overall result is a U-shaped groove which encircles the front and sides of the body, in the lee of which a dagger-shaped ridge may be found.

Frequently formed by turbidity currents as they drive over mud beds, and occasionally fashioned by river floods, flute

marks are probably the commonest and most widespread of scour structures. They are horseshoe-shaped depressions centimeters to decimeters long with arms that open out downcurrent. Typically, they occur in dense groups and are preserved as casts on the undersides of sandstone beds. Experimentally, flute marks are generated most readily by stripping and/or corrasion at negative defects, such as the tops of burrows or shrinkage cracks. Flow separation occurs along the upstream edge of the defect, with the result that enhanced turbulence is advected to the downstream side, where the flow reattaches. The erosion rate is greatest here. Consequently, the defect gradually evolves through differential erosion into a horseshoe-shaped hollow which is symmetrical about the line of flow. Each mature flute mark contains a well-established separated flow, similar to that found in the lee of many sand ripples and dunes. If a surface is scattered with defects, a field of intersecting flute marks can quickly become established. However, a single, isolated flute mark when mature can trigger the formation of secondary marks.

Potholes have most often been reported from powerful rock-bound rivers, but are also known from river floodplains and even intertidal and shallow-marine environments where mud beds can be affected. Wave-action alone may generate them in the marine realm. Fossilized as pothole-casts, they range from shallow hollows to deep, steep-sided shafts drilled into the substrate by the action of swirling masses of sand and gravel which corrade the surface. Potholes range in size from a decimeter or so wide and deep to giants with depths in the neighborhood of 20 m and widths of about 10 m. They seem almost invariably to be initiated at defects in the substrate, such as minor faults, joints or shrinkage cracks. Potholes in fluvial environments are economically important, for when being filled with sediment, they act as traps for placer minerals.

Scour marks record the fact that surfaces affected by aqueous currents or the wind can experience differential erosion reflecting either patterns of flow and fluid force existing in the current or patterns excited in the current by the presence of some gross irregularity of the bed. Most have directional properties which can be used to infer ancient current directions.

SEAWATER: TEMPORAL CHANGES IN THE MAJOR SOLUTES

Introduction

The exceptional paper by Rubey (1951), entitled “Geologic history of seawater: an attempt to state the problem”, crystallized thought concerning the factors affecting seawater composition. After review of the available information, Rubey concluded that the composition of seawater had varied within narrow limits over much of geological time. The systematic nature of his approach and the strength of his arguments resulted in a 50-year consensus that the conclusion was correct. His arguments did not preclude temporal changes to minor and trace solute contents and there are numerous recent papers which indicate that minor and trace element compositions of seawater varied over time (deRonde *et al.*, 1997; Cicero and Lohmann, 2001).

The arguments of Rubey were sufficiently persuasive that only the “more profitable” lines of evidence were pursued and documented in detail until recently. Canfield *et al.* (2000) challenged Rubey’s conclusion by presenting evidence that sulfate was low in Archean seawater and had increased in abundance since about 2.5 Ga. The conclusion, however, was most strongly, and convincingly challenged by Lowenstein *et al.* (2001) who demonstrated that Mg/Ca ratio varied between latest Precambrian time and the present, and that the variation was sufficient for aragonite rather than calcite to have precipitated from seawater. These Mg/Ca variations result primarily from the rates of generation of oceanic crust through which seawater circulates *via* thermally driven convection cells (near oceanic ridges). The greater the rate of seafloor generation, the greater the amount of interaction with oceanic crust and the higher Mg/Ca in seawater.

Generation of oceanic crust and implications concerning seawater composition were not considered by Rubey, primarily because such concepts awaited elucidation some 30 years later (Edmond *et al.*, 1979; Sleep *et al.*, 1983; Thompson, 1983). These ideas coupled with the study of Lowenstein *et al.* (2001) and Canfield *et al.* (2000) demonstrate that the concentrations of the major solutes of seawater varied through the Proterozoic and Phanerozoic Eons. There is also evidence that its composition varied appreciably through the Archean Eon. Following Rubey, “lines of evidence” for continual change to major solute contents of seawater are developed here. Unfortunately, the dearth of reliable information (and detailed study) prevents firm conclusions from being drawn about seawater compositions during early periods.

Major solute fluxes to the seawater reservoir

Rubey was unaware of the important role that oceanic crust-seawater interactions had on seawater composition. Neither was he aware of recent findings concerning the compositional evolution of the crust because fundamentally important aspects of its evolution, now apparent, were unknown 50 years ago. The arguments of Rubey (1951) concerning seawater composition are reconsidered in light of recent findings regarding geochemical cycles.

A simple geochemical cycle applicable to all major elements of seawater (Figure S4) emphasizes that seawater constituents

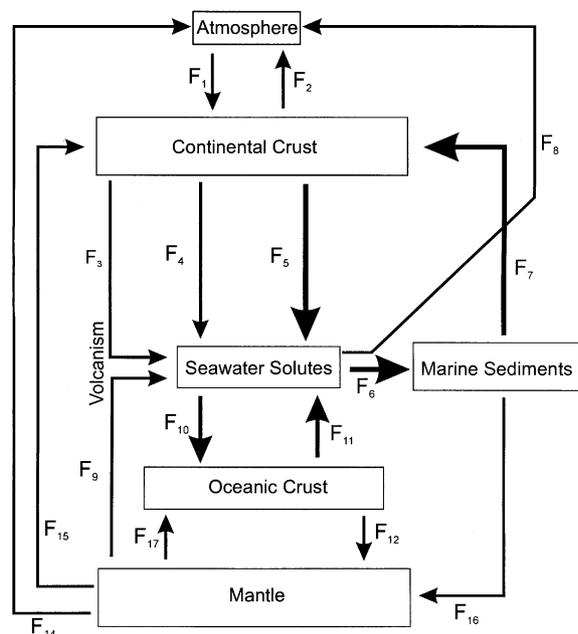

Figure S4 Geochemical cycle applicable to the major solutes of seawater. Each box represents a separate reservoir and each arrow a flux (labelled "F"). The contribution from each reservoir and the magnitude of each flux differs for each major solute. The thicker arrows indicate major fluxes important to major solutes, although this is a generalization.

are derived from the continental crust, oceanic crust, and the mantle. Details of the mantle- and oceanic crust-seawater solute fluxes have been addressed recently (Edmond *et al.*, 1979; Sleep *et al.*, 1983; Thompson, 1983; Wolery and Sleep, 1988; Lowenstein *et al.*, 2001). The continental crust is the single largest source for solutes today and may have been in the past (Berner and Berner, 1996), and of these fluxes (Figure S4, F_3 , F_4 , F_5) river water fluxes (F_5) are the greatest (Berner and Berner, 1996).

Exposed continental crust and seawater composition

The major solutes of seawater are derived in greatest part from chemical, and biological weathering of the Exposed Continental Crust (ECC) (Berner and Berner, 1996) so that the major solute content of seawater is expected to evolve as the composition of the ECC evolves. Aspects controlling the compositional evolution of the ECC may be addressed *via* another geochemical cycle. Figure S5 sub-divides the continental crust into different reservoirs. Most importantly, the ECC is separated from other crustal components. Thus Figure S5 accentuates the various contributions affecting the composition of the ECC.

The composition of the ECC has changed between the Hadean and (at least) late Precambrian time, and much of its compositional evolution can be assessed from geological observations and considerations summarized below. Blatt and Jones (1975) provide a sound estimate of the major geologic units contributing to the ECC. Of the rocks exposed at the surface of the continents; 66 percent are sedimentary and 34 percent are crystalline (defined to include plutonic,

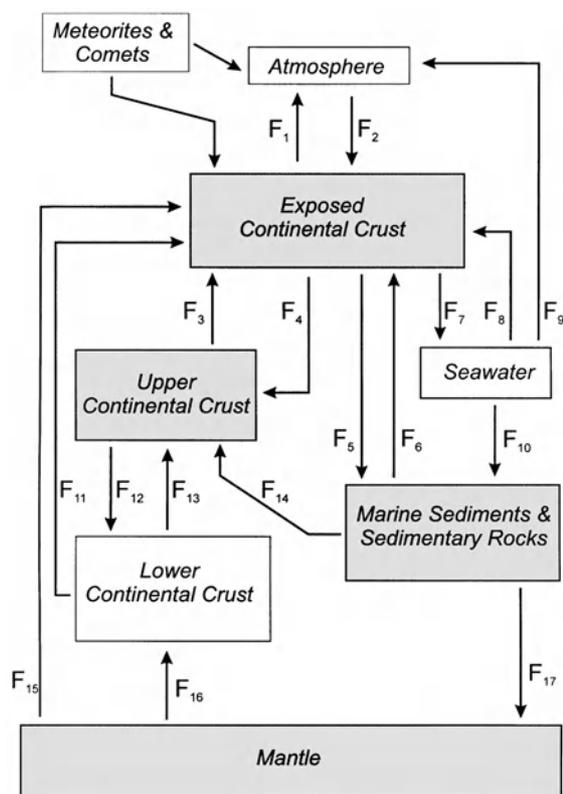

Figure S5 Geochemical cycle applicable to the composition of the Exposed Continental Crust (ECC). Boxes and arrows has the same meaning as in Figure S4. The shaded boxes represent the reservoirs representing the major compositional input to the ECC.

extrusive and metamorphic rocks). Of the crystalline rocks, the extrusives (volcanic rocks) constitute about a quarter (8–10 percent of the exposed crust), the remainder (about 25 percent) being plutonic and metamorphic.

Rejuvenation of the ECC proceeds continuously in response to tectonic processes, thus replenishing materials removed by chemical weathering and erosion. The sources of materials for rejuvenation are apparent from Figure S5. They are: marine sedimentary rocks; the upper crust from which volcanic, plutonic and metamorphic rocks are provided; the mantle from which volcanic rocks primarily are provided. The lower crust, seawater, the atmosphere and the extraterrestrial reservoir contribute to the exposed crust, but their contributions are smaller than those from the previously-mentioned reservoirs (Figure S5). The lower crust, for example, may contribute extrusive materials directly to the exposed crust but few other avenues are available for transport directly to the ECC. Lower crustal material more likely enters the upper crustal reservoir before being exposed at the surface. Seawater provides H_2O and salts directly to the continents by subsurface infiltration and indirectly *via* the sedimentary rock (pore waters) and atmospheric (aerosols and solutes of rainwater) reservoirs.

The extraterrestrial contribution (Figure S5, Meteorites and comets reservoir) supplies small amounts of debris to the continents *via* micrometeorites to large bolides. This flux to the

ECC is now negligible but must have been important during the first few hundred Ma of Earth history.

Temporal compositional changes to the ECC

The sedimentary rock reservoir includes carbonates, sandstones and shales. Their proportions exposed at the surface likely is similar to their abundance in the rock record, measurements and estimates of which lead to evaporite:sandstone:carbonate:shale proportions of 3:15:20:62 (Garrels and Mackenzie, 1971, p.206, p.247 and p.249). Because they represent 66 percent of the ECC, and because the ECC is the major contributor to seawater composition, a change in sedimentary rock proportions likely would be reflected in seawater composition. There are well recognized temporal changes to the sedimentary rock reservoir (Vinogradov and Ronov, 1956; Garrels and Mackenzie, 1971; Veizer, 1979, 1985; Godderis and Veizer, 2000) and sympathetic changes to seawater composition almost certainly have occurred.

Sedimentary rock–ECC fluxes

The development of large sedimentary platforms and deposition of compositionally mature platformal sediments commenced at about 3 Ga, the Witswatersrand, Pongola and Buhwa platforms being examples (Fedó *et al.*, 1996). Platform development was diachronous and extended beyond the end of the Archean (2.5 Ga). The first extensive platformal sequence associated with the Canadian Shield is the Huronian sequence (Young, 1995) with an age no older than 2.3 Ga.

Addition of a mature sedimentary rock platformal “blanket” to the exposed continents near the end of the Archean should have changed appreciably the rate of supply of solutes to streams and to seawater. These changes to rates of supply likely resulted in changes to the major alkali and alkaline earth solutes of seawater. Mature siliciclastic sediments are depleted of Na, K, Mg, and Ca relative to the crystalline or volcanic rocks exposed at the surface. Seawater Na, K, and Mg likely declined in abundance as these weathered materials covered at least half of the previously exposed crystalline rocks (preventing their weathering).

Mantle–ECC fluxes

The mantle supplies materials to the ECC *via* volcanism primarily, producing large volcanic fields and “basaltic plateaus”. Extrusive rocks today represent about 8–10 percent of the exposed crust but as Blatt and Jones (1975) emphasize, their contribution to marine sediments probably is double this value (contributes 15–20 percent to the sedimentary reservoir). Chemical weathering of volcanic materials is rapid and they should yield solutes to stream and river waters at a rate akin to the rate of production of detritus from the ECC (at least 15–20 percent of seawater solutes supplied by weathering and erosion of mantle-derived volcanics).

The nature of mantle volcanic materials supplied to the ECC has changed over time. Komatiites are found in Archean volcanic sequences but are absent from volcanic sequences of younger age. With the change in mantle input to the ECC, seawater composition likely changed in response. The high Mg content and the labile nature of the constituents of komatiites and high Mg-basalts volcanic rocks probably affected Ca, Mg,

and Si contents of seawater, and its salinity may have been greater during the Archean.

Veizer (1979) noted that the sedimentary rocks are considerably more mafic (on average) than average upper crust. He argues that this was due to an early mafic–ultramafic crustal component being added to, and recycled within the sedimentary mass. Veizer estimated that about 30 percent of oceanic basalt would have to be added to 70 percent upper continental crust to generate compositions consistent with the sedimentary rock compositions. The finding attests to the temporal changes to the ECC resulting from mantle–ECC interaction.

Continental crust–ECC fluxes

Theories for genesis of continental crust can be grouped into three categories: (1) homogeneous accretion; (2) inhomogeneous accretion; (3) terrestrial models (Condie, 1989). Brown and Mussett (1981) summarize arguments related to the first two groups and both imply development of a crust during accretion (before the first 300 Ma of Earth history). Much study has been focused on terrestrial models. They consist of two groups, those based on the assumption that the majority of the crust evolved very early without its volume having change greatly over geological time (Armstrong, 1968; Fyfe, 1978; Rudnick, 1995; Sylvester *et al.*, 1997) and those based on the assumption that the early crust was initially of small volume and that its volume increased over time, perhaps dramatically at approximately 2.5 Ga (Godderis and Veizer, 2000). Models of all types have associated ambiguities and inconsistencies and little can be concluded with certainty. The moon, however, has an anorthositic crust which formed prior to, or early during, the late heavy bombardment (3.8 Ga). If the moon and Earth are genetically related as commonly proposed (Taylor, 1997), the Earth almost certainly generated a crust (perhaps anorthositic?) at the same time as (or before) the moon. If the initial crust were primarily anorthositic its weathering would have produced solute contents much different from present-day seawater.

Taylor and McLennan (1985) conclude that the Archean crust was compositionally different from the post-Archean crust, the dramatic change occurring near 2.5 Ga, although recognized to be diachronous. The change was from a dominantly plagioclase, quartz and mafic minerals-dominated Archean crust to a post-Archean crust which included K-rich granites.

As previously noted, the upper continental crust constitutes about 25 percent of the ECC but must have been as much as 50 percent of the ECC prior to 2.5 Ga. Development of sedimentary platforms bordering continents and their subsequent exposure (incorporation into the ECC reservoir), coupled with the simultaneous decrease in the amount of exposed crystalline crust, must have had significant effect on the composition of seawater during the period since about 3 Ga. Canfield *et al.* (2000) corroborate the conclusion; they demonstrate that sulfate content was low during the Archean but increased to present levels beginning at about the Archean–Proterozoic transition (about 2.5 Ga).

Extraterrestrial–ECC fluxes

The history of the Hadean Eon (4.5 Ga to 3.8 Ga), although highly speculative, has been deduced in some detail (Taylor,

1997). Noble gas ratios and abundances indicate that the present atmosphere and hydrosphere are secondary (Cogley and Henderson-Sellers, 1984; Taylor, 1997). The implication is that the hydrosphere developed either during accretion (after separation of the Moon) or between about 4.2 Ga and 3.8 Ga, the period of "late heavy bombardment". If the crust formed during accretion its composition would have been modified by incorporation of material captured during the late heavy bombardment. Taylor (1997) summarizes the effects on the composition of the mantle of such capture. By analogy, there must have been similar or greater compositional effect on the upper crust and on the ECC. These materials probably were derived from meteorites of carbonaceous chondritic composition or from comets (Chyba, 1990; Taylor, 1997), both of which contain appreciable amounts of water (generally greater than 10 wt. percent, Brown *et al.*, 2000). If ECC composition were affected by the "late heavy bombardment" then seawater composition undoubtedly would have been affected by the extraterrestrial input. The effects of such contributions await study.

Summary

There is compelling evidence that seawater composition has changed continuously during the entire history of the Earth. Compositional change probably was rapid during the transition from the Hadean Eon through the late heavy bombardment and into the Precambrian Era. Changes to the composition of the upper continental crust during the late Archean likely caused change to the major solute concentrations of seawater. The development of stable platforms during the late Archean and Proterozoic, and the incorporation of chemically mature platformal sedimentary rocks into the Exposed Continental Crust (ECC) must have resulted in change to seawater composition. Canfield *et al.* (2000) demonstrate that sulfate content has changed during the Proterozoic Eon and Lowenstein *et al.* (2001) demonstrate major solute changes during the Phanerozoic Eon.

Chloride has the longest residence time of any major element in the oceans (about 100,000 years; Berner and Berner, 1996). Based on this residence time, major constituents of seawater may achieve steady state within 100,000–300,000 years. Some trace constituents may take longer to achieve steady state (e.g., Br) in part because their crustal abundances may vary much more. Although seawater has evolved continuously over geological time, an essentially steady state composition may have been achieved many times, the steady state composition likely being different during each steady state stage.

SEDIMENT FLUXES AND RATES OF SEDIMENTATION

An understanding of sediment fluxes, both at the local and global scale, involves identifying sites where sediment is produced, the processes involved in liberating this sediment, and processes and rates involved in the transport of the sediment to depositional environments. Sediment production occurs at sites where sedimentary particles form, across sites of temporary storage of these sediment particles, and even at sites of long-term storage, given tectonic movement within geological systems. While terminology remains an important part of compartmentalizing and understanding earth science, consistency in use of terms is not universal. Here we describe a few of the important terms related to sediment fluxes and sedimentation rates.

Definitions and concepts

Weathering is the rate-limiting step in the entire sequence of events. Weathering involves both chemical and biogeochemical processes that work to dissolve minerals within rock faces and the cements holding together the detrital grains within sedimentary rocks. Using a complex of natural inorganic and organic compounds found universally within aerosols and surface water, grains are liberated, fractures are weakened and material is generated for subsequent transport. Active weathering also involves mechanical processes that apply physics to the destruction of rock surfaces. Mechanical processes include the freeze thaw action of water, wind or water abrasion involving grain on grain impact, the action of glaciers (ice on rock abrasion, rock carried by ice on rock; quarrying), and the generation and impact of rockslides. Younger mountains shed more sediment (up to a factor of seven) than indurated and older mountains (Pinet and Souriau, 1988).

Sediment undergoes remobilization through sheet, rill and gully erosion of hillslopes, through landslides, and through channel erosion. The mass of sediment that passes by a given cross-section per unit time is known as the *transport load* (M), given in units of kg per second or MT per year. The terms *transport rate* and *sediment discharge* are used interchangeably with transport load. The transport load consists of the *dissolved load* (Q_D) and the *detrital load* (Q_T), or just one if specified. *Yield* (Y) is the transport load normalized per unit drainage basin area (A_{db}), often given in units of T/km² per year, kg/m² per year, or g/cm² per year, and can include both detrital and dissolved load (Table S1). The *rate of erosion* (E_R) has the same meaning as yield except that it tends to be used in

Table S1 Relationships (see text for terminology details)

$C_s = M/V$	[M/L ³]
$Q_s = C_s Q$	[M/T]
$Q_T = Q_s + Q_b$	[M/T]
$M/T = Q_D + Q_T$	[M/T]
$Y = M/A_{db}/T$	[M/(L ² T)]
$D = Y/\rho$	[L/T]
$Q_T = Q_{T0} + \rho(E_R - D_R)$	[M/(L ² T)]
$\eta = (E_R - D_R)/\rho$	[L/T]
$\eta = Q_T/\rho A_{dep}$	[L/T]

more local environments and to reflect shorter events. Over time the exposed land surface is weathered and lowered with respect to a datum, at a rate known as the *denudation rate* (D), in units of length per time (mm/kyr). The denudation rate is a measure of earth surface removal, and takes into account both dissolved and detrital surface lowering.

Most dissolved load is transported within surface and subsurface waters flowing to the ocean. A much smaller portion is transported in the form of aerosols, within the atmospheric circulation. While most of the dissolved load initially ends up in the ocean as dissolved salt, uptake by plankton and other primary producers converts much of the dissolved load back into a solid form, including tests of silica and carbonate, larger shells and coral reefs. Subsequent chemical and mechanical degradation of reefs, and transport of these biogenic grains along with other shell fragments and tests, adds to the detrital load being transported across the depositional environments.

Detrital grains are transported primarily by water and wind, as *bed load* (Q_b) and *suspended load* (Q_s), but regionally may also be transported by flowing ice (ice-sheets, glaciers, icebergs, sea ice). Bed load, sometimes called *contact load*, consists of coarser particles that travel along the bed by traction and or saltation, essentially in continuous contact with the bed. Bed load particles move through the influence of shear stress or drag imposed by the moving fluid (water or air), along with other grain-to-grain interactions. If the flowing fluid is unable exceed some threshold in stream power or critical shear stress, bed load transport ceases. The suspended load consists of particles suspended within the fluid by turbulence or by colloidal suspension. The suspended load consists of both a *bed-material load* (i.e., of the same range of grain size as found on the bed), and a *washload* (finer material than bed particles).

Often the term *sediment load* is used interchangeably with suspended load, as bed load is typically a minor component of the total load. The local sediment load is then the upstream load (Q_{T0}) plus the density-corrected difference between the erosion rate and the depositional rate, a relationship known as the *Exner equation*. *Sediment concentration* (C_s) is the dry weight of suspended sediment per unit volume of water or air (V), at any given time and place. Thus the suspended sediment load is simply the sediment concentration times the *discharge rate*, (Q), i.e., the fluid volume moved per unit time.

The *sedimentation rate*, also known as the *deposition rate* (D_R), is the vertical flux of sediment to the depositional surface, such as the seafloor in the case of a marine environment (e.g., kg/m² per year). Sedimentation rates vary across time, because periods of rapid sedimentation alternate with periods of slower deposition, quiescence, or erosion. Thus

sedimentation rates in various depositional environments refer to average values of net sedimentation.

The rate of sedimentation within a basin strongly depends on the proximity to the sediment source, such as a river mouth or ice terminus. Typically, the sedimentation rate decreases exponentially away from the source. If the sediment source location is fixed in time, fluctuations in sedimentation rate are a function of sediment supply. However, the location of a sediment source is commonly variable in geological time, determined by variations in sea level, the position of an ice terminus or river mouth. During a period of rising sea level, the river mouth moves landward and thus the rate of offshore sedimentation will decrease. Sedimentation rate therefore depends on both the yield of sediment from land and the distance that the sediment load has to travel to a particular location. This leads to two axioms (Syvitski, 1993):

- Constant or increasing accumulation rates indicates either: (i) increasing sediment input; or (ii) decreasing distance from the source.
- Decreasing accumulation rates indicate either: (i) constant or decreasing sediment input; or (ii) increasing distance from source.

The shoreline is therefore an arbitrary boundary within the detrital sediment transport system.

Accumulation rate (η) is the vertical change in the depositional surface due to the composite sedimentation history (e.g., mm per year), and equals the deposition rate minus the erosion rate times the sediment bulk density. *Sediment bulk density* (ρ) is a function of distance from the sediment supply (grain size and excess pore pressure as conditioned by the rate of sedimentation), burial depth and time (compaction). Erosion events (such as sediment failures or wave resuspension) work to decrease the accumulation rate in the shallower portions of a basin and increase the rates in the deeper water sections. Accumulation rates are influenced by biological, chemical, geological, and geographical factors, and are highly variable within depositional environments, between depositional environments and across geological time.

Accumulation rate is often reported as a site-specific measurement, such as determined from the thickness of sediment between two dated horizons within a sediment core. However, basin shape can greatly affect the accumulation rate. Given a constant depositional rate, the local accumulation rate will decrease as a power function with time, due to the ever-increasing width of a basin floor concomitant with sedimentary fill of the basin (Syvitski, 1993). For example, the initially high (up to 9 m per year, Powell, 1983) accumulation rates within fjords seem extremely high because the basin floors are very narrow. After a few thousand years, when fjords are filled with hundreds of meters of sediment, accumulation rates will

appear to have decreased by orders-of-magnitude, even if the depositional rate is held constant. Therefore when comparing different basins, it is useful to calculate accumulation rates at the regional level (Syvitski, 1993): i.e., the total mass of sediment between dated unit boundaries, normalized to the depositional area (A_{dep}).

Influences and rates

The erosion of bedrock takes place almost entirely in the headwaters of the catchment. This newly eroded sediment is then transported toward the coastal zone. How long it takes for this transport and how sediment makes the journey are important questions. However, denudation rate and/or regional erosion rates are similarly independent of the magnitude of the terrestrial flux of sediment to the ocean (Kirchner *et al.*, 2001). Very little (≈ 10 percent) of the sediment that is eroded from the mountains and hilltops actually makes it to the ocean. Most of the sediment is either in flux, or being sequestered in interior drainage basins, lakes, subsiding alluvial fans, flood plains, coastal plains and deltaic plains (Meade, 1996). Holeman (1980) notes that 20th century erosion across the conterminous US (5.3 GT per year) is an order-of-magnitude higher than the fluvial discharge of sediment (0.445 GT per year: Curtis *et al.*, 1973). And while eolian transport to the global ocean is small (Table S2), wind erosion dominates water erosion at the continental scale (Smith *et al.*, 2001).

At the seasonal scale, sediment is stored in riverbeds and along their banks at low or falling discharge, only to be resuspended at high or rising discharges. Often temporarily stored sediment is washed out of the system before peak discharge is reached. At the decade to century timescale, sediment moves down the drainage system as a series of kinematic waves, wherein it might take decades for the sediment to reach the lower reaches of the flood basin. At even longer timescales (millennia), tectonics plays an important role and there are large variations between subsiding basins and basins being exhumed (uplifted). Understanding these scales plays an important role in deciphering the difference between soil erosion and sediment discharge by rivers (Meade, 1996).

Most of the sediment delivered to the ocean is by rivers, which accounts for approximately 95 percent of the global flux from land to sea (Table S1). Most of that flux is as suspended sediment load. Dissolved load and bed load are nearly an order-of-magnitude less than the suspended load. Detrital denudation rates range from 1 mm/kyr for the St. Lawrence River basin, to 670 mm/kyr for the Brahmaputra River system. Small mountainous rivers have detrital denudation rates that can exceed 40,000 mm/kyr (Milliman and Syvitski,

Table S2 Global estimates of the flux of sediment from land to the ocean

Transport mechanism	Global flux GT per year	Estimate grade	Reference
Rivers: suspended load	18	B ⁺	Milliman and Syvitski, 1992
bed load	2	B ⁻	Milliman and Syvitski, 1992
dissolved load	5	B ⁺	Summerfield and Hulton, 1994
Glaciers, sea ice, icebergs	2	C	Hay, 1994
Wind	0.7	C	Garrels and Mackenzie, 1971
Coastal Erosion	0.4	D	Hay, 1994

1992). Chemical denudation rates are typically smaller and range from 1 mm/kyr for the Kolyma, Niger, and Nile basins, to 27 mm/kyr for the Chiang Jiang basin (Summerfield and Hulton, 1994). For anomalously low sediment-discharge rivers, like the Dnepr or St. Lawrence, chemical denudation can account for between 86 percent and 94 percent of the basin denudation (Summerfield and Hulton, 1994).

The “natural” sediment load is influenced by a variety of nonanthropogenic factors, including:

- (1) Size of drainage basin (Wilson, 1973; Milliman and Syvitski, 1992);
- (2) Large scale relief (Hay and Southam, 1977; Pinet and Souriau, 1988; Milliman and Syvitski, 1992; Harrison, 1994);
- (3) Local relief (Schumm 1965; Ahnert, 1970; Jansen and Painter, 1974);
- (4) Geology of the drainage basin (Pinet and Souriau, 1988; Milliman and Syvitski, 1992; Inman and Jenkins, 1999);
- (5) Climate (Fournier, 1960; Schumm, 1965; Jansen and Painter, 1974; Hay *et al.*, 1987);
- (6) Runoff (Walling, 1987; Milliman and Syvitski, 1992);
- (7) Vegetation (Douglas, 1967); and
- (8) Lakes (Milliman, 1980);

Relief and area-dependent runoff are the two most important factors (Table S3). Competence of rivers to transport sediment is governed by the volume flow, gradient, and the sediment load itself. The runoff on large rivers is influenced by snowmelt, in some cases ice-melt, rainfall, and groundwater efflux (which accounts for 30 percent of runoff at the global scale).

For large rivers, interannual differences in sediment discharge are significantly smaller than the interseasonal differences (Meade, 1996). On decadal timescales, large floods can cause marked increases in the sediment discharge of rivers of moderate size (e.g., Eel where 3 days of peak flooding in 1964, transported more sediment than during the previous 8 years of river flow combined; Syvitski and Morehead, 1999). On multi-decadal timescale, river loads relate more to fluctuations in climate. One of the largest impacts of climate change is through changes in the overall water balance with subsequent impacts on land cover density and thus erosion rates. Knox (1993) emphasizes that relatively modest shifts in average climate conditions (i.e., 1–2 °C; <20 percent precipitation) have large impacts on the behavior of a river’s flood response and thus sediment yield. Bed load transport is particularly susceptible to the frequency-magnitude distribu-

tion of floods. The ratio of magnitude of 100-yr floods and annual floods is greater in arid than in humid environments (Molnar, 2001). Thus a shift toward more arid conditions, despite a decrease in precipitation and discharge, could double the bed load transport and thus the incision rate (Molnar, 2001).

Human impact on the flux of sediment to the global ocean is well recognized (Milliman *et al.*, 1987; Hu *et al.*, 2001). Land use is probably the dominant control on particulate fluxes in areas of low relief and large-scale urbanization, in difference to mountainous regions where natural processes are likely to still dominate. Land clearing in low relief areas increases sediment yields by more than an order of magnitude (Douglas, 1993). The effect increases with decreasing drainage area. Changes due to man affect small river basins more dramatically than larger river basins, due to the modulating ability of large rivers. Some investigators of large rivers therefore argue that modern values of sediment flux remain relatively constant across geological time (Summerfield and Hulton, 1994). While there is no accepted value for the “pre-anthropogenic” influenced flux of sediment to the coastal oceans, Milliman and Syvitski (1992) argue that the modern 20 GT per year global detrital flux estimate might be 50 percent smaller circa 2000 years ago before human impact was great.

The Mediterranean landscape is arguably the most human impacted terrain on earth. Dedkov and Mozzherin (1992) note that 75 percent of the average sediment yield (1,100 T/km² per year) of Mediterranean basins may be attributed to human activity. The terrain is naturally vulnerable to processes of erosion with its steep slopes, high relative relief, fissile sedimentary rocks, thin erodible soil covers, and active tectonic settings (Woodward, 1995). Severe land degradation has taken place including badland formation as representative of acute land deterioration. Elsewhere, deforestation in tropical areas may account for the extraordinary loads from Oceania (Hu *et al.*, 2001; Milliman and Syvitski, 1992). Countering this increased erosion due to human activity is the rapid development of reservoirs worldwide. About 2,500 years ago the sediment discharge of the Yellow River was about 1/10th what it was 30 years ago when it peaked with rapid cultivation of the loess plateau (Milliman *et al.*, 1987; Saito *et al.*, 1994). A combination of soil preservation practices of the 1980s and dam construction (3,380 reservoirs and another 30,000 diversion works of various scales) have sharply reduced both water and sediment discharge. The decrease in sediment load carried by the Yellow River has in turn rapidly increased coastal erosion (Saito *et al.* 1994).

Table S3 The global flux of suspended sediment (Q_s) as influenced by maximum basin relief and contributing land surface area (Milliman and Syvitski, 1992)

Basins with Relief (m)	Land surface		Load	Global load	
	Mkm ²	%*	MT per year	MT per year	%**
>3,000	16.3	12.5	4,500	9804	52.5
1,000–3,000	26.4	20.4	3,783	8,248	44.1
500–1,000	4.9	3.8	200	436	2.3
100–500	11.9	9.2	96	209	1.1
<100	0.2	0.2	1	2	—
Total	59.7	46.1	8,580	18,692	100

* Given the total land area of earth is $\approx 130 \times 10^6$ km²

** Proportioned load assumes that the distribution of measured rivers is representative of the earth’s topography and land area.

Global sediment fluxes are known to change across broad geologic time. Hay (1994) notes that Holocene fluxes to marginal seas are typically 1.5 to 4 times higher than that for similar periods during the Pleistocene. Quaternary sediment was deposited at globally averaged accumulation rates of 4 g/cm² per year, which is 54 percent higher than the Pliocene and 3 times higher than the Miocene rates (Hay, 1994). Carbonate sediment accounts for 18.4 percent of the total Quaternary sediments in the ocean basins, whereas it accounts for 40 to 50 percent of Miocene and earlier sediments. Peizhen *et al.* (2001) show that global sediment accumulation rates increased by 2–10 times beginning 2–4 Myr ago, when climate switched from a long period of climate stability, to a time of frequent abrupt changes in temperature, precipitation, and vegetation. The result was that during the Quaternary, the landscaped moved away from equilibrium configurations to periods of high sediment production from landscapes out of equilibrium.

Ice sheets and glaciers create sediment through abrasion, quarrying, and channelized and nonchannelized fluid flow at their base. Estimates of the global flux of glacial detritus range from 1.5 GT per year to 50 GT per year with the lower value probable (Table S2). The higher estimates do not effectively take into account the recycling of glacial marine sediment back into the ice mass (R. Powell, Pers. comm., 2001). The sediment delivery rate from ice sheets and glaciers to the ocean depends on a variety of processes. Their marine termini melt at a rate dependent on the temperature of the ocean water and the strength of the currents flowing across the termini (Syvitski, 1989). The sediment delivery rate will thus depend on the melt rate and the concentration of sediment (supraglacial, englacial and subglacial) within the glacier. Sediment is also transported at the base of a glacier as basal till, through a variety of subglacial processes (Andrews and Syvitski, 1994). Fast flowing ice streams are more able to transport till compared with cold-based or slow flowing ice sheets (Syvitski, 1993). Meltwater flowing within and beneath the ice mass is able to carry large volumes of sediment, and this is particularly true for Alaskan glaciers. Sediment delivery from the melt of drifting icebergs is perhaps the greatest sediment-dispersal

mechanisms as icebergs are able to transit hundreds to thousands of kilometers (Syvitski *et al.*, 1996a,b).

The wind borne flux of sediment to the ocean is in the order of 0.5 GT per year to 0.9 GT per year (Table S2), but greatly varies with time (Garrels and Mackenzie, 1971). While river discharge is the largest global contributor of sediment (Table S2), eolian transport is of equal magnitude to that of river flux for the continent of Africa (*cf.* Prospero, 1981; and Milliman and Syvitski, 1992). While eolian transport is important today, fluvial transport dominated the supply of sediment to the Arabian Sea during the last glacial period.

Coastal erosion is not well-known but global estimates vary from 0.2 GT per year to 0.9 GT per year (Hay, 1994), with anthropogenic effects of significance at the regional level. Sea ice, where ubiquitous, is also able to carry large volumes of coastal sediment into the deeper ocean, including sediment that was initially transported to the coast by wind or streams (Gilbert, 1983).

Rates of sedimentation

There are a variety of methods used in the determination of sedimentation rates (Table S4). In brief these are:

Direct Observations: systematic comparison between old and new soundings (best suited to high sedimentation rate environments such as deltas, lagoons, bays and estuaries), sediment trap studies, and repeated coring (Nittrouer, 1999).

Theoretical Calculations: detrital sedimentation rates may be obtained by subtracting the amount of sediment leaving from the amount of sediment entering a depositional setting. The method is particularly good for semi-closed basins such as deep silled fjords (Syvitski *et al.*, 1988). As an example, Piper (1991) quantified both sources and sinks of Holocene sediment on the Scotian and Labrador shelves. On the Scotian shelf, sediment supply from rivers is roughly 5.5×10^6 T per year and supply from current and wave erosion of older Quaternary shelf deposits is 10.5×10^6 T per year. Together these sources balance the annual sediment sink of 16×10^6 T per year, measured from the volume of Holocene sediment on the shelf

Table S4 Modern Accumulation Rates (from Olsen, 1978; Syvitski *et al.*, 1987; Hay, 1994; and references therein)

Environment	Accumulation Rates
Flood Plains	mm/yr to cm/yr
Lakes	mm/yr to cm/yr*
Eolian loess	0.1 to 1 mm/yr
Deltas	cm/yr to m/yr
Prodeltas	mm/yr to cm/yr
Estuaries and bays	mm/yr to cm/yr
Fjords	mm/yr to m/yr
Tidal marshes and bogs	mm/yr to cm/yr
Carbonate Reefs/Platforms	mm/yr to cm/yr
Continental Shelves	0 (bypassing) to 10 cm/yr**
Submarine Canyons	0.1–1 mm/yr
Inland Seas	0.01 to 2 mm/yr
Slope and Rise	0.01 to 4 mm/yr**
Abyssal Plain	0.01 to 2 mm/yr

*larger in glacial and proglacial lake environments, or after catastrophic events like debris flow emplacements.

** highest values from the California STRATAFORM site: Sommerfield and Nittrouer (1999); Alexander and Simoneau (1999).

and slope. On the Labrador shelf, the Holocene sediment sources included rivers (50 km^3), submarine erosion by iceberg turbation (20 km^3), and ice rafting (2.4 km^3). The sinks include coastal basins (35 km^3), shelf troughs (24 km^3) and the continental slope (13.4 km^3).

Radiometric Dating: measures that use the decay constant of radionuclides and determining their decrease in concentration to secular equilibrium values, with depth in the sediment column. Some of these decaying isotopes include U^{234} , Th^{230} , Pa^{231} , C^{14} , Pb^{210} (with half lives of 250,000, 75,000, 35,000, 5,730 and 22.3 years, respectively). Other radionuclides used in the determination of sedimentation rates include Be^{10} , Al^{26} , Si^{32} and the K–Ar method (see Olsen, 1978, and references therein).

Amino Acid Racemization: proteins of organisms buried in sediment undergo slow racemization or molecular change in their structure. The rate of change is affected by temperature and thus the method works best for environments of relative constant temperatures (Miller *et al.*, 1997).

Varves: in certain lakes and fjords and other deep coastal basins, the annual sedimentation is visually recognized by the color of winter layers often in contrast to the color of summer sedimentation layer(s). Assuming that sedimentation occurs every year, then the layers are counted to produce a time versus sediment depth history of the sedimentation rates (Hughen *et al.*, 1996).

Pollutants and other Tracers: the distribution of pollutants in sediments can be used to date through historical forensic analysis the onset of layers within sediments associated with anthropogenic events. For example Fe^{55} and Cs^{137} are radionuclides produced by nuclear testing that peaked worldwide in the late 1950s and early 1960s (Alexander and Simoneau, 1999). Other tracers include DDT (dichlorodiphenyltrichloroethane), products of synthetic detergents, paint lead, and PCPs.

Depositional environments

River courses are divided between a degradational section where the stream gradient is relatively steep and little sediment storage takes place, and an aggradational section where gradient is sharply reduced through meandering and *flood plain* storage (Table S4). Not all rivers flow to the ocean, as large areas of the earth's landmass drain internally. Along stream pathways, the sediment load may also become trapped *in lakes*. Mid to high-latitude rivers are particularly affected by the filtering effect of glacial lakes (Table S4). Man-made reservoirs have reduced the sediment load of some rivers by two-orders of magnitude (Nile, US Colorado), while others such as the Indus or Mississippi have had their load cut by a factor of between 5 and 2, respectively (Milliman and Syvitski, 1992). Elsewhere on continents, wind-borne loess deposits accumulate episodically at relatively low rates (Table S4).

While most of the sediment discharge is reported as delivery to the ocean, a more realistic wording would be delivery to the *delta plain* which could trap much of the sediment. The ultimate sink for river sediments, on a millennial to multi-millennial timescale, is the coastal zone. The role between sediment supply and sea level rise distinguishes between coastlines with *coastal embayments* (undersupply), and those with long coastlines (balanced supply), from those with coastal protrusions, i.e., *deltas* (over-supply). All of the modern river deltas appear to be <10,000 years old (Stanley and Warne,

1994). In the case of the Amazon, 20 percent of the annually delivered load (1 BT per year) is retained by its delta; the remaining 80 percent is deposited on the continental shelf and coast with none reaching the deep sea. In the case of the Ganges and Brahmaputra Rivers, 55 percent of the annually delivered load (1.1 BT per year) is retained by its delta; the remaining 45 percent is deposited on the continental shelf and coast (36 percent) with (9 percent) reaching the deep sea. In the case of the Yellow River, 82 percent of the annually delivered load (1.1 BT per year) is retained by its delta; the remaining 18 percent is deposited on the *continental shelf* and coast (36 percent) with none reaching the deep sea (see Meade, 1996).

Deltaic sedimentation (Table S4) is dominated by four processes (Syvitski *et al.*, 1988): (1) deposition of bed material load at the river mouth the main point for hydraulic transition; (2) sedimentation under the seaward-flowing river plume that carries the wash load across the *prodelta* region; (3) sediment bypassing processes, such as turbidity currents that may result from delta-front failure, or hyperpycnal flows that result from the super-elevated sediment concentrations carried by some rivers (Mulder and Syvitski, 1995); and (4) diffusive processes that work to smear sediment down-slope from tidal and wave action.

Sediment accumulation in *estuaries* (Table S4) depends on the sediment supply from both river and offshore sources, and the mixing energy within the estuary (Wang *et al.*, 1998) i.e., a balance of buoyancy forces set up by river discharge and processes such as those associated with tidal action that work to mix the fresh water with the denser salt-water layers. A *fjord* is a deep high-latitude estuary which has been, or is presently being, excavated or modified by land-based ice (Syvitski *et al.*, 1987) and can range from low to high sedimentation systems. Fjords are sites of net sediment accumulation, and globally may have retained 25 percent of the sediment removed from the land over the last 100,000 years (Syvitski and Shaw, 1995). Typically sediments are spread over a great distance from the river mouth due to the fjord margins confining the fluvial plume emanating from the river, and the propensity of fjords to experience long-traveling sediment gravity flows.

In *continental shelf* settings, tide, storm, and wave-driven currents operate to produce an equilibrium shelf gradient and to change the configuration of the coastline (Wang *et al.*, 1998). In the *upper slope* region, sediments are delivered from the shelf *via* boundary layer currents including fluid muds, and nepheloid—hemipelagic sedimentation. These upper slope sediments are then reworked down slope by a variety of processes characterized as diffusive (i.e., submarine landslides, mudflows, and creep). Sediment gravity flows comprise the major processes operating in the mid- to *lower slope* region of the profile. Upper-slope diffusive processes operate in concert with sediment gravity flow processes in the lower slope and *rise* environments to produce a wide range in accumulation rates (Table S4; Syvitski *et al.*, 1996c; Hay, 1994).

About 40 percent of the world's continental shelves are carbonate shelves (Hay, 1994). Biogenic production (Table S4) was highest in glacial times, possibly as a result of the changes in the rates of ocean mixing and nutrient supply to the photic zone (Hay, 1994). Subaerial exposure and subsequent flooding of the continental shelves affected the sites of carbonate deposition and the global carbonate budget (Milliman, 1993).

Summary

- (1) Weathering is the rate-limiting step in the entire sequence of events determining global sediment fluxes and rates of sedimentation.
- (2) Sedimentation rates vary across time, because periods of rapid sedimentation alternate with periods of slower deposition, quiescence, or erosion. Sedimentation rates in various depositional environments are therefore average values of net sedimentation.
- (3) The rate of sedimentation within a basin strongly depends on the proximity to the sediment source, such as a river mouth or ice terminus.
- (4) Very little (≈ 10 percent) of the sediment eroded from mountains and hilltops actually makes it to the ocean. Most of the sediment is either in flux, or being sequestered in interior drainage basins, lakes, subsiding alluvial fans, flood plains, coastal plains and deltaic plains.
- (5) Sediment delivery *via* rivers accounts for approximately 95 percent of the global flux from land to sea. Most of that flux is as suspended sediment load. Dissolved load and bed load are almost an order-of-magnitude less than the suspended load, with important regional exceptions.
- (6) Drainage basin area and relief are the most important “geological” factors in controlling the sediment load of rivers. However, modern rivers are greatly impacted by human activity, either through increases in soil erosion, or through sediment load reduction from reservoir filtration.
- (7) While contributing less to the modern global flux of sediment, sediment transport by ice, wind and waves, remains important in regions dominated by these processes, and achieve more global significance at earlier times in the Quaternary.

SEDIMENT TRANSPORT BY TIDES

Tidal currents

Tidal currents are unique among the processes responsible for sediment transport and deposition because of their regularity, with the speed and direction varying with the frequency of the governing astronomical period (see *Tides and Tidal Rhythmites*). In coastal settings where the shorelines constrain the flow, the landward- (flood) and seaward-directed (ebb) currents typically have directions 180° apart, in a pattern that is termed rectilinear. A period of little or no current (i.e., *slack-water*) varying in length from a few to several tens of minutes generally accompanies each flow reversal. As a result, sediment transport is intermittent, with episodes of sand transport (if the currents are sufficiently strong) alternating with periods of mud deposition during the slack-water intervals (Figure S6). In open-shelf settings removed from the confining influence of coastlines, tidal currents are rotary because of the influence of the Coriolis force (Allen, 1997), with the direction changing progressively through 360° over one complete tidal period. In such situations, there is no slack-water period, although the currents transverse to the primary flow directions generally are slower than the main ebb and flood currents. As a result, mud deposition is inhibited. Typically, the highest maximum speeds are found in constricted, inshore areas, where they may be as high as 1–2 m/s. As a result, the transport and deposition of sediment by tides is most important in coastal zones, with tidal currents dominating sedimentation inside the sheltered confines of estuaries, lagoons, and deltaic distributary channels where wave action is minimal (see *Neritic Carbonate Depositional; Environments Deltas and Estuaries*).

In the ideal case, tidal-current speeds vary sinusoidally over an individual ebb or flood period, with equal durations and speeds in the opposing directions. In this case, there is no net (residual) sediment transport (Figure S6(A)). In reality, however, various factors cause deviations from the ideal, producing a *time-velocity asymmetry* that causes an inequality in the amount of sediment transported in the two directions (Figure S6(B)).

Tidal-wave deformation: in the shallow water of the coastal zone, the crest of the tidal wave travels faster than the trough because the latter experiences greater frictional retardation.

Convergence of the shoreline, creating a landward decrease in the cross-sectional area, compounds this distortion. As a result, the flood tide typically has a shorter duration and higher maximum speed than the ebb tide (Dyer, 1995).

Hypsometric influences: because the area-elevation distribution (the *hypsometry*) of coastal areas is generally not linear, the volume of water passing through any channel will vary in response to temporal changes in size of the area being flooded or drained (Boon and Byrne, 1981). Thus, the maximum current speeds will tend to occur when the largest area is being flooded or drained rather than at mid-tide. Such hypsometric influences can also cause inequalities between the maximum ebb and flood currents (Friedrichs and Aubrey, 1988).

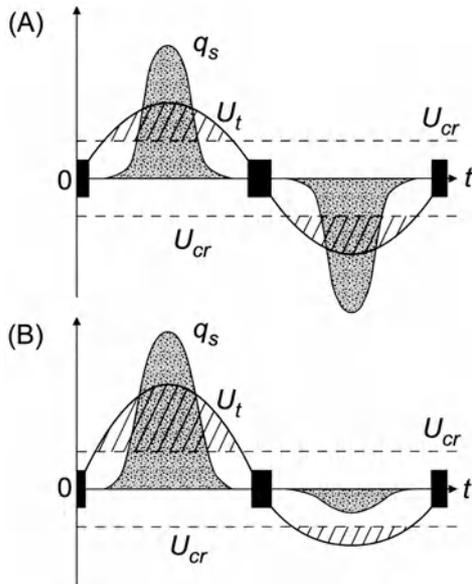

Figure S6 Transport of bedload sediment by: (A) an idealized, symmetrical tidal current; and (B) a tidal current with a pronounced time-velocity asymmetry. The bedload discharge (stippled area) is approximated as: $q_s \propto [U_t - U_{cr}]^3$, for $U_t > U_{cr}$ (the cross-hatched areas), where U_t is the depth-averaged tidal-current speed and U_{cr} is the threshold of bedload movement. In (A) the bedload discharges in the opposite directions are equal, such that there is no net transport. In (B) the short-duration high speeds on one half of the tide generate more transport than the slower, longer-duration flow in the opposite direction, yielding a residual transport in the direction of the faster currents. The black rectangles at the times of near-zero current speeds represent the periods when mud can be deposited.

Residual, estuarine circulation: at tidally influenced river mouths, fresh water rides above denser seawater (Figure S7). This generates a net seaward flow in the upper layer and a residual landward flow in the near-bed salt wedge (Nichols and Biggs, 1985; Dyer, 1995). This so-called *estuarine circulation*, which occurs in estuaries and delta distributary channels, becomes progressively less important as the tidal range increases, because strong tidal currents and intense turbulence destroy the salinity stratification.

Superimposed currents: wind forcing and oceanic circulation are responsible for slow water movement on timescales ranging from hours to years. Such currents may not be sufficient by themselves to initiate sediment movement, but may lead to residual transport when they are superimposed on the stronger tidal flows.

Bathymetric influence: local bathymetric irregularities, including bedrock promontories and current-generated sea-bed topography (e.g., tidal bars), cause spatial variability in the bed shear stress, with areas facing into the current experiencing stronger currents than areas sheltered from the main flow. Because of tidal flow reversals, these areas of exposure and sheltering alternate positions on each ebb and flood tide. This in turn produces inequalities between the ebb and flood currents at most locations.

Bedload transport

The transport of sand-sized bed-load sediment by tidal currents is generally describable using the concepts developed for unidirectional flow (see *Sediment Transport by Unidirectional Flows*). The unsteadiness associated with flow acceleration and deceleration over each tidal cycle has relatively little affect, because sand-sized sediment responses rapidly to changes in bed shear stress (Van Rijn, 1993). Consequently, bed-load-transport equations developed for unidirectional flows can be integrated over a complete tidal cycle, using the instantaneously measured mean current speeds and water depths, to obtain the residual bed-load discharge, provided salinity stratification is not pronounced. Because the discharge of bed-load is a power function of the current speed, the direction of residual sand transport can commonly be determined by comparing only the maximum speeds in the ebb and flood directions, with lesser regard for the durations of weaker currents (Figure S6(B)). Thus, the factors that determine the residual transport of sand are those that most strongly influence the inequality of the peak speeds.

Bathymetric and hypsometric influences, coupled with any fluvial discharge, create systems of *mutually evasive channels*: channels that open in a seaward direction tend to be flood

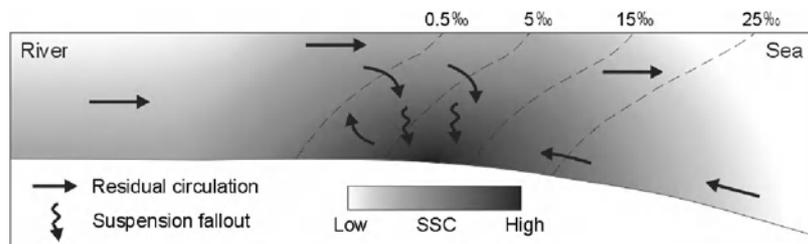

Figure S7 Formation of a salt wedge, as shown by the inclined salinity contours (dashed lines), in the zone of mixing between fresh water and seawater. The resulting, residual estuarine circulation (outward flow in the surface layer; landward flow near the bed) traps fine-grained material and develops a zone of elevated suspended-sediment concentrations (SSCs) called the *turbidity maximum*.

dominant, whereas channels that connect directly to a river tend to be ebb dominant. Elongate tidal bars separate such channels and have opposite directions of net sand transport on either side of their crest (Dalrymple and Rhodes, 1995). Erosional *bed-load partings* are produced at locations where the directions of residual transport diverge (i.e., there are opposing directions of net transport on either side of the parting; Harris *et al.*, 1995). Conversely, net deposition occurs in areas where the residual transport converges. Such a *bed-load convergence* appears to be present within all estuaries and in the mouth-bar area of tidally influenced or dominated deltas: sand can be moved landward from the shelf because of the general flood dominance caused by the shallow-water distortion of the tidal wave, whereas the seaward movement of river-supplied sediment is slowed by the periodic current reversals. On tide-dominated continental shelves, bed-load partings and convergences are separated by areas with a consistent direction of net sand transport. These *sediment-transport pathways* may be tens to hundreds of kilometers long and display a predictable succession of bedforms (Belderson *et al.*, 1982; see also *Surface Forms*).

Suspended-load transport

Compared to bed-load, the transport of suspended material is more strongly influenced by flow unsteadiness and weak residual currents, because fine-grained material continues to move for some time after currents have dropped below the threshold for bed-load movement. Thus, the transport of fine-grained sediment may be strongly influenced by weak, residual currents, and the net transport of bed-load and suspended-load sediment may be in different, even opposing, directions.

In detail, the movement of suspended sediment lags behind the water movement, both during deposition from a decelerating current and during erosion by an accelerating current. Van Straaten and Kuenen (1958; *cf.* Nichols and Biggs, 1985; Dyer, 1995) developed a simplified, yet elegant, model to account for the more important affects (Figure S8). In this model, the tide is assumed to be symmetrical and to show a linear, landward decrease in the maximum current speed. Two lags are considered: *settling lag*—the distance (and time) taken for suspended sediment to settle to the bed as the current speed decreases toward slack water (Figure S8(A)); and *scour lag*—a delay in resuspension from the bed because the current speed needed to erode fine-grained sediment is greater than the current speed at which deposition occurs (Figure S8(B)). These two lags operate at both the landward and seaward ends of a sediment-particle's excursion over a half tidal cycle. However, because the distance-velocity distributions are asymmetrical (even though speeds at any point are sinusoidal), the lags are longer at the landward end. Furthermore, the water and particle excursion distances decrease toward the land (i.e., $E-E'$ is shorter than $F-F'$; Figure S8). Thus, there is a net landward migration of the particle and a resulting tendency for fine-grained sediment to accumulate near the landward margin of tidal flats and at the head of estuaries.

The foregoing illustrates that the transport and deposition of fine-grained sediment is strongly influenced by the factors governing the erosion threshold. Unlike noncohesive sand for which the threshold-of-motion is essentially constant for a give grain size, the erosion threshold for mud is not constant and increases as the degree of consolidation increases (Parchure and Mehta, 1986). Thus, the longer slack-water period that

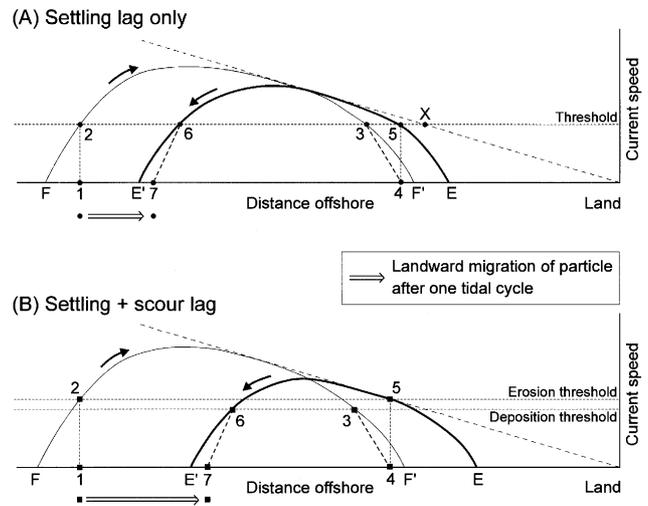

Figure S8 Transport history of suspended sediment in a tidal environment, based on Van Straaten and Kuenen (1958), in a situation where the maximum current speeds decrease toward the land (dashed diagonal line in (A) and (B)). The presence of a single upper bound for both the flood and ebb current speeds implies that the water movement is symmetrical, with no net water discharge. In (A) only the effect of settling lag is examined. Water originating at point F on the flood tide entrains a particle at location 1 when the speed exceeds the threshold velocity (2). The particle then travels landward with the current, eventually being deposited at 4, which is located some distance landward of point 3 where the current speed falls below the threshold for continued movement. The distance (and corresponding time interval) between 3 and 4 is termed the *settling lag*. On the ensuing ebb tide, water originating at F' retraces the F-F' trajectory, but is not able to re-entrain the particle because the speed has not reached the threshold by the time the water reaches location 4. Instead, water originating at E re-entrains the particle, carries it seaward along the trajectory E-E', and deposits it at 7. The distance of travel between 6 and 7 is also a result of the settling lag. However, because of the distance-velocity asymmetry and the shorter excursion on the ebb tide, the particle experiences a net landward displacement (1→7). Note that a particle coming to rest landward of point X in (A) cannot be re-entrained by the tidal currents shown because the maximum current speed is always below the threshold. (B) shows a similar transport history but introduces separate erosion and deposition thresholds, which is more realistic than the situation shown in (A). As a result of the higher erosion threshold, point E is located further landward than in (A). This causes an increased delay in the re-entrainment of the particle which Van Straaten and Kuenen (1958) termed the *scour lag*. (Note that the definition of scour lag given by Nichols and Biggs (1985) and Dyer (1995) is not precisely the same as the original definition). Because of the scour lag, the particle does not travel as far seaward and experiences a greater, net landward displacement than in (A). (A) and (B) after Figures S7 and 4, respectively, of Van Straaten and Kuenen (1958).

characterizes more landward locations promotes higher erosion thresholds, longer scour lags, and preferential mud deposition. Exposure to the atmosphere, especially at times of high evaporation potential, and the growth of microbial coatings are particularly effective at producing cohesion (see *Tidal Flats*).

The residual estuarine circulation discussed above is also significant with regard to the trapping of suspended sediment in coastal settings. The suspended sediment introduced by the river moves seaward in the surficial layer, but then settles into the landward-moving lower layer (Figure S7), a process that is

aided by the *flocculation* of fine-grained sediment that occurs in this region (Nichols and Biggs, 1985; Burban *et al.*, 1989; Dyer, 1995). This circulation leads to the increase of suspended-sediment concentrations (SSCs) near the limit of salt-water intrusion (Nichols and Biggs, 1985; Dyer, 1995). The higher transport capacity that characterizes the flood tide in many cases, because of the shallow-water deformation of the tidal wave (see above), also contributes to the trapping of fine-grained sediment near the landward limit of tidal influence. The combined influence of these factors produces a *turbidity maximum* in which SSCs are elevated relative to areas further landward or seaward (Figure S7). SSCs in the turbidity maximum tend to increase as the tidal energy increases, and thus tend to be highest in macrotidal areas and at spring tides, because of greater resuspension of mud. Near-bed SSCs can exceed 10 gl^{-1} producing mobile sediment bodies that are called *fluid mud* (Faas, 1991). These dense suspensions occupy channel-bottom locations where they can form anomalously thick mud deposits. The high SSCs promote this deposition by decreasing the bed shear stress (Li and Gust, 2000) during the ensuing tidal current. As a result, higher mean current speeds are needed to resuspend the sediment than would be the case in the absence of the high SSCs.

Summary

The transport of sediment by tidal currents is complex because of the pronounced temporal and spatial variability of flow strength and direction. Sediment particles of different sizes respond to the flow unsteadiness with different amounts of lag, such that bed-load and suspended load can display different directions of residual transport: bed-load tends to move in the direction of the current with the higher peak speed, whereas the suspended load commonly moves in the direction of the residual water movement. Bathymetric and hypsometric influences produce spatial inequalities in the strengths of the flood and ebb currents, creating complex transport pathways characterized in coastal areas by mutually evasive channels. The common development of a flood dominance because of the distortion of the tidal wave in shallow water, coupled with the presence of a density-driven estuarine circulation, leads to the trapping of both bed-load and suspended-load material within estuaries and/or at the mouth of deltaic distributaries. Fluid mud is commonly formed beneath the turbidity maximum that forms as a result of this trapping.

SEDIMENT TRANSPORT BY UNIDIRECTIONAL WATER FLOWS

Sediment properties

Description of sediment movement involves terms such as grain size, shape and density, settling velocity, and sediment transport rate. For the range of grain size, shape and density of sediment available for transport see *Grain Size and Shape*. Methods of measuring and analyzing these grain properties are described also in Carver (1971) and McManus (1988). A sediment grain immersed in water experiences a hydrostatic pressure that is greater on its base than on its top: an upward directed buoyancy force equal to the weight of water displaced by the grain. If the weight of the grain exceeds the buoyancy force, the grain will sink. The *immersed weight* of the grain is the gravity force minus the buoyancy force, given by $Vg(\sigma - \rho)$, where V is grain volume, g is gravitational acceleration, σ is sediment density, and ρ is fluid density.

Drag on sediment grains

A fluid moving relative to a solid boundary, such as water flowing over a bed of sediment or a sediment grain settling in water, experiences resistance to motion due to the action of various types of frictional forces (e.g., viscous shear stress, dynamic pressure). This resistance to motion is called *drag*. Drag due to viscous shear is called surface drag or skin-friction drag, whereas drag due to fluid pressure is called form drag. In turbulent flows, form drag is normally much more important than surface drag.

A general equation for the drag force is:

$$F_D = C_D a(\rho V_r^2/2) \quad (\text{Eq. 1})$$

where C_D is a drag coefficient, a is the cross-sectional area exposed to the drag, and V_r is the relative velocity of the solid and fluid. The term in brackets is actually the dynamic pressure on the area of the solid that faces the fluid flow, but this term also accounts for the pressures on the lee-side of the solid associated with flow separation, and for viscous forces. Flow separation produces a pressure against the flow (form drag). The drag coefficient takes into account whether or not flow separation occurs behind a solid body, and the nature of such flow separation, including the size of the separation eddies. The drag coefficient therefore depends on the geometry of the solid body, and specifically how streamlined it is. The drag coefficient is also dependent on an appropriate Reynolds number, as this determines the relative importance of viscous drag and form drag. The drag equation is used in two important cases: (1) the settling of grains in fluids (See *Grain Threshold, Grain Settling*); and, (2) fluid moving over beds of sediment.

Drag and lift on bed grains

The mean drag force acting on bed grains is commonly resolved into components parallel to the bed (drag) and normal to the bed (lift). The mean drag on a sediment grain can be expressed as:

$$F_D = C_D a(\rho u^2/2) \quad (\text{Eq. 2})$$

where u is the mean velocity of the fluid at the level of effective mean drag. This velocity is proportional to the square root of the bed shear stress, τ_o . The level of effective drag depends on the shape of the grain and its position in the bed. The drag coefficient for single grains resting on the bed is similar to that for settling grains. The area exposed to drag depends on the shape of the grain, and how it is packed in the sediment bed. This area will be proportional to the square of grain size. Thus, it can be shown that

$$F_D \propto \tau_o D^2 \quad (\text{Eq. 3})$$

where the constant of proportionality depends on the grain shape and orientation, its relative protrusion above the mean bed level, and the grain Reynolds number.

Both turbulent and nonturbulent fluid lift forces can act on bed grains (summary in Bridge and Dominic, 1984). Nonturbulent lift forces are pressures caused by asymmetrical flow around near-bed grains. As turbulence originates very close to the bed of a stream, bed grains are undoubtedly affected by turbulent lift, and this is most likely to be dominant over nonturbulent lift (outside the viscous sublayer). Fluid lift is commonly expressed in a similar way to drag, but using a lift coefficient instead of a drag coefficient.

The threshold of transport of cohesionless sediment (sand and gravel)

If fluid drag and lift forces exceed the forces keeping sediment grains in place on the bed (gravity and cohesive forces associated with vegetation, microbial coatings, cementation, and clay minerals), the grains will be entrained by the flow. In the case of *cohesionless* grains, the threshold of entrainment depends on the balance between the drag and gravity forces, F_D and F_G respectively, as long as fluid lift is assumed to be a

linear function of drag. As

$$F_D \propto \tau_o D^2 \quad (\text{Eq. 4})$$

and

$$F_G \propto (\sigma - \rho)gD^3 \quad (\text{Eq. 5})$$

the threshold of entrainment should depend on

$$F_D/F_G \propto \tau_o/(\sigma - \rho)g D = \Theta \quad (\text{Eq. 6})$$

where Θ is referred to as the *dimensionless bed shear stress* (a measure of sediment mobility) and D is a grain size representative of all grains in the bed. Values of dimensionless bed shear stress at the threshold of motion are typically between 0.03 and 0.06 (Figure S9: based on numerous theoretical and experimental studies, reviewed in Miller *et al.*, 1977; Yalin and Karahan, 1979; Wiberg and Smith, 1987; Bridge and Bennett, 1992; Komar, 1996; Buffington and Montgomery, 1997). The exact value of Θ depends on the degree to which the grains are immersed in the viscous sublayer, the relative magnitude of the lift component of drag, the bed slope, and the relative size, shape and arrangement of the grains in the bed.

The boundary grain Reynolds number (Figure S9) is defined as

$$Re_b = U^*D/\nu \approx 10D/\delta \quad (\text{Eq. 7})$$

where $U^* = \sqrt{(\tau_o/\rho)}$ is the shear velocity, ν is kinematic viscosity, and δ is the thickness of the viscous sublayer. Thus,

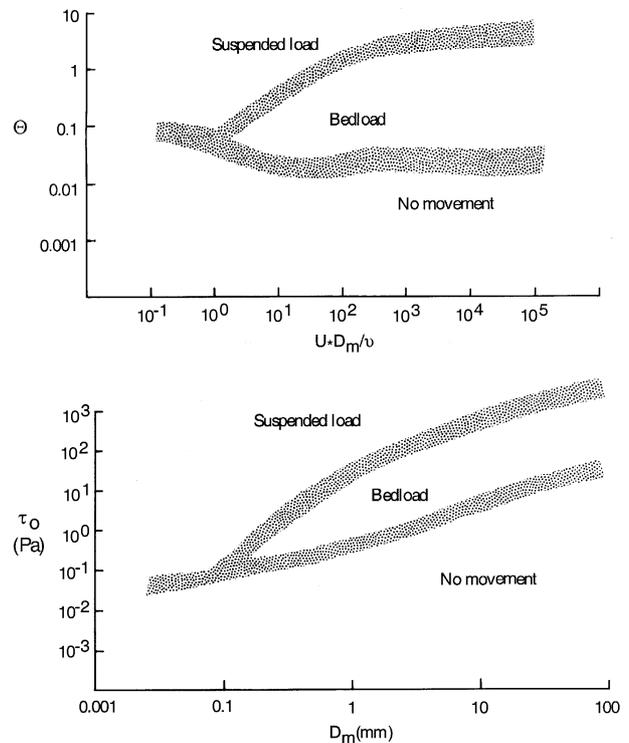

Figure S9 Threshold of motion (shaded zones) for bed load and suspended load for the case of cohesionless sediment. Based on numerous experimental and theoretical studies discussed in text.

the boundary grain Reynolds number is proportional to the ratio of grain diameter/thickness of the viscous sublayer. For Re_b less than 5 to 10 (hydraulically smooth flow), the grains are immersed in the viscous sublayer, are subjected mainly to viscous forces, and are sheltered from the much greater drag forces of the turbulent flow above. This is the reason why the dimensionless bed shear stress must be relatively large to entrain these grains (Figure S9). However, this is also partly to do with increasing effects of cohesion in very small grains. If bed grains project high above the viscous sublayer ($Re_b > 70$ to 100; hydraulically rough flow), turbulent shear stresses and form drag are dominant, viscous forces are negligible, and the threshold of motion becomes independent of Reynolds number (Figure S9). For fixed values of fluid and sediment density, the threshold of entrainment can be expressed in terms of bed shear stress and grain size (Figure S9).

The threshold of motion shown in Figure S9 is composed of a range of experimentally determined values. This range exists partly because not all of the controlling parameters (such as bed slope and relative size, shape and arrangement of grains on the bed) are represented on plots of dimensionless bed shear stress and boundary grain Reynolds number. However, perhaps the main reason for the range is the difficulty in defining the threshold of motion. Turbulent flow is associated with fluid drag and lift forces that vary greatly in time and space. These forces are acting upon grains that vary in size, shape, and arrangement on the bed. Thus, a locally high instantaneous fluid force may dislodge a few of the most easily moved grains, but may not produce general sustained movement. Such intermittent movement may be difficult to observe (see *Grain Threshold*).

The threshold of motion defined in Figure S9 only applies to *planar beds* with relatively small slopes. Some theories take into account the effects of bed slope (e.g., Wiberg and Smith, 1987; Bridge and Bennett, 1992). If there are bed waves such as ripples or dunes present on the bed, the threshold of motion is complicated by non-negligible bed slope and the fact that the spatially averaged bed shear stress includes components of bed-form drag that do not effectively act on bed grains. Thus, in order to define the threshold of motion on bed waves, it is necessary to define local fluid drag and lift on their upstream sides, and to account for the upstream sloping bed surface.

The threshold of motion defined in Figure S9 only applies to the *mean* grain size of grains that do not vary much in size, shape, and density. Prediction of the threshold of entrainment of individual grains in a mixture of grains of different size, shape, and density requires much more detailed analysis of the forces involved, including turbulent variations in fluid drag and lift. There are a number of different theoretical and empirical approaches to this problem (reviews by Bridge and Bennett, 1992; Komar, 1996; Buffington and Montgomery, 1997; Bridge, 2003). All of the approaches predict that the threshold of motion for a particular grain size in the mixture depends on its size relative to the median size of the mixture. Larger-than-average grains are relatively easier to entrain than if all grains were the same size, whereas the opposite is true for the smaller-than-average grains. This is because large grains protrude relatively higher into the flow where average fluid velocity is greater, and because friction angles are relatively low. Such grains may have dimensionless bed shear stress as low as 0.01 at the threshold of motion. In contrast, small grains sit low in the flow and have large friction angles, or are hidden by the larger grains. In rare cases, the threshold of

motion of the large and small grains may be so similar that they are almost equally mobile. However, these predictions are based on consideration of time-averaged fluid drag and lift. It is important to consider turbulent variations in fluid drag and lift, as these cause different fractions to move at different times. Small grains may not actually be hidden from turbulent lift associated with flow separation to the lee of larger grains. The largest grains may only move under the influence of the largest instantaneous fluid drag or lift, and not by the mean values. Lack of consideration of turbulence may lead to underestimation of the threshold shear stresses for the larger grains, and vice versa for small grains.

In view of the fact that fluid turbulence has a dominating influence on sediment entrainment, and that turbulent motions vary in time and space, it is not surprising that when a particular size fraction starts to move on the bed, not all of the grains of that size fraction on the bed will be moving. This will be particularly true for the coarsest fractions that require the largest instantaneous turbulent stresses for movement. The condition where some of the grains of a given size on the bed move within a given time interval, but not all of them move, has been called partial transport by Wilcock and McArdeil (1997). Partial transport is thought to be common in many gravel-bed rivers. As would be expected, the proportion of grains present in the bed that are mobile is greatest for the finest sizes and least for the coarsest sizes.

The threshold of transport of cohesive sediment (mud)

Cohesion in muds is the dominant control on resistance to entrainment (review by Black *et al.*, 2002). Cohesion is partly due to electro-chemical forces, the magnitude of which depends on mineralogy (e.g., exchangeable cations), the size, shape, and spatial arrangement of the clay flakes, and the ionic properties of the pore water and eroding water. However, cohesion can also be due to microbial organisms (bacteria, microphytobenthos). Resistance properties also depend on the state and history of consolidation. For example, there may be a flocculated structure, a pelleted structure due to desiccation and bioturbation, or fissility due to compaction. Certainly, compacted and dry clays are more difficult to erode than soft, wet clays. Many experimental studies have been conducted to establish relationships between critical bed shear stress for entrainment and some gross property of the clay such as cohesive shear strength, liquid and plastic limits, percent clay, density, permeability and porosity. These parameters have usually been linked to critical shear stress one or two at a time using only one type of clay-water complex. There are no universal correlations for all types of clays in all aqueous environments. The nature of entrainment also depends on the state and history of consolidation, which will determine whether the clay is eroded as individual flakes, floccules, or fragments of consolidated mud. Also, direct fluid stress may be augmented by impacts on the bed of grains already in motion.

Bed load

Sediment grains with diameters greater than approximately 0.1 mm (sand and gravel) generally move close to the boundary (within ten grain diameters) by rolling, sliding and saltating (jumping). These grains move more slowly than the surrounding fluid because of their intermittent collisions with the bed

and each other. These grains form the *bedload*. The continuing movement of bed-load grains requires the existence of an upward dispersive force (Bagnold, 1966, 1973) that must be exactly balanced by the immersed weight of the moving grains for steady bed-load transport. The two ways of dispersing grains normal to the flow boundary are by collisions between the grains and bed, and by fluid lift.

Saltation is the dominant mode of bed-load transport, with rolling and sliding only occurring near the threshold of entrainment and between individual jumps (summary in Bridge and Dominic, 1984). As the downstream velocity of rolling and sliding grains increases over an irregular bed, the grains are frequently launched upward as they are forced over protruding immobile grains, thus initiating saltations. At low transport rates, saltation trajectories are unlikely to be interrupted by collisions with other moving grains. However, at higher sediment transport rates (greater concentration of bed-load grains), saltations will be more interrupted by collisions between moving grains, and these collisions will contribute to the upward dispersive stress.

Both turbulent and non-turbulent fluid lift forces can act on bed-load grains (summary in Bridge and Dominic, 1984). Non-turbulent lift forces are pressures arising from a net relative velocity between grains and surrounding fluid. They are caused by asymmetrical flow around near-bed grains, the reduced grain velocity relative to the velocity gradient in the surrounding fluid (shear drift), and the effects of grain rotation (Magnus lift). It is very difficult to specify their individual contribution to net lift, particularly when complex grain collisions occur within the bed load, and when turbulent lift forces are dominant.

As turbulence originates very close to the bed of a stream, bed-load grains are undoubtedly affected by turbulent lift as well as by drag. As near-bed turbulent fluctuations increase with bed shear stress (or shear velocity), grain saltations are modified more and more by turbulence as bed shear stress and sediment transport rate increase. Turbulence affects different sized grains in different ways, depending on immersed weight of grains and the direction and magnitude of turbulent fluid motions (review by Bridge, 2003).

The mean height of the bed-load (saltation) zone controls the effective roughness of the bed, and must be known to calculate bed-load transport rate. Many approaches to determining the mean height of the bed-load zone are theoretical-empirical, predicting that saltation height increases with sediment size and some measure of sediment transport rate (reviews by Bridge and Dominic, 1984; Bridge and Bennett, 1992; Bridge, 2003). In general, saltation height is proportional to grain diameter. Theoretical models of saltation trajectories of individual grains have also been used to determine saltation height. However, it is very difficult to model the influence on saltating grains of turbulent fluid motions, and the effects on grain trajectories of impacts among grains are not considered.

Suspended load

Grains of clay, silt and very fine sand generally travel within the flow, supported by upward-directed fluid turbulence. These grains, the *suspended load*, travel at approximately the same speed as the surrounding fluid because they are not decelerated by intermittent collisions with the bed. Maintenance of a suspended-sediment load requires the existence of a net upward-directed fluid stress to balance the immersed weight of the suspended grains. This can only arise if the vertical

component of turbulence is anisotropic (Bagnold, 1966). This anisotropy can be associated with the turbulent bursting phenomenon, whereby sediment is suspended mainly in vigorous upward ejections of fluid, and then returns to the bed under the influence of gravity and downward-directed turbulent motions. This idea is supported by experimental observations of discrete clouds of suspended sediment associated with turbulent ejections, and the wavy trajectories of suspended grains (review in Bridge, 2003). However, sediment is also suspended in vortices generated by eddy shedding from the separated boundary layer in the trough regions of ripples and dunes. With dunes, these vortices can reach the water surface as boils or kolks. Provided that a grain experiences more upward directed turbulent motions than the combination of downward directed turbulent motions and gravitational settling, it will remain in suspension.

Two criteria for the suspension of sediment are:

$$rms v'_+ > V_g \quad (\text{Eq. 8})$$

$$rms v'_+ - rms v'_- > V_g \quad (\text{Eq. 9})$$

where $rms v'$ is the root mean square of the vertical turbulent fluctuations of the flow, the subscripts refer to upward motions (+) or downward motions (-), and V_g is the mean terminal settling velocity of the sediment. The first criterion indicates that, as long as time-averaged upward-directed turbulent velocities are in excess of V_g , sediment can be moved upward within the flow, even if the sediment eventually returns to the bed. The second criterion indicates that for a grain to *remain* in suspension the time-averaged upward-directed turbulent velocity experienced by the grain must exceed the downward-directed velocity plus the settling velocity of the grain. There is an empirical relationship between the time-averaged upward and downward directed velocities and the overall $rms v'$ near the bed, such that the two suspension criteria above become

$$armsv' > V_g \quad \text{where } a \text{ is } 1.2 \text{ to } 1.5 \quad (\text{Eq. 10})$$

$$brmsv' > V_g \quad \text{where } b \text{ is } 0.4 \text{ to } 0.9 \quad (\text{Eq. 11})$$

Furthermore, $rmsv'/U^* \approx 1$ near the bed, so that the suspension criteria for near-bed conditions are

$$aU^* > V_g \quad \text{and} \quad bU^* > V_g \quad (\text{Eq. 12})$$

Also, as the shear velocity and the settling velocity can be related to the dimensionless bed shear stress and the grain Reynolds number, the threshold of suspension can be represented on the threshold of entrainment diagrams (Figure S9). As the bed shear stress varies in time and space, sediment with a particular settling velocity (or grain size) may travel as both bed load and sediment load. This is particularly true of the sand sizes coarser than about 0.1 mm. This is called *intermittently suspended load*.

The *washload* is commonly distinguished from *suspended bed-material load*. Wash load is very fine grained and suspended even at low flow velocity. Furthermore, the volume concentration of wash load does not vary much with distance from the bed, whereas the volume concentration of suspended bed-material load decreases markedly with distance from the bed. Whereas the suspended bed-material load originates from the bed, the wash load can come from bank erosion and overland flow. Perhaps, the two different suspension criteria effectively distinguish wash load from suspended bed-material load.

Effect of sediment transport on flow characteristics

In uniform, turbulent boundary layers over planar beds with sediment transport, it is generally recognized that the moving sediment modifies flow characteristics. Many scientists in the 1940s to 1960s (reviewed in ASCE, 1975) suggested that the presence of sediment in the flow caused a reduction in turbulent eddy sizes and in the degree of turbulent mixing. The main effect of sediment on turbulence was expected to be near the bed where sediment concentration is highest. These conclusions have been substantially confirmed by recent studies (review by Bridge, 2003). The nature of the interaction between sediment grains and fluid turbulence actually depends on the relative velocity of the grains and the turbulent fluid (which depends on grain weight), and the relative size of the grains and the turbulent eddies. If the relative velocity of the grains and fluid is large (i.e., large, heavy grains), turbulence intensity (particularly of the smallest eddies) is increased as a result of vortex shedding or inertial effects. If the relative velocity is small (i.e., small grains), turbulence intensity is decreased as the turbulent energy is transferred to the grains. More recently it has been suggested that turbulent mixing is suppressed because of the *density stratification* brought about by an upward decrease in suspended sediment concentration, as represented by a *flux Richardson number*. However, this idea is not well supported by natural data (Bennett *et al.*, 1998). In natural flows, bed forms have an overwhelming effect on turbulence intensities and eddy sizes.

Sediment transport rate (bed load)

The *sediment transport rate* is the amount (weight, mass, or volume) of sediment that can be moved past a given width of flow in a given time. The sediment transport rate controls the development of bed forms such as ripples and dunes, the nature of *erosion* and *deposition*, and the dispersal of physically transported pollutants. There is a vast and complicated literature on the subject (reviews in Graf, 1971; ASCE, 1975; Yalin, 1977; Van Rijn, 1984a,b,c; Chang, 1988; and many others) and only the basics will be presented here.

Bed-load transport rate can be expressed as

$$i_b = Wu_b \quad (\text{Eq. 13})$$

where i_b is the bed-load transport rate as immersed weight passed per unit width, W is the immersed weight of bed-load grains over unit bed area, and u_b is the mean bed-load grain velocity. The contacts between bed-load grains and the bed result in resistance to forward motion. Therefore, the fluid must exert a mean downstream force on the grains to maintain their steady motion. For bed-load transport on a bed of slope angle β , the force balance parallel to the bed can be expressed as

$$\tau_o + W \sin \beta = T + \tau_r \quad (\text{Eq. 14})$$

where τ_o is the bed shear stress applied to the moving grains and immobile bed (but excluding form drag due to bed forms and banks), $W \sin \beta$ is the down-slope weight component of the moving grains per unit bed area (with $\sin \beta$ positive if the bed slopes down flow), T is the shear resistance due to the moving bed load, and τ_r is the residual shear stress carried by the immobile bed. Bed-load shear resistance can be expressed as

$$T = (W \cos \beta - F_L) \tan \alpha \quad (\text{Eq. 15})$$

where F_L is the net fluid lift on bed-load grains per unit bed area, taken as resulting dominantly from anisotropic turbulence, and given by

$$F_L = W(bU^*/V_g)^2 \quad (\text{Eq. 16})$$

and $\tan \alpha$ is the dynamic friction coefficient. From experiments on shearing of grains in dry grain flows and coaxial drums, where volumetric grain concentrations are approximately 0.5, $\tan \alpha$ commonly lies between 0.4 and 0.75 (review in Bridge and Dominic, 1984; Bridge and Bennett, 1992). The residual fluid stress τ_r equals the bed shear stress at the threshold of motion τ_c according to Bagnold (1956, 1966). Thus, once the applied fluid stress exceeds the value necessary for entrainment, grains will be entrained until the bed-load resistance caused by their motion reduces the applied fluid stress to the threshold value of τ_c . Therefore, the immersed weight of grains moving per unit bed area is given, from equations 14 to 16, as

$$W = \frac{\tau_o - \tau_c}{\tan \alpha [\cos \beta - (bU^*/V_g)^2] - \sin \beta} \quad (\text{Eq. 17})$$

As the threshold of suspension is reached, the term in square brackets approaches zero, indicating that the weight of bed-load grains approaches infinity. In reality, this situation could not arise because high grain concentrations in the bed load layer would occlude the bed from fluid drag and lift, thus limiting the weight of bed-load grains (e.g., Bagnold, 1966). Furthermore, high concentrations of near-bed grains modify turbulence characteristics above the bed. In many natural flows, the bed-slope is small enough such that $\sin \beta$ tends to zero, and the term in square brackets tends to 1, so that

$$W = \frac{\tau_o - \tau_c}{\tan \alpha} \quad (\text{Eq. 18})$$

The mean velocity of the average bed-load grain is given by

$$u_b = u_D - u_R \quad (\text{Eq. 19})$$

where u_D is the time-averaged flow velocity at the level of effective drag on the grain, and u_R is the relative velocity of the fluid and the grain. The relative velocity is that at which the fluid drag plus down-slope weight component on the grain is in equilibrium with the bed-load shear resistance:

$$F_D + F_G \sin \beta = F_G \tan \alpha (\cos \beta - (bU^*/V_g)^2) \quad (\text{Eq. 20})$$

Using the general drag equation for F_D , and the fact that F_G is equal to the fluid drag at a grain's terminal settling velocity, results in

$$u_R = V_g (\tan \alpha (\cos \beta - (bU^*/V_g)^2) - \sin \beta)^{0.5} \quad (\text{Eq. 21})$$

Finally, as $u_D/U^* = a$, the mean velocity of bed-load grains is given by

$$u_b = aU^* - V_g (\tan \alpha (\cos \beta - (bU^*/V_g)^2) - \sin \beta)^{0.5} \quad (\text{Eq. 22})$$

or approximately as

$$u_b = aU^* - V_g (\tan \alpha)^{0.5} \quad (\text{Eq. 23})$$

Furthermore, as the grain velocity must be zero at the threshold of grain motion, this equation may also be written as

$$u_b = a(U^* - U_{*c} (\tan \alpha / \tan \alpha_c)^{0.5}) \quad (\text{Eq. 24})$$

Determination of the value of a requires knowledge of the height above the bed level of the effective drag on the grains (that varies with the saltation height) and details of the near-bed velocity profile. There have been numerous attempts to relate saltation height to some measure of flow stage (review in Bridge and Bennett, 1992). The flow velocity at the height of effective drag depends on whether the flow is hydraulically smooth, transitional or rough. For transitional and rough flows, a is about 8–12 (Bridge and Dominic, 1984). Also, at the threshold of suspension, the grain velocity approximately equals the fluid velocity and $u_b = aU_*$, which is another suspension criterion.

Thus, the final approximate bed-load transport equation can be written as

$$i_b = \frac{a}{\tan \alpha} (U_* - U_{*c})(\tau_o - \tau_c) \quad (\text{Eq. 25})$$

Equations of this form have been developed, using similar principles, by a number of workers (details in Bridge and Dominic, 1984). This equation agrees very well with experimental data for flows over plane beds. For low sediment transport rates (lower-stage plane beds), $a/\tan \alpha$ is approximately 10, but is approximately 17 for high sediment transport rates (upper-stage plane beds). For beds covered with bed forms such as ripples and dunes, the bed-load transport equation can be applied by determining the average bed shear stress over a number of bed forms, and to remove the part of the total average stress that is due to form drag in the lee of the bed forms, because it is ineffective in moving bed-load grains (e.g., Engelund and Hansen, 1972; Engelund and Fredsoe, 1982; Nelson and Smith, 1989). However, bed-load transport rates associated with ripples and dunes can also be calculated from knowledge of their mean height and downstream migration rate.

The bed-load transport theory developed above is for mean flow and sediment characteristics, but it can be adapted for use with heterogeneous sediment and with temporal variations in bed shear stress (e.g., Bridge and Bennett, 1992). In this case, it is necessary to specify the proportion of the different grain fractions available in the bed for transport, and the thresholds of entrainment and suspension for each of the grain fractions. It is also necessary to specify the proportion of time that a particular bed shear stress acts upon the bed-load, requiring a frequency distribution of bed shear stress. Bridge and Bennett's (1992) bed-load transport model for heterogeneous sediment agrees well with natural data. Models such as this (e.g., Wiberg and Smith, 1989; Parker, 1990) are essential for quantitative understanding of sediment sorting during erosion, transport and deposition.

Sediment transport rate (suspended load)

Suspended-sediment transport rate at a point in the flow is commonly expressed as

$$i_s = u_s C \quad (\text{Eq. 26})$$

where u_s is the average speed of the sediment (approximately the same as the fluid velocity), and C is the volume concentration of suspended sediment. The units of i_s are therefore volume of sediment transported per unit cross-sectional area normal to the flow direction per unit time. The vertical variation of the velocity of suspended sediment and fluid can be calculated using an appropriate velocity profile

law (e.g., the law of the wall). Calculation of the vertical variation of C in steady, uniform water flows is traditionally based on the balance of downward settling of grains and their upward diffusion in turbulent eddies, i.e.,

$$V_g C + \epsilon_s dC/dy = 0 \quad (\text{Eq. 27})$$

where the first term is the rate of settling of a particular volume of grains per unit volume of fluid, the second term is rate of turbulent diffusion of sediment per unit volume, and ϵ_s is the diffusivity of suspended sediment (equivalent to a kinematic eddy viscosity, ϵ). This balance can also be written for individual grain fractions. In order to determine C at any height above the bed, y , it is necessary to calculate the vertical variation in ϵ_s . Assuming that $\epsilon_s = \beta\epsilon$, where β is close to 1, and that the law of the wall extends throughout the flow depth, results in the well-known Rouse equation

$$\frac{C}{C_a} = \left[\frac{d-y}{y} \cdot \frac{a}{d-a} \right]^z : z = \frac{V_g}{\beta\kappa U_*} \quad (\text{Eq. 28})$$

where C_a is the value of C at $y=a$. This equation predicts that C decreases continuously and smoothly with distance from the bed, as would be expected in view of the fact that turbulence intensity also decreases with distance from the bed. The distribution of suspended sediment becomes more uniform throughout the flow depth as exponent z decreases, that is as settling velocity (grain size) decreases and/or as shear velocity (near-bed turbulence intensity) increases (Figure S10). For example, a decrease in water temperature causes an increase in fluid viscosity, which may in turn cause a decrease in settling velocity and an increase in suspended sediment concentration. The Rouse equation has been shown to agree with measured suspended-sediment concentrations in the lower part of stream flows but concentrations tend to be overestimated in the upper parts (figure S2). This discrepancy is addressed below.

Some of the assumptions used in developing the Rouse equation have been criticized: mainly the choice of velocity profile (law of the wall), and the fact that the interaction between suspended sediment, fluid properties and turbulence is not considered. Perhaps the most serious concern with the Rouse equation is that the sediment diffusivity has rarely been calculated directly using quantitative observations of the motion of sediment in turbulent eddies. Thus, there is doubt about the vertical variation of ϵ_s and β (e.g., ASCE, 1975; Coleman, 1970; Van Rijn, 1984b). Bennett *et al.* (1998) have measured turbulent motions of suspended sediment and concluded that β is indeed close to 1. However, suspended sediment concentration in the upper half of the flow depth in natural flows is commonly larger than predicted by the Rouse equation. One reason for this discrepancy could be that sediment grains that are suspended to the higher levels in the flow are not associated with mean turbulence characteristics as specified in the Rouse equation, but with turbulent eddies with the greatest turbulence intensities and mixing lengths (Bennett *et al.*, 1998). Thus, the Rouse equation, based on average turbulence characteristics, may only be strictly applicable for the lower parts of the flow.

Application of the Rouse equation in practice requires calculation of C_a and a , and there are various methods for doing this (review by Bridge, 2003). Normally, C_a is calculated at a position within or at the top of the bed-load layer. If bed waves are present, a can be taken as half bed-wave height or equivalent roughness height (Van Rijn, 1984c). The mean volume concentration of grains in the bed-load layer, C_b , is the

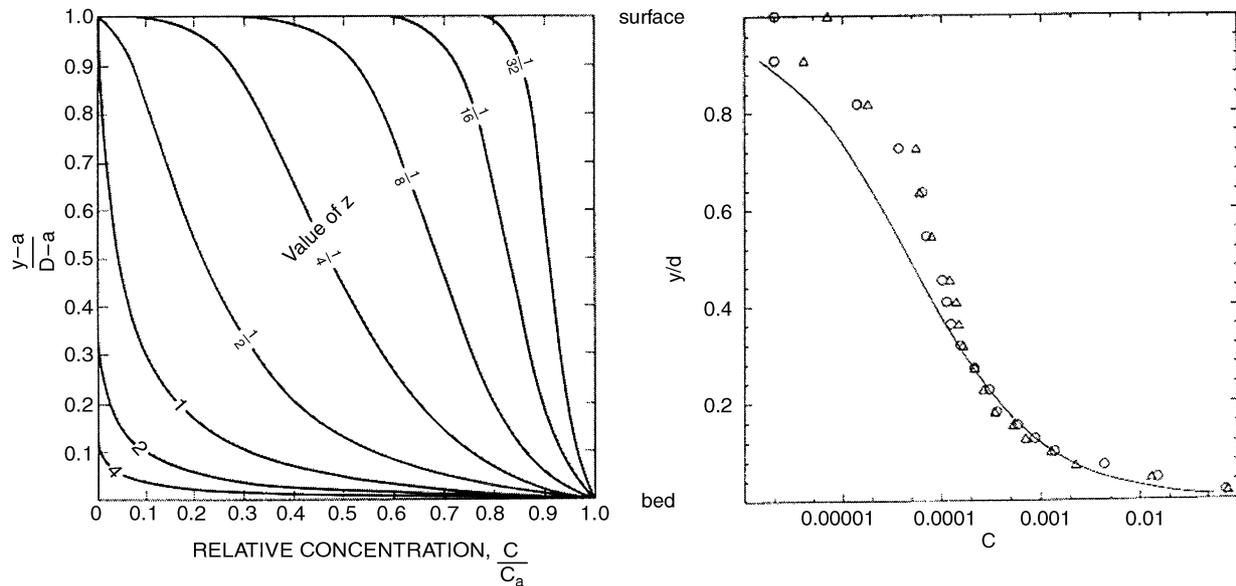

Figure S10 A) Variation of relative concentration of suspended sediment with distance from the bed as a function of z according to the Rouse equation (after ASCE, 1975). The distribution of suspended sediment becomes more uniform throughout the flow depth as exponent z decreases, that is as settling velocity (grain size) decreases and/or as shear velocity (near-bed turbulence intensity) increases. B) Comparison between the Rouse equation and data from an upper stage plane bed (from Bennett *et al.*, 1998). Predicted suspended sediment concentration is less than observed in the upper part of the flow.

volume of grains per unit bed area divided by the mean thickness of the bed-load layer, y_b , given using Bridge and Dominic's (1984) model as

$$C_b = \frac{\tau_o - \tau_c}{(\sigma - \rho)g y_b \tan \alpha} \quad (\text{Eq. 29})$$

The mean grain concentration can be assumed to occur at a distance from the bed of half the thickness of the bed-load layer, or half the equivalent roughness height.

An alternative to the convection-diffusion approach to calculating suspended sediment concentration in water flow is that based on the mechanics of two-phase flows (e.g., McTigue, 1981; Cao *et al.*, 1995; Greimann *et al.*, 1999; Greimann and Holly, 2001). The two-phase flow approach is useful for simulating interactions between grains, and the effects of grain inertia. Interactions between particles lead to an increase in the ability of the flow to suspend particles. Particle interactions are only important near the bed where local grain concentrations exceed about 0.1. Also, particle inertia is only important for large grains near the bed. Unfortunately, this approach is not fully developed, and cannot yet be applied easily to real rivers.

Evaluation of sediment transport rate models

There are many different models for sediment transport rate in steady, uniform flows. Some are for bed load only, whereas others predict bed load and suspended load either separately or together (total load). Important differences in these models depend on whether or not they consider individual sediment size-density fractions, the sediment available in the bed, and the effects of turbulent variations in fluid drag and lift on bed

load; the way in which flow over bed forms such as ripples and dunes is treated; the description of the vertical variation in flow velocity, turbulence intensity, and diffusivities of fluid momentum and suspended sediment, and; how moving sediment interacts with and modifies the water flow. Most sediment transport models are both theoretical and empirical, but it is desirable to minimize the use of empirical factors that limit the general applicability of a model. There have been many comparisons of the performances of the various sediment transport models (e.g., Graf, 1971; ASCE, 1975; Yalin, 1977; Chang, 1988; Gomez and Church, 1989).

Variation of sediment transport rate in time and space

Sediment transport rate varies over a large range of time and space scales, associated for example with fluid turbulence, the migration of bed waves (such as ripples, dunes, and bars), the break-up of armored or partially cemented beds, bank slumps, seasonal floods, flow diversions, and earthquake-induced changes in sediment supply. A characteristic feature of unsteady, nonuniform flows is that sediment transport rate commonly varies incongruently with temporal and spatial changes in water discharge: i.e., there is a lag or hysteresis. This may be due to variations in available sediment supply, or due to the lag of sediment and water flow behind a faster moving flood wave. Wash load is never well correlated with water discharge, and commonly reaches a peak during rising discharge because of an overland flow source. The lag of bed-load transport rate behind a spatial change in flow characteristics is very small (order of grain diameters); however, for suspended sediment this spatial lag is on the order of flow depth.

Sorting and abrasion of grains during transport

The fact that bed load and suspended load travel at different speeds and in different parts of a turbulent flow leads to the possibility of *sorting*, or physical separation of grains with different settling velocities (determined partly by grain size, shape and density). Figure S11 indicates *approximately* the range of grain sizes (for a given grain shape and density) that can be transported as bed load for a particular bed shear stress. The actual grain size range in the bed load depends on what is available for transport, the threshold of entrainment or suspension for individual grain fractions, and turbulent fluctuations in bed shear stress (Bridge and Bennett, 1992). Nevertheless, Figure S11 explains in a general way why intermittently suspended load exists, and why it requires temporal variations in bed shear stress. It is now possible to calculate theoretically the range of sizes of grains with a specific shape and density that will form the bed load and intermittently suspended load, given a distribution of available sediment (Bridge and Bennett, 1992; Bennett and Bridge, 1995). In general, the mean and standard deviation of grain size in the bed load increases as the bed shear stress increases (Figure S11). The size distribution of suspended sediment is more difficult to specify. Although the coarse end of the distribution is controlled by bed shear stress, the overall distribution is controlled by sediment availability.

Collisions between near-bed grains in transport results in *attrition* (*abrasion*) of the grains (see *Attrition, Fluvial*). Experimental studies of abrasion of gravel during river transport indicate that grain size is reduced and grain shape is modified, depending on the hardness of the grains and distance of transport. Abrasion of sand in water is negligible (in contrast to that in air flows).

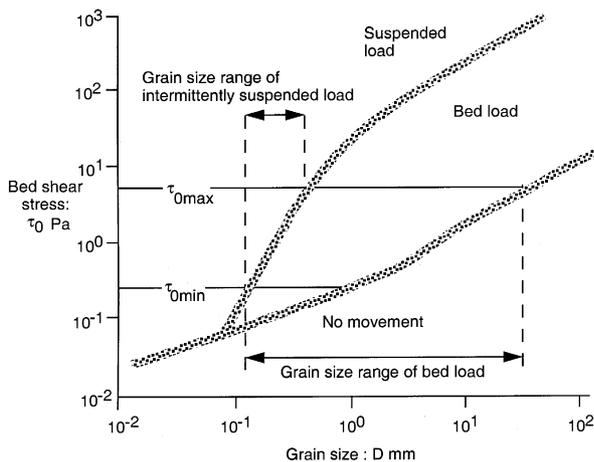

Figure S11 Approximate prediction of grain-size range of bed load and intermittently-suspended load where bed shear stress is allowed to vary between limits τ_{0min} and τ_{0max} . The mean grain size and range of sizes increases as instantaneous bed shear stress increases. The prediction is only approximate because the thresholds of motion and suspension of individual grains in a mixture of different-sized grains are not necessarily exactly as shown. Threshold curves are based on sediment of constant grain size and density, and time-averaged bed shear stress.

Erosion and deposition

Erosion and deposition are due to changes in sediment transport rate in space (mainly) and in time (minor), as expressed in the equation of conservation of sediment mass (sediment continuity equation). A one-dimensional version of this equation is

$$-C_b dh/dt = di_x/dx + di_x/u_{sx} dt \quad (\text{Eq. 30})$$

where C_b is the volume concentration of sediment in the bed ($1 - \text{porosity}$), h is bed height, t is time, i_x is the downstream sediment transport rate by volume, x is downstream distance, and u_{sx} is downstream velocity of the sediment. In uniform flow, $di_x/dx = 0$, but an increase in sediment transport rate in time ($di_x/u_{sx} dt > 0$) would result in erosion. Such erosion would involve entrainment of a layer of bed grains amounting to an average thickness not exceeding a few grain diameters. In other words, erosion and deposition in uniform, unsteady flows is normally negligible. In contrast, rates of erosion and deposition in nonuniform flows can be substantial, depending on the magnitude of di_x/dx . Erosion occurs in spatially accelerating flows where di_x/dx is positive, and deposition occurs in spatially decelerating flows where di_x/dx is negative.

It is very common in nature for relatively long periods of little net erosion or deposition to be punctuated by relatively short periods (e.g., during seasonal floods) when there is marked erosion followed by marked deposition or *vice versa* (i.e., the terms in equation 30 vary over time). This explains why sedimentary strata are normally bounded by planes that record erosion or nondeposition. If di_x/dx is negative and does not vary very much in space, a layer of sediment will be deposited that varies little in thickness laterally. If di_x/dx is negative but changes markedly in space, sediment will be deposited as mounds or ridges (e.g., ripples, dunes, and bars). Similarly, a surface of erosion will tend to be planar if di_x/dx is positive and does not vary very much in space, whereas it will tend to be strongly curved (e.g., trough-shaped or spoon-shaped) if di_x/dx is positive and changes locally. In reality, di_x/dx varies in space on various different scales, such that there are different scales of variation in the geometry of strata and erosion surfaces superimposed.

Deposition rates and erosion rates depend on the time scale and space scale of measurement. Vertical deposition rates averaged over a few years and over bed waves like ripples, dunes and bars, can range from fractions of a millimeter per year to tens of meters per year (Bridge and Leeder, 1979; Sadler, 1981; Enos, 1991). However, as many deposits will be completely or partially eroded before final burial, deposition rates over progressively longer time periods tend to decrease. Deposition rates and erosion rates averaged over millions of years are typically on the order of 0.1 mm per year. The deposits with the best *preservation potential* were deposited in the topographically lowest areas (e.g., deepest parts of channels) and those that subsided rapidly.

Sediment sorting and orientation during deposition

Application of equation 30 to individual grain fractions leads to prediction of *sorting* in deposited sediment. Rational prediction of the sorting of deposits requires knowledge of: (1) the sediment types available for transport; (2) the time and space variations in flow and sediment transport rates of individual grain fractions, and; (3) the flow and sediment

transport over bed forms such as ripples, dunes and bars. Such prediction has been attempted in only very limited cases (e.g., Bennett and Bridge, 1995; Cui *et al.*, 1996), using sediment routing models as discussed below. In general, when erosion occurs, the coarsest and/or densest grains are most likely to remain in the bed. The large, immobile grains that are left on an eroded bed surface are commonly referred to as a *lag deposit*. The term *armor* refers to the situation where there are sufficient large immobile (or only intermittently mobile) grains on an eroding bed to protect the potentially mobile grains underneath from entrainment (see *Armor*). Armored beds commonly occur in gravel-bed rivers during falling flow stages after floods. The development of armor results in an increase in bed roughness and a decrease in sediment transport rate (Gomez, 1993; Hassan and Church, 2000). The increase in bed roughness is partly due to increasing bed sediment size, and partly due to the development of bed structures such as pebble clusters. When deposition occurs, the coarsest and/or densest grain fractions in the bed-load are preferentially deposited, but the texture of the deposited sediment is closely related to that of the bed-load from which it was derived. It is common for the deposits associated with flood conditions (high bed shear stress) to be coarser grained than those associated with falling and low flow stages (low bed shear stress), because mean grain size of sediment in transport and being deposited is directly related to bed shear stress. Thus, layers of sediment deposited during floods tend to have fine-grained tops, unless bed armor occurred.

Mean grain size of sediment in the bed surface and in transport commonly decreases exponentially in the direction of transport. This is mainly due to downstream decrease in the bed shear stress and turbulence intensity of the transporting and depositing flow, such that the coarsest bed load grains are progressively lost in the downstream direction (review in Bridge, 2003). Downstream reduction in size due to progressive abrasion associated with grain collisions is of minor importance, as only the larger and softer gravel grains suffer appreciable abrasion. Intermittently suspended grains may be deposited with bed load grains, either as a relatively fine-grained surficial layer, or by infiltrating the pore spaces between the larger grains in the bed (thus reducing the degree of sorting). Most of the suspended load is not deposited with bed load, but accumulates in places where turbulence intensity is low (e.g., flood basins, lakes, and ponds). Suspended sediment can be sorted by selective deposition according to settling velocity.

Heavy minerals (e.g., iron compounds, gold) in the bed load and suspended load are commonly finer grained than associated light minerals (see *Heavy Minerals*). Heavy minerals may be concentrated in the bed where a flow that is powerful enough to entrain and transport all grain fractions decelerates and deposits some of them. The relatively small heavy minerals become protected from re-entrainment by the larger light minerals, and some may infiltrate into the pore spaces between the larger grains in the bed. Subsequent erosion may remove the large light minerals but not the small heavies. Such conditions are found in association with various types of bed forms.

Grains tend to be oriented during transport on the bed immediately prior to deposition. On plane beds, ellipsoidal or rod-shaped grains tend to be oriented with their long axes approximately parallel to flow, and disc- and tabular-shaped pebbles tend to be oriented with their maximum projection planes dipping upstream (*imbrication*, *q.v.*). However, these

characteristic orientations are modified where bed forms are present.

Grain size, shape, grain orientation and packing (fabric) in sediments influence *porosity and permeability*, with the most important controls being mean grain size, size sorting, and fabric (Brayshaw *et al.*, 1996; see *Fabric, Porosity, Permeability*). The spatial variation of porosity and permeability varies greatly with spatial variation in texture and fabric (i.e., with stratification).

Nature of erosion

The amount of erosion at a point is limited by two main factors. The first is bed armor, such that the progressive accumulation of the heaviest grains on the bed protects the underlying sediment from further erosion. The other factor is the generation during vertical erosion of a progressively larger depression in the sediment bed. Such a depression leads to expansion and deceleration of the flow, thereby leading to cessation of vertical erosion, or at least to relocation of the zone of erosion.

Surfaces of erosion are recognizable by truncation of underlying strata and by a single overlying layer of the coarsest and/or densest grains from the underlying material that could not be entrained (i.e., a *lag deposit*). Features indicative of local erosion include *current crescents*, horseshoe-shaped scours around the upstream margins of immobile obstacles to the flow (e.g., large grains, tree trunks). The eroded material is commonly deposited on the lee side as a ridge of sediment or *sand shadow*. Other erosional features include elongate, flow-parallel channels called *gutter casts*, and large-scale features such as channels.

Erosion of cohesive mud depends on the degree and nature of consolidation of the mud. Soft mud that is entrained as mud-sized particles travels in suspension. However, various bed features may be eroded into the mud by the flow according to the bed shear stress (Allen, 1982; see *Scour, Scour Marks*): *straight or meandering longitudinal grooves and ridges*; *flute marks*; *transverse ridge marks*. Soft mud is also eroded and molded by various hard objects (tools) carried by the flow. *Tool marks* are commonly long grooves of varying width and depth due to objects (e.g., shells, bits of wood, shale chips) sliding and rolling along the bed and eroding into the mud. There are also marks due to intermittent contacts of objects with the bed (e.g., bounce, skip and prod marks). These and the current-formed marks are normally preserved as coarser sediment covers the mud more-or-less immediately following mark formation (e.g., *sole marks* on the base of sandstone strata). Consolidated (compacted) mud is commonly eroded as pellets or flat chips of sand or gravel that then travel as bed load. Such relatively large grains may occur as lag deposits. Erosion marks in consolidated mud include steep-walled gutters and potholes.

Sediment routing models

The only rational way of analyzing and predicting bed-elevation changes and sediment sorting during erosion, transport, and deposition is with *sediment routing models* (reviewed by Bridge, 2003). Sediment routing models are used to deal with problems such as bed erosion and armor downstream of dams, and reservoir sedimentation. Sediment routing models normally require treatment of unsteady,

gradually varied flow acting upon movable, heterogeneous sediment beds. A realistic sediment routing model requires specification of: (1) sediment types available for transport; (2) the mean and turbulent fluctuating values of fluid force acting upon sediment grains, and how these vary in time and space; (3) the interaction between fluid forces and individual sediment fractions, resulting in their entrainment and transport as bed-load or suspended load; (4) erosion and deposition as determined by a sediment continuity equation applied to different grain fractions; (5) the concept of an active bed layer to which sediment can be added or be removed; and (6) an accounting scheme to record the nature of deposited sediment or armored, eroded surfaces. Many sediment routing models do not have all of these desirable features, and contain many arbitrary correction factors. Examples of the use of sediment routing models to predict the nature of sediment transport, erosion and deposition, the development or armor layers, and the sorting of sediment by size and density are given by Vogel *et al.* (1992), Bennett and Bridge (1995), and see *Numerical Models and Simulation*.

Sediment transport and bed forms

One of the most striking and important characteristics of sediment transport over a bed of cohesionless sediment is the development of bed forms such as ripples, dunes and bars. These are important to sedimentary geologists because they are associated with certain kinds of sedimentary structures, and to engineers because they influence flow resistance and sediment transport rate. The origin, geometry, flow and sedimentary processes of bed forms are reviewed by Allen (1982), Bridge (2003) and see *Surface Forms*.

SEDIMENT TRANSPORT BY WAVES

Water waves

Water waves are periodic undulations of the air–water interface (Figure S12) defined by their *height* (H), *wavelength* (L), *period of oscillation* (T) and *speed of propagation* (C). The water moves in quasi-circular or elliptical *orbits*; the *orbital diameter* (d_o) equals the wave height at the air–water interface and decays with increasing water depth. At depths $>L/2$ the oscillation is essentially dissipated; at depths $<L/2$, the

oscillation interacts with the bed to form an *oscillatory boundary layer*. Waves are found wherever wind blows over a significant body of water (e.g., the deep ocean, the continental shelf, the shoreface, estuaries, lakes, etc.). They can be *progressive* (e.g., *wind waves*) or *standing* (e.g., a lake *seiche*) and either actively *forced* (*sea*) or *free* (propagate freely; e.g., *swell*). Swift (1976) defined *hydraulic provinces* stretching from the deep ocean to the coastline. In the innermost zone (*shoreface*), both the hydrodynamics and sediment transport are controlled by waves, while further offshore (*continental shelf*) waves play a major role in the *entrainment* of sediment (Cacchione and Drake, 1990), although the transport may be dominated by other flows. Modern wave theory dates back to the classic work of Stokes (1847) and a recent theoretical treatment of the hydrodynamics of water waves is given by Le Mehauté (1976; especially Part 3). Smith (1977), Sleath (1984), Grant and Madsen (1979; 1982), Nielsen (1992), Fredsøe and Deigaard (1992) and Van Rijn (1993) review the theory of sediment transport under waves.

Water waves are classified by their period (frequency) of oscillation and the force generating them as well as the force restoring equilibrium of the water surface (Kinsman, 1975). The most important waves outside the zone of wave breaking (*surf zone*) are *gravity waves* (forced by wind and restored by gravity), with periods ranging from 1–25 s. Their magnitude depends upon the wind speed, duration of time the wind blows and the *fetch* length (length of open water over which the wind blows). A modulation of wave height is common and *gravity waves* propagate as *groups* of large waves separated by several smaller waves (Figure S13). This modulation forces a secondary wave, the *group-bound long wave*, which propagates at the *group* speed and has a period equal to the *group* period. Waves with periods of ~ 25 s to several minutes or longer (frequencies of 0.004–0.04 Hz) are *infragravity waves* (called *surf beat* by Munk, 1949). They are generally small (<1 cm high) in the deep ocean, but increase in size shoreward and are important to water circulation and sediment transport within the *surf zone* (Bowen and Huntley, 1984). In intermediate water depths, infragravity energy results from wave–wave interactions and consists of a mixture of *forced* and *free* wave motions (Herbers *et al.*, 1995). Several mechanisms associated with wave breaking in the *surf zone* have been proposed for their generation including: (i) release of the *group bound long*

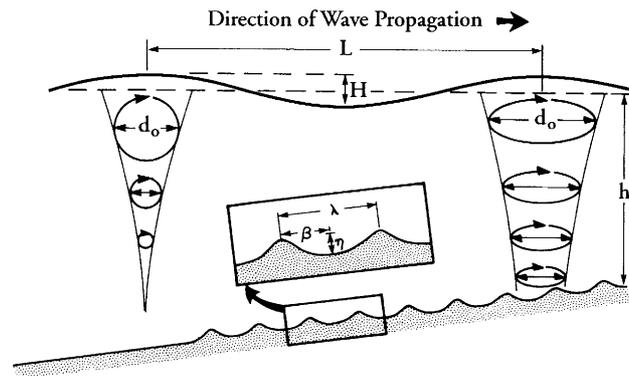

Figure S12 The surface form of deep water and shoaling surface gravity waves, the orbital motion beneath the surface, the interaction of the wave with a rippled bed and the characteristic wave and ripple properties (modified after Clifton, 1984). L = wave length; H = wave height; d_o = orbital diameter; h = water depth; λ = ripple wavelength; η = ripple height; β = ripple crest-to-trough distance.

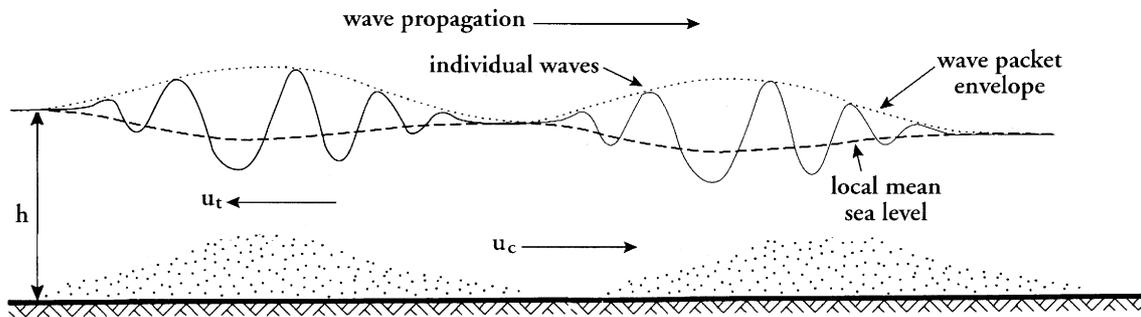

Figure S13 The surface profiles of high frequency surface gravity waves (solid line), the wave envelope (dotted line) and the forced group bound long wave (dashed line). The horizontal near-bed velocities under the long wave crest and trough (u_c and u_t) and the relative sediment concentrations (stippled) are also shown, as is the water depth (h). Note the coupling of large sediment concentrations induced by the large gravity waves with the upwave (offshore) velocity under the trough of the long wave; there is often a small phase lag in this relationship.

wave (List, 1992); (ii) periodic shift in the position of wave breaking (Symonds *et al.*, 1982); (iii) persistence of *groupiness* into the *surf zone* causing a rise and fall of water at the shoreline (Watson and Peregrine, 1992). Nearshore *infragravity energy* can take several forms including standing and progressive *edge waves* (trapped to the shoreline by refraction) and long *leaky waves* (reflected seaward without trapping; Huntley, 1976). An important characteristic of *infragravity waves* in the *surf zone* is that they increase in height as the offshore wave height increases. In contrast, *gravity waves* are *saturated* in shallow water and thus decrease in importance proportionally during storms. *Shear waves* are a subset of the *infragravity field* (periods range from several tens of seconds to several tens of minutes) and they form within the *surf zone* through *instabilities* in the *longshore current*. They appear as large fluctuations in the current (Bowen and Holman, 1989; Oltman-Shay *et al.*, 1989) and can contribute significantly to both the cross-shore and alongshore transport of sediment (e.g., Aagaard and Greenwood, 1995).

Wave propagation

Propagating *gravity waves* transfer energy and momentum, and as they move into shallow water they *shoal*. With increased frictional drag, the orbital motions are deformed, wave speed and length decreases and height increases. The *specific energy density* (according to linear theory, $E = 1/8\rho_f g H^2$) increases until the wave breaks. Energy may also be re-distributed laterally (parallel to the wave crests) through the processes of *refraction* and *diffraction*. Further, the simple *near-sinusoidal* shape, characteristic of deep water, becomes increasing non-symmetrical about the horizontal and vertical axes (*wave skewness* and *asymmetry*). These non-linearities (Figure S14) are critical to the *net* transport by waves as they introduce asymmetries in the oscillatory velocities. In very shallow water, waves become unstable and break when $H/h \approx 0.4-1.0$. The wave form may be destroyed in a *plunging breaker*, producing a large *roller vortex*, or the wave may propagate further as a *spilling breaker* or *surf bore* with reduced height. The *surf zone* is a complex hydrodynamic environment, where interactions with *secondary waves* and *quasi-steady currents* of various origins occur. Ultimately *wave energy* is dissipated in the reversing currents of the *swash* on the *beach face*; the *uprush* and *backwash* induce high frequency, reversing sediment transport similar to that of waves. Transport is complicated

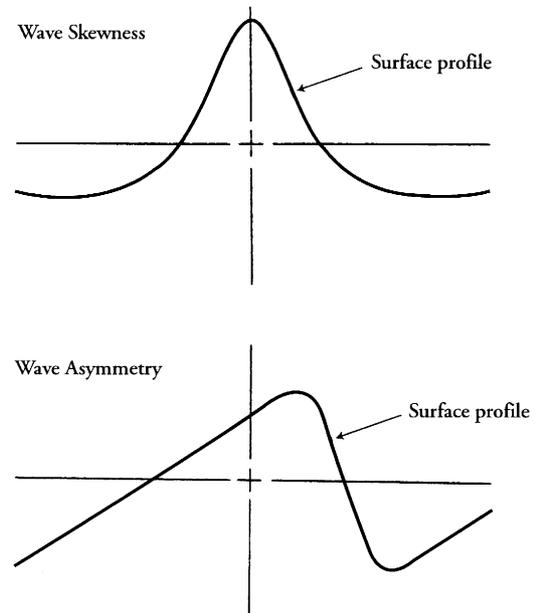

Figure S14 Surface gravity wave profiles for nonsymmetric waves. The *skewed* surface profile denotes a lack of symmetry with respect to the horizontal axis; oscillatory velocities will increase under the crest relative to those under the trough, although they will last for a shorter period of time. The *asymmetrical* surface profile denotes a lack of symmetry with respect to the vertical axis, resulting in marked differences in accelerations between the leading and trailing faces of the wave.

by extremely small water depths, large Froude Numbers, large pressure gradients near *bore fronts* and the infiltration or exfiltration of water from the *beach face water table* (for a review see Butt and Russell, 2000). With propagation over a sedimentary bed, a distinct *wave boundary layer* develops and decays each half-wave cycle, passing from laminar ($Re < 10^5$) to turbulent ($Re > 10^6$) and back to laminar flow (Jensen *et al.*, 1989). This layer may be small (~ 10 cm) but the velocity gradients and thus the instantaneous stresses may be large. Theoretically, gravity waves propagating over a permeable bed induce an oscillating flow even within the bed, as a result of the spatial variation in pressures over a single wavelength. Flows normal to the bed surface are also predicted; flow is out of the

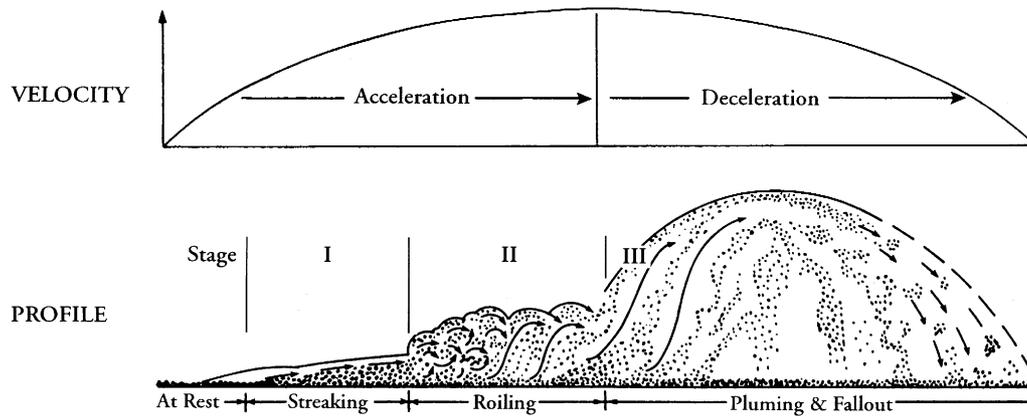

Figure S15 Sequence of development of the fluid-granular boundary layer under stresses associated with flow acceleration and deceleration under waves (modified after Conley and Inman, 1992). Note that the *streaking-roiling* transition marks the change from laminar to turbulent flow and that the boundary layer expands upward dramatically during the deceleration phase.

bed and into the fluid (*injection*) under the wave trough, and out of the fluid and into the bed (*suction*) under the crest, resulting in a “ventilation” of the boundary layer. For detailed reviews of wave and combined-flow boundary layers see Grant and Madsen (1986) and Sleath (1990).

Bed stress and modes of transport

The total bed stress under waves can be divided into two components: (i) *form drag*; (ii) *skin friction*. The latter is the stress primarily responsible for transport (the *effective stress*) and is defined using the quadratic stress law as:

$$\tau_w^{sf} = \frac{1}{2} \rho_f f u_w^2 \quad (\text{Eq. 1})$$

where τ_w^{sf} = skin friction (*sf*) stress under waves (*w*), ρ_f = fluid density, f = a wave friction factor, and u_w = maximum horizontal oscillatory velocity at the bed. The skin friction *Shields parameter* (or number) under waves is defined as:

$$\theta_w = \frac{\tau_w^{sf}}{(\rho_s - \rho_f) g D} \quad (\text{Eq. 2})$$

where ρ_s = particle density and D = particle diameter. Theoretically, the *effective stresses* imposed on the bed are periodic and decay to zero at the flow reversal. Once the *threshold* for the *initiation of motion* (see *Grain Threshold*) is exceeded, particles will roll back-and-forth in place. As flow accelerates, a *fluid-granular* boundary layer may develop, with three distinct phases (Figure S15): (i) *streaking*: as flow starts, grains roll and may separate by density into *streaks* or *lambda-shaped* patterns under laminar conditions; (ii) *roiling*: continuing acceleration causes *sheetflow*, with sediment ejected upward into the fluid sporadically. In this phase also, stream-wise periodicities in the sediment may form *transition ripples*; (iii) *pluming*: as flow decelerates, the *sheetflow* layer may lift off the bed, forcing sediment up through the boundary layer and into the free stream, where it ultimately diffuses and settles. The change from *streaking* to *roiling* marks the transition from laminar to turbulent flow and also the transition from *bed-load* to combined *bed* and *suspended* load.

Sediment transport modes are directly related to *bed roughness* (Figure S12) and distinct regimes of flow occur similar to

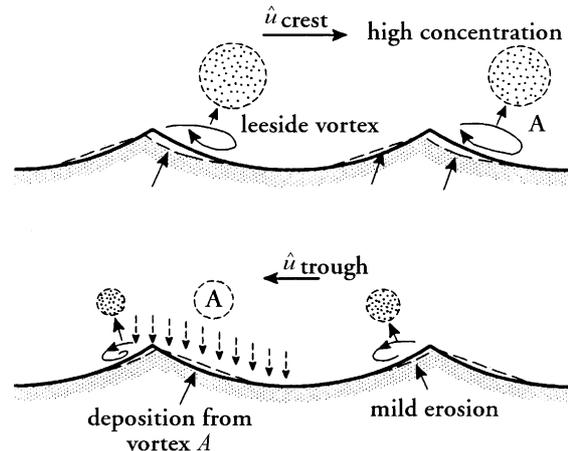

Figure S16 Lee vortex generation and ejection over a steep rippled bed during passage of a successive wave crest and trough (\hat{u} = maximum oscillatory velocity; A = ejected vortex). Note that the larger vortex produced during the passage of the *gravity* wave crest may be advected in a direction opposite to that of the wave advance. The opposite would be true for the smaller vortex formed under the wave trough, resulting in a net transport in a direction opposite to that of the wave propagation direction (modified after Van Rijn, 1993).

that of quasi-steady flow (Clifton *et al.*, 1976; Davidson-Arnott and Greenwood, 1976; see *Bars, Littoral; Surface Forms*). Two distinct regimes occur under near-symmetric waves: (i) a *ripple regime* (*Shields numbers* < 0.8); and (ii) a *sheetflow regime* (Ribberink and Al-Salem, 1995), where bedforms are erased (*Shields numbers* > 0.8–1.0). Theoretically, *sheetflow* is supported by inter-granular forces and sediment-flow interaction. Mass concentrations exceed $\sim 200 \text{ kg m}^{-3}$ and the *sheetflow* layer increases in thickness with decreasing grain size. In contrast, *suspended load* is supported by Reynolds stresses, and several mechanisms are responsible for the entrainment and vertical mixing of sediment: (i) *flow separation* and *vortex generation* in the lee of bedform crests, and the release of these vortices from the bed as flows reverse (Figure S16). The vortex

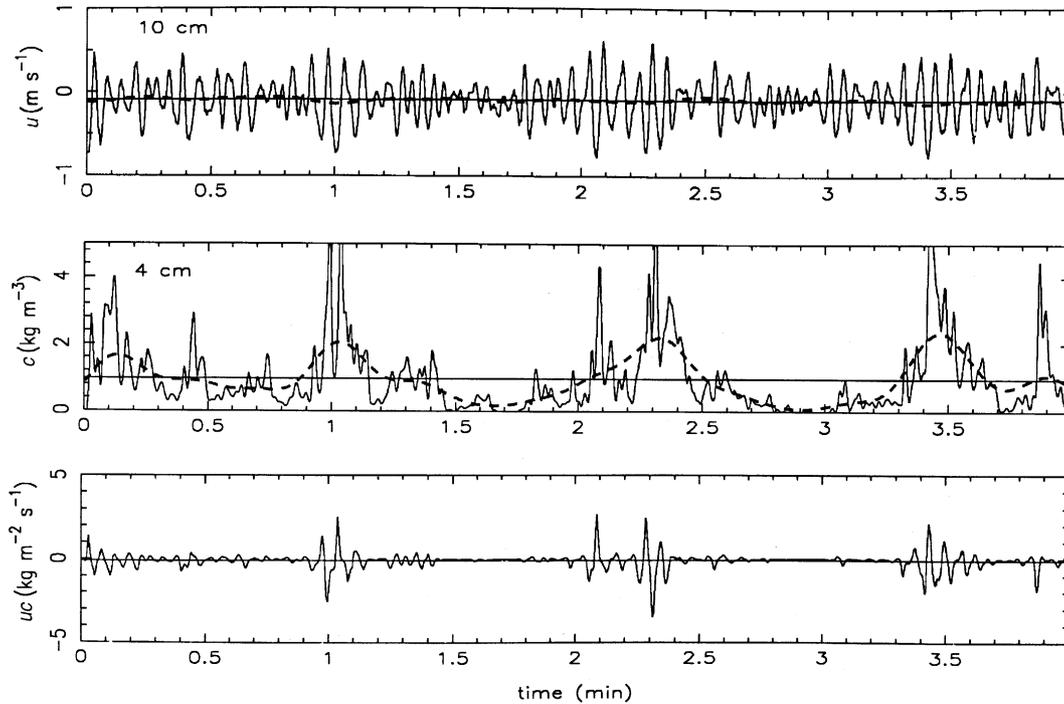

Figure S17 Time series of near-bed horizontal velocity (u ; $z=0.01$ m), suspended sediment concentration (c ; $z=0.04$ m) and net sediment transport (uc) measured in the field under shoaling “groupy” waves over a bed with a mean grain diameter of $130\ \mu\text{m}$. The dashed line in the upper panel is the filtered long wave motion; a similar filter is applied to the concentrations in the center panel. Note the “episodic” nature of sediment suspension, the response to individual waves and wave groups, the good correlation between suspension “episodes” and the long wave motion, and the small overall down-wave (onshore) net sediment transport.

carries sediment away from the bed and then, rapidly unwinds, diffusing sediment outward, resulting in sediment settling, creating a strongly *episodic* pattern of suspension transport (Figure S17). A distinct *phase lag* between the horizontal currents and sediment concentration at any elevation is created. These *phaselags* determine both the rate and direction of the net suspension transport, and may result in a net transport directed opposite to that of the oscillatory current initiating the sediment motion. Bedform asymmetry will cause significant differences in the size and intensities of the vortices associated with the two directions of motion; this inequality may also lead to complex net transport patterns; (ii) turbulence generated through interaction between the fluid and the bed, and between the vortices and the surrounding fluid induces a vertical diffusion of sediment; (iii) *ventilation* of the wave boundary layer may also contribute to the suspended load.

The relative importance of *bed-load* and *suspended load* is an open question (*cf.* Komar, 1978; Sternberg *et al.*, 1989) and almost certainly depends on the level of applied stress. In deep water, sediment will move as *bed-load* just above the threshold and *bedforms* will develop; their migration may play a major role in the *net sediment transport* (e.g., Traykovski *et al.*, 1999) even though suspension is enhanced by bedforms. As depth decreases and waves become asymmetric and break, suspension load usually dominates, at least for the *net transport* (e.g., Aagaard *et al.*, 2002). Time-averaged sediment concentrations do increase continuously from the top of the suspended load

layer to the immobile particles at the *bed*, and follow a logarithmic law similar to that in quasi-steady flows (Osborne and Greenwood, 1993). However, as the *granular layer* accelerates and decelerates during each half-wave cycle, sediment may move from *bed-load* into *suspended load* and back again. In practice, the two modes cannot be separated even with fast response optical and acoustic sensors (White, 1998).

Transport rates

Net sediment transport rates are a product of the sediment mass in motion and the velocity with which the mass moves, integrated over space and time:

$$\vec{i} = (\rho_s - \rho_f) g \int_0^T \int_0^{z_o} N_z \vec{U}_z dz \quad (\text{Eq. 3})$$

where i = immersed weight transport rate across a unit width, ρ_s = mass density of the solid, ρ_f = mass density of the water, g = acceleration due to gravity, N = sediment volume concentration, U = horizontal sediment velocity, z = elevation, z_o = elevation at the top of the mobile sediment, and T = some measure of time (usually the wave period). Theory indicates that the *local net sediment transport* is a function of the balance between *perturbations* of the symmetric oscillatory velocity field and gravity acting on a slope (e.g., Bagnold, 1963;

Bowen, 1980; Bailard, 1981). It is rare that oscillatory motion is perfectly symmetrical in nature, and rare to find a perfectly horizontal, flat bed where gravity has no effect. Thus, there is always a secondary stress superimposed on the symmetrical oscillatory stress. This may be induced by *streaming* in the wave boundary layer (mass transport), by *skewness* and/or *asymmetry* of the waveform (Figure S13), or by some other process in shallow water (e.g., *undertows*, *longshore currents*, *drift velocities* associated with *infragravity waves*, etc.). Differences exist between the onshore and offshore velocities as shoaling occurs; generally, larger velocities under the crest will entrain larger volumes of sediment and larger sizes than the smaller velocities under the trough. Since transport rates have been related to the velocity raised to some exponent (values from 3 to 7 have been suggested; Dyer and Soulsby, 1988; Sleath, 1995), small variations in the on-offshore velocities can be very important to sediment transport.

A simple concept of waves “*stirring*” and currents “*transporting*” sediment, has often been used to *model* transport under waves (Bagnold, 1963). The shoreface is viewed as a balance between the cross-shore component of *mass transport* associated with the incident waves, which is landward and a seaward directed mean current (e.g., *undertow*; Roelvink and Stive, 1988). The oscillation itself may be responsible for a significant part of the transport, at least for the suspended load owing to the nature of the *flux coupling* between velocity and sediment concentration (Jaffe *et al.*, 1985), especially over bedforms. Outside the surf zone, oscillatory transport associated with the incident wave band is directed onshore, while an offshore transport is associated with the group-forced bound long wave. Sediment transport at low frequencies results from the increased sediment concentrations due to the passage of groups of large waves and transport directed offshore by the currents associated with the trough of the long wave (see Figure S13). Outside the surf zone, the *net sediment transport rate* is generally positive (i.e., sediment moves in the direction of wave propagation), except on very steep beaches sloping upward in the direction of wave propagation, where gravity may reverse the transport (Fredsoe and Deigaard, 1992). On plane, horizontal beds the important mechanisms contributing to this positive flux are: *wave skewness* and *asymmetry*, *wave drift* and *streaming* in the wave boundary layer. In contrast, transport by second order waves, such as the *group bound long wave*, is directed up-wave or offshore. Greater sediment concentrations in the water column are associated with the larger waves in a group which coincide with the trough (upwave or offshore flow) of the long wave. Shi and Larsen (1984) demonstrated this theoretically, but it has also been well documented in the field (e.g., Osborne and Greenwood, 1992). *Infragravity waves* influence transport in the surf zone, especially in the case of deposition in periodic bar forms (e.g., Bauer and Greenwood, 1990); it is assumed that the transport is induced either by the second order drift velocities associated with standing infragravity waves or by the primary orbital motions.

However, in all instances the direction and rate of transport is strongly influenced by the *phase coupling* between the horizontal velocities in the wave-current boundary layer and the concentrations of sediment produced by the ejection of separation vortices from bottom roughness. At times the phase lag may cause the suspended load to be transported up wave or offshore (see Figure S17).

Cross-shore and longshore sediment transport

The *wave orbital motion* and *cross-shore mean currents* within and immediately above the *wave boundary layer* dominate the cross-shore transport. Complex nonlinear interactions occur between the *oscillatory currents*, the *mean currents* and the small-scale *bed roughness* (e.g., vortex ripples; see *Surface Forms; Bars, Littoral*). Assuming a no-slip condition between the fluid and sediment grains, the time-averaged local net sediment transport rate $\langle q_s \rangle_n$ is given by:

$$\langle q_s \rangle_n = \frac{1}{T} \int_0^T \int_0^h u_{(z,t)}' c_{(z,t)}' dz dt \quad (\text{Eq. 4})$$

where T = wave period, t = time, z = elevation, h = water depth, u' = instantaneous velocity and c' = instantaneous mass concentration. In terms of the steady, periodic and random components, this may be written as:

$$\langle q_s \rangle_n = \int_0^h \langle u_{(z,t)}' \rangle \langle c_{(z,t)}' \rangle + \langle \tilde{u}_{(z,t)} \tilde{c}_{(z,t)} \rangle + \langle u'_{(z,t)} c'_{(z,t)} \rangle dz$$

where $\langle \rangle$ = time average, $\langle u'_{(z,t)} \rangle \langle c'_{(z,t)} \rangle$ = transport by time-averaged, quasi-steady, mean currents, and \tilde{u} and \tilde{c} are the periodic and random components respectively. The latter is generally considered to be small where the periodic component is large. According to Jaffe *et al.* (1985) the term $u'_{(z,t)} c'_{(z,t)}$ is a measure of the correlation between fluctuations in velocity and sediment concentration (typically nonzero) and represents the time-varying sediment flux due to waves. A convenient way of computing this quantity is through cross-spectral analysis (Huntley and Hanes, 1987), as the cospectrum (the real part of the cross-spectrum) yields the cross product of velocity and concentration as a function of frequency. The local net oscillatory suspended sediment transport rate may thus be computed from:

$$\langle q_s \rangle_{osc} = \frac{\Delta f}{F} \int_0^\infty C_{uc}(f) \quad (\text{Eq. 6})$$

where $C_{uc}(f)$ = the cospectral variance at a given frequency (f), Δf = the cospectral resolution and F = the cospectral frequency range. The cospectrum reveals the relative contribution of different frequency bands to both the direction and rate of suspended sediment transport and can be used to identify transport due to wind waves, infragravity waves (such as the group-bound long wave, edge waves, etc.) and far infragravity waves such as shear waves.

Osborne and Greenwood (1992) found good agreement between the quantities $\langle q_s \rangle_n$ and $(\langle q_s \rangle_m + \langle q_s \rangle_{osc})$. While this procedure incorporates some of the nonlinear effects in a shoaling, irregular wave field, others are omitted. For example, part of the transport associated with *wave skewness* is included in the cospectral estimates through the coupling between larger onshore (or offshore) current velocities and larger sediment concentrations. However, other non-linear effects such as *wave asymmetry* or the higher order moments of the velocity field (e.g., Guza and Thornton, 1985) are not accounted for.

Time-averaged oscillatory currents

Stokes second order theory suggests a *Lagrangian* water motion (*wave drift*) occurs under shoaling waves, being largest at the surface and decreasing exponentially with depth. Longuet-Higgins (1953) defined a *Eulerian mass transport* velocity, with a vertical structure which varied with the wave number ($\kappa=2\pi/L$). This mass transport was directed down-wave near the bed and at the surface, and directed up-wave at intermediate depths. At the bed it was:

$$\bar{u}_b = \frac{5}{4} \left(\frac{\pi H}{L} \right)^2 C \frac{1}{(\sinh(\kappa h))^2} \quad (\text{Eq. 7})$$

where u_b = velocity at the bed, overbar = time-averaged mean, H = wave height, C = wave celerity, h = water depth and κ = wave number ($2\pi/L$). It has been suggested that it is this current that maintains the onshore sediment flux to create the upwardly sloping shoreface profile in balance with gravity.

As waves break, *secondary waves* and *quasi-steady currents* are common. Transport becomes complex and the net transport vector will depend upon the interaction of several mechanisms, resulting in both *shore-parallel* as well as *cross-shore* motion. Generally, onshore transport still results from the *skewed* and *asymmetric* breaking waves and *bores*, although turbulence induced by the breaking wave at the surface becomes important. Offshore transport may be induced by: (i) *undertow*; (ii) *rip* currents; (iii) oscillatory and drift velocities associated with secondary waves, such as *edge waves* or *leaky waves* or *shear waves*. Within the *surf zone*, pressure gradient driven, time-averaged mean flows directed seaward (*undertows*) are caused by water level *setup* at the shoreline. *Wave setup* results from the onshore flux of momentum due to waves (*radiation stress*) and is combined with a *mass flux* of water directed onshore by the waves plus any applied *wind stress*.

When waves break at an oblique angle to the shoreline, the alongshore component of the *radiation stress* creates a shore-parallel current or *longshore current*. Pressure gradients due to setup differentials along shore, as well as the shore-parallel component of the *wind stress* can enhance this forcing. The volume of sediment transported alongshore by these quasi-steady *longshore currents* is termed *littoral drift* and essentially confined to the *surf zone*. Transport reaches its maximum at a cross-shore position between that of the maximum current velocity and the breaker line and decreases rapidly offshore; there is a subsidiary peak of transport in the *swash zone*. *Rip currents* are discrete, narrow, high velocity *jets* of offshore-directed flow across the *surf zone*. They are often associated with bathymetric forms such as cross-shore oriented depressions (*rip channels*) or breaks in a quasi-shore parallel bar, but are found also on uniformly sloping beaches. Rip currents are not generally *steady state* phenomena, but are capable of transporting large volumes of both coarse bed-load, especially in migrating megaripples (e.g., Gruszczynski *et al.*, 1993), and suspended load.

Size fractionation

An important characteristic of waves shoaling across the shoreface are bed-sediments of similar density which increase in size from deep to shallow water, in association with increasing local slope (e.g., Guillen and Hoekstra, 1996). On

the upper shoreface grain-size distributions are more variable, reflecting local variations in bathymetry and the rapid changes in hydrodynamics associated with wave breaking and complex nearshore circulation, especially in the presence of *bars* (see *Bar, Littoral*). Suggested mechanisms for size-sorting include: (i) onshore coarse bed-load transport by mass transport within the wave boundary layer, and an offshore movement of fines by the return flow at mid-water depths; (ii) a near-bed velocity asymmetry (amplitude and duration) induced by wave shoaling, enabling all sediment sizes to move landward under the wave crests, but only finer sediments move offshore under the trough; (iii) setup-induced undertow and/or rip currents, which continue offshore from the breaker zone; and (iv) a net transport induced by group-forced long waves. Greenwood and Xu (2001) review size-fractionation processes and show that under shoaling waves over a near-horizontal, rippled bed, a distinct horizontal fractionation of sediment by size occurs by suspension transport alone.

Transport models

Models of sediment transport under waves depend upon the spatial and temporal scales of integration used in equation 3: (i) at the individual wave cycle-storm cycle scale (10^{-2} – 10^0 years); these models incorporate the fundamental physical processes as far as possible; (ii) at the decadal time scale (10^1 to 10^2 years); these may be time-integrated, physical-based models, but more usually are highly parameterized models or morphological models (see List and Terwindt, 1995 for examples); and (iii) at the geologic time scale ($>10^3$ years); these models are based either on simple geometric rules (e.g., the “*Brunn Rule*”) and sediment conservation (e.g., Cowell *et al.*, 1999) or diffusion rules (Kauffman *et al.*, 1992); a more detailed process-response approach has been attempted recently by Storms *et al.* (2002). Physically based models are developed on the basis of the physics of individual wave cycles and then integrated to the scale of storms. However, it is clear that integrating small-scale processes to larger spatial and temporal scales is problematic, as it involves interactions between the wave climate, sea level, availability of sediment and the shoreface morphology (slope). In this complex geomorphic system, non-linear processes are often driven by stochastic boundary conditions.

Two approaches to wave-scale modeling have been adopted: (i) the energetics approach of Bagnold (1963; 1966; Bailard, 1981); (ii) the applied stress approach (Grant and Madsen, 1982). Soulsby (1997) gives an extensive review of a large range of models for suspended and bed-load transport in both waves and combined flows and Schoones and Theron (1995) evaluated ten different time-dependent sediment transport models and concluded that the *energetics* approach was generally the best. However, this model does not consider the *threshold of motion*, assumes an instantaneous response of the bed and does not consider the increased turbulence associated with wave breaking. One major difficulty encountered in the modeling of suspended sediment transport is the existence of phase lags between the near-bed horizontal velocity and sediment concentration noted earlier.

Longshore transport under quasi-steady, wave-forced currents in the *surf zone* has been relatively well understood and modeled for the last three decades (for a review see Komar, 1998). The basic energy flux approach of R.A. Bagnold is

again prominent; the flux rate is:

$$I_L = (\rho_s - \rho_f) g d' S_L = K P_L \quad (\text{Eq. 8})$$

where K = a proportionality constant, I_L = immersed weight transport rate; ρ_s, ρ_f = mass densities of solid and fluid respectively; g = gravitational constant; d' = porosity; S_L = longshore transport volume, and:

$$P_L = E C n \cos \alpha \sin \alpha \quad (\text{Eq. 9})$$

where n = ratio of group speed to wave speed, E = specific energy density; C = wave speed; n = ratio of wave speed to group speed; and α = the angle of wave breaking at the shoreline. For a recent detailed evaluation of some well-known models, see Bayram *et al.* (2001).

SEDIMENTARY GEOLOGY

The discipline devoted to the scientific study of sediments and sedimentary rocks has been described by a number of names.

Petrology is the science that studies rocks, particularly their mineralogy, textures, and origins. From the beginnings of the discipline, some petrologists devoted themselves to sedimentary rocks, and texts on petrology included sections or volumes devoted to Sedimentary Petrology: early examples include Hatch and Rastall's *Petrology of the Sedimentary Rocks* (1913) and Milner's *Introduction to Sedimentary Petrography* (1922)—the latter being largely devoted to the study of heavy minerals and size analysis. When the Society for Economic Paleontologists and Mineralogists was founded in 1927, it derived its name from two groups of specialized researchers, then largely working in petroleum exploration: those who studied microfossils (the “economic paleontologists”) and those who studied heavy minerals (“the economic mineralogists”); it was thought at that time that heavy minerals would be useful to correlate oil sands that contained no microfossils. In 1931, SEPM began publication of the first journal devoted exclusively to sediments and sedimentary rocks, under the name *Journal of Sedimentary Petrology*.

Before 1920 most authors did not differentiate the study of sedimentary rocks from *Stratigraphy*, which is the study of stratified rocks, concerned “not only with the original succession and age relations of rock strata, but also with their form, distribution, lithologic composition, fossil content, geophysical and geochemical properties—indeed, with all characters and attributes of rocks as *strata*; and their interpretation in terms of environment or mode of origin, and geologic history.” (AGI *Glossary of Geology*, 2nd edn, 1980). In the 1920s, however, most research in stratigraphy consisted in classifying, dating, and correlating rock units, and it became apparent that more attention should be devoted to understanding how sedimentary rocks had been deposited. Accordingly, the National Research Council of the United States established a Committee on Sedimentation, which began gathering material for a *Treatise on Sedimentation*, eventually published in 1926 (2nd edn, 1932). The term *Sedimentology* was originally proposed by A.C. Trowbridge in 1925, and published by Waddell in 1933: it was essentially synonymous with “*sedimentation*” (as used by Twenhofel) and may be defined as the study of natural sediments, both lithified and unlithified, and of the processes by which they were formed.

Sedimentation and Sedimentology are distinguished from Stratigraphy by the fact they they confine attention to sediments, and do not concern themselves directly with dating or correlating sedimentary strata, or with fossils, except in so far as they contribute to the formation of sediment (e.g., as grains, or as organisms binding or burrowing into sediment; see *Bioerosion*, *Biogenic Structures*, *Taphonomy*). The term *Sedimentology* was not widely used until the International Association of Sedimentologists was founded in Europe and its first Congress held in Belgium in 1946.

In the 1980s there was a renaissance of Stratigraphy, largely under the impetus of first *Seismic Stratigraphy*, and then *Sequence Stratigraphy*. When the Geological Society of America decided to set up a section devoted to sedimentary rocks, therefore, they wished to emphasize that it would be devoted not only to sedimentary petrology, or to sedimentology (in its restricted definition) but also to the “new” stratigraphy and the broader aspects of sedimentary basin analysis: the name approved in 1985 was the Division of Sedimentary Geology. In the next year SEPM formally changed its name, retaining only the initials, and adding “The Society for Sedimentary

Geology.” In 1994, the *Journal of Sedimentary Petrology* became the *Journal of Sedimentary Research*.

Thus, *Sedimentary Geology* includes geological sedimentology, stratigraphy, and geological (rather than geophysical) aspects of basin analysis. Sedimentary Petrography and Petrology include descriptive and theoretical aspects of natural sediments and sedimentary rocks. Sedimentology is somewhat broader, in that it includes studies of all kinds of sediments, and of the fundamental chemical, biological and physical processes that lead to their formation, but not all practitioners would distinguish it from Sedimentary Petrology. A few authors have interpreted sedimentology in terms as broad as sedimentary geology, but most exclude those aspects of stratigraphy that deal with the dating, correlation, and classification of large bodies of stratified rocks.

SEDIMENTARY STRUCTURES AS WAY-UP INDICATORS

Criteria for determining the original stratigraphic facing direction or way-up in vertical or overturned strata are important both for determining correct stratigraphic succession and for correctly interpreting complex tectonic structures. Any original feature of sedimentary or igneous rocks that reflects the way-up during their formation qualifies. Examples include features known to indicate unambiguously either the bottom or top of sedimentary beds or of lava flows. Cross bedding, symmetric ripples, and graded bedding were among the first sedimentary features to be invoked for way-up determination with the many kinds of sole marks coming into play much later.

The value of cross-bedding was recognized in southwestern Ireland in the mid-nineteenth century. In 1856 Patrick Ganly published clear diagrams showing that the truncated tops and asymptotic bases of cross laminae in folded Silurian sandstones on the Dingle Peninsula provide an unambiguous criterion of the original up direction. He also emphasized that individual cross laminae tend to thin toward their bases. He even showed sketches of ripple cross lamination in modern fluvial sands for analogy. Ganly's shrewd insight was generally ignored and soon forgotten, so had to be re-discovered.

While mapping Precambrian strata in the Florence iron district of Wisconsin in 1910, William O. Hotchkiss wrote in a letter to C.R. Van Hise (June 26, 1910) that “an inspiration came to me that the cross-bedding gives the basal direction for a formation as well as any other criterion.” Way-up criteria prior to that time included only such things as ripple marks, drag folds, and cleavage-bedding relationships. Hotchkiss' independent discovery (Figure S18) might well have suffered the same fate as Ganly's, for he himself never published it. Instead, it was reported in publications by other Wisconsin workers (Cox and Dake, 1916; Shrock, 1948; Dott, 2001).

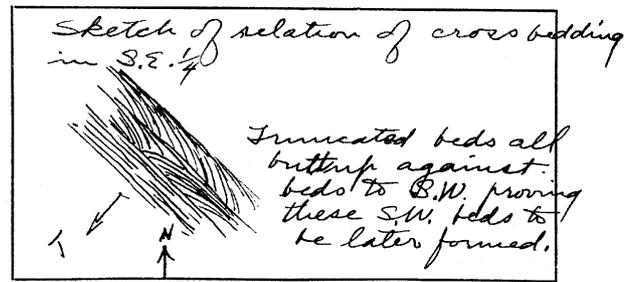

Figure S18 Field notebook sketch of cross bedding in overturned quartzite by W.O. Hotchkiss (1910, Hotchkiss Notebook No. 1, Wisconsin Geological and Natural History Survey).

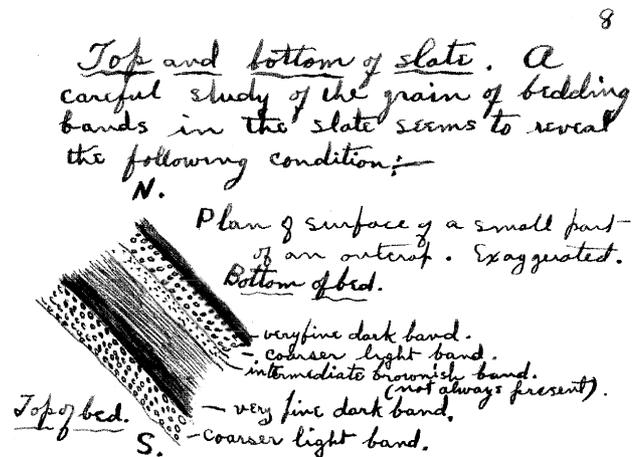

Figure S19 Field notebook sketch of graded bedding in overturned strata by C.L. Dake (1910, Dake Notebook No. 1, Wisconsin Geological and Natural History Survey).

Hotchkiss also recognized the potential of graded bedding for way-up determination as reported by his field assistant, Charles L. Dake, who was assigned to test the value of graded bedding with observations in the field (Figure S19) and in oriented thin sections (Cox and Dake, 1916, 50–52).

Ripple marks were cited as a way-up criterion almost as early as cross-bedding by Irish geologist J. Beetes Jukes in *The Student's Manual of Geology* (1862, 192). It was but a passing observation, however, with no distinction made between symmetric and asymmetric ripples for this determination; asymmetric ones are ambiguous because bottom and top surfaces appear much the same. In 1896, Charles R. Van Hise, one of Hotchkiss' mentors, cited Jukes and discussed how ripples could distinguish way-up. Although Van Hise's illustration was of an unusual example of superimposed symmetric ripples of two scales, he gave no overt indication that asymmetric ripples are of no value. His protégé, Charles K. Leith, did make this distinction clearly, however, when he reproduced Van Hise' diagram in his 1913 structural geology textbook. Leith's book was the first widely available reference to way-up criteria, although the discussion was brief. Included were cross-bedding, symmetric ripple marks, and graded bedding.

Dissemination of the re-discovered value of sedimentary way-up indicators had a complex history. In 1924 two young University of Wisconsin graduates, Olaf Rove and Sherwood Buckstaff, showed an older Norwegian geologist, Thorolf Vogt, that a complex succession at Ballachulish in the Scottish Highlands must be inverted because of the orientation of truncated cross-bedding (Vogt, 1930; Dott, 2001). Vogt conveyed this revelation to the man who had mapped the area, Edward B. Bailey, who received the news with skepticism; he did not know of Leith's 1913 textbook, although several of his countrymen had cited it. Bailey's edification did not begin until 1927, when he was invited to accompany a Princeton University field trip across Canada. In the Precambrian shield north of Lake Superior, Geological Survey of Canada geologist Thomas L. Tanton, who had received his PhD. from Wisconsin (1915), showed the Princeton group how both cross-bedding and graded bedding indicate way-up. In 1929, Bailey hosted the Princeton field trip in the Highlands. Tanton came, too, and finally convinced Bailey that, indeed, the entire Ballachulish succession was inverted. Once converted, Bailey quickly arranged for a joint publication in the 1930 *Geological Magazine* of companion papers by Vogt (reinterpretation of the Ballachulish structure), by Tanton (summary of way-up criteria), and one by himself (cross-bedding and graded bedding as hallmarks of two fundamentally different facies groups). Bailey's paper became a classic.

General recognition of the value of sedimentary structures for way-up determination during the 1920s is evidenced by brief notes in the *Treatise on Sedimentation* (Twenhofel, 1926) about cross-bedding (p. 619) and symmetric ripples (pp. 665–666). Tanton's 1930 list of indicators included cross-bedding, channelling, mud cracks, texture gradation (graded bedding), pebble dints (depression of underlying laminae), symmetric ripple marks, vesiculated tops of lava flows, pillow lavas, curved fracture cleavage, drag folds, and cleavage-bedding relations. In later years, such additional criteria as sole marks, rain drop impressions, convexity of shells and of stromatolites and the like were recognized and catalogued in detail by Shrock (1948), who from 1928 to 1937 had been on the University of Wisconsin faculty. The value of sedimentary features for structural interpretation has never again been forgotten.

SEDIMENTOLOGY, HISTORY

Sedimentology may be defined as the study of natural sediments, both lithified (sedimentary rocks) and unlithified, and of the processes by which they were formed. The term *sedimentology* was first used by A.C. Trowbridge in 1925 (Waddell, 1933), but did not come into common usage until the 1950s (see *Sedimentary Geology*). An interest in sedimentation and the origin of sedimentary rocks dates back to the very beginnings of geology. For an annotated list of earlier reviews of its history, see Potter (1978). In the following discussion, the history of the subject has been divided into six periods, divided by the dates: 1830, 1894, 1931, 1950, and 1977.

The major developments marking the end of each period were: (i) general acceptance of actualism as a basis for geology (Lyell's *Principles*, 1830); (ii) the theoretical elaboration of actualism as the basis of a specific science of sedimentary rocks (the "comparative lithology" of Walther's *Einleitung*, 1893–1894) and the practical demonstration of actualistic methods by such major investigations as the *Challenger* expedition, and the Funafuti boring; (iii) growth in professionalization culminating in the founding of SEPM and the publication of the first sedimentological journal (*Journal of Sedimentary Petrology*, 1931); (iv) the beginning of large-scale studies of modern sediments and introduction of many new techniques, particularly in marine geology. These developments coincided with major conceptual and instrumental advances in geochemistry, and in the interpretation of carbonate rocks, sandstones, and sedimentary structures; and (v) the revival of interest in stratigraphic interpretation and the large-scale geometry of sedimentary bodies brought about by seismic stratigraphy.

Such a division is inevitably arbitrary, and the criteria used to select the dates are not based on uniform criteria. The first two dates are defined conceptually, the third date is defined mainly in terms of a social phenomenon (the definition of "sedimentation," "sedimentary petrology," or "sedimentology" as a subdivision of geology, with its own professional specialists), and the fourth and final dates by advances in both concepts and techniques. Before 1894, sedimentology scarcely existed, except as a part of stratigraphy. Only after 1950 was it common to find specialists who studied sedimentary rocks, but declined to be called stratigraphers, and since 1977 an increasing number of specialists refuse to make a hard distinction between sedimentology and at least some aspects of paleontology and stratigraphy, which they include together as "sedimentary geology" (q.v.)

First period (–1830)

The end of the first period is marked by the date when uniformitarianism, or the actualistic method, became generally accepted as the basis for geology. As with most changes in science, this was a gradual process. Actualism ("the present is

the key to the past”) had been proposed before James Hutton and John Playfair, and its general acceptance was not achieved by them. It was not even achieved at first by Charles Lyell (Cannon, 1960; Hallam, 1989, Chapter 2) but the date of appearance of the first volume of Lyell’s *Principles* (1830) is a convenient one with which to limit a history of sedimentology. At some time not long after 1830, there was widespread acceptance of the general actualistic paradigm: “that, during the ages contemplated by geology, there has never been any interruption to the agency of the same, uniform laws of change. The same assemblage of general causes. . . may have been sufficient to produce by their various manifestations, the endless diversity of effects of which the shell of the earth has preserved the memorials. . .” Since the beginning of the age of solar system exploration (Sputnik I, 1957) it became possible to recognize the importance of some processes on earth that had not previously been given much attention, such as impact cratering, and to begin to speculate scientifically about the very early history of the earth, when conditions were certainly very different from the present. Since then, an exaggerated contrast between “uniformitarianism” (the doctrine that the *intensity* of natural causes remained nearly constant in the past) and “catastrophism” (that much of geological history was characterized by much more intense causes than at present) is no longer an issue.

After 1830, geology rapidly became professionalized, largely by the establishment of state and national surveys, and the use of geology as an aid in the search for and exploitation of coal and mineral deposits. The central paradigm for professionalization, however, was not actualism as much as it was the concept of “strata identified by fossils,” propounded slightly earlier by William Smith, and by Georges Cuvier and Alexandre Brongniart. Many accomplished stratigraphers continued to hold “nonuniformitarian” views on the origin of sedimentary rocks.

Although actualism is a central paradigm for sedimentology, the science itself can scarcely be said to have begun with Lyell. Actualism only made the science possible, but Lyell and his contemporaries did not develop its principles. They were more concerned with establishing the basic working method of historical geology as a whole, than they were with detailed investigations of the origin of sedimentary rocks. Lyell’s *Principles* contained many observations that we would now regard as within the scope of sedimentology, for example, his discussion (borrowed in part from C.E.A. Von Hoff; see Hamm, 1993) of rivers, deltas, and coastal processes, but these phenomena were presented more to prove uniformitarianism than to form the basis for an interpretation of sedimentary rocks. Lyell’s own systematic discussion of sedimentary rocks (volume 3 of the *Principles*, which later became the *Elements*) tended to follow Smith’s stratigraphic paradigm, rather than his own actualistic one. Most of the *Elements* could equally well have been written by a catastrophist, such as William Smith himself, Georges Cuvier, or Adam Sedgwick.

For many years, the great success of stratigraphy diverted the attention of geologists away from investigating sedimentary rocks themselves, to the study of their correlation and enclosed fossils. It is, nevertheless, worth mentioning a few exceptions. The Comte de Buffon (in his *Natural History*, 1778) recognized the vegetable origin of coal, and in the same year von Beroldingen gave a more detailed account, proposing the *in situ* (autochthonous) origin and describing how peat was formed and transformed into coal (see Moore, 1940). The

vegetable origin of coal was also held by James Hutton, and later confirmed by microscopic investigation (by W. Hutton, no relation to James, and by Whitham, both in 1833, see Moore, 1940). Abraham Werner (1786) gave precise descriptions of many sedimentary rock types, including “graywacke”. Antoine Lavoisier (1789) proposed a model of how sediments vary with distance from the shore, distinguished *littoral* from *pelagic* deposits, and discussed the principles of transgressive and regressive overlap (see Carozzi, 1965: unfortunately only the littoral/pelagic distinction was known to most later investigators). Dolomieu described dolomite (1791; see Carozzi and Zenger, 1981; and McKenzie, in Müller *et al.*, 1991 for the long and complex history of this mineral). William Buckland (1823; see Cadée, 1991) investigated cave sediments in a thoroughly actualistic manner, despite his reputation as a catastrophist. Thomas Webster (1826; see Cadée, 1991) interpreted enigmatic “dirt beds” as fossil soils. Hutton’s idea of the “geological cycle” was neglected, then revived many times, perhaps most fruitfully in the form of geochemical cycles, after the development of plate tectonics (Gregor, 1992; Oldroyd, 1996, Chapter 12).

Second period (1830–1894)

Almost as soon as it was recognized that fossils characterized sedimentary rocks of a given age, it was also realized that different types of sediments, deposited at the same time, do not all contain the same types of fossils, because of the different environments in which they were deposited. The general aspect of sediments deposited in different environments was called *facies*, and the concept was developed particularly by the Swiss geologist Amanz Gressly (1838; see *Facies Models*; Wegmann, 1963; Nelson, 1985; Cross and Homewood, 1997).

Perhaps the first major success of the actualistic method was, however, the glacial theory developed by Louis Agassiz (1840; after earlier work by other Swiss geologists, see Hallam, 1989, Chapter 3; Tinkler, 1985, Chapter 7) from observations of modern Swiss glaciers and their sediments. It was early supported by Buckland and, at first, by Lyell: but Lyell’s uniformitarianism later persuaded him that the role of continental ice sheets had been exaggerated, and that most glacial phenomena were better explained by the action of floating ice. After Agassiz moved to the United States he soon persuaded most American geologists to adopt the theory of continental glaciation, though there were some nonbelievers, such as J.W. Dawson (Sheets-Pyenson, 1996, p.138–140).

Early investigations of modern sediments were limited to accessible areas (e.g., the Mediterranean coast, Gressly, 1861; see Cadée, 1991) but were extended by investigation of coral reefs (Darwin, 1837, 1842; see Stoddart, 1976; see also *Sedimentologists: Vaughan, Murray, Walther*), deserts (Walther, 1890; see *Sedimentologists: Walther*), evaporites (Ochsenius, 1877, see Kirkland and Evans, 1973), and deep-sea sediments (Murray and Renard, 1891; see *Sedimentologists: Murray*). The origin of coal was a subject of intense investigation (the allochthonous versus autochthonous debate, essentially resolved by the recognition of the significance of “underclays” by William Logan, 1840, confirmed by H.D. Rogers and J.W. Dawson in America; see Moore, 1940; Torrens, 1999).

The earliest microscopic observations, begun with the investigation of coal, were extended to other types of sedimentary rocks with spectacular results. Ehrenburg (1854; see Jahn, in Gillispie, 1971, Volume 4) showed the organic

origins of diatomite, radiolarian chert, and chalk. In 1850 H.C. Sorby (see *Sedimentologists: Sorby*) began the use of the petrographic microscope, and by the end of the period he had, almost single-handedly, established the science of sedimentary petrology, using a technique originally developed by Nicol to study fossil wood.

In this period, sedimentary structures were first clearly described. Sedgwick (1847) distinguished between bedding and cleavage, and Thomson (1861; see Durney, 1978) developed a theory of pressure-solution. Sorby (1852; see *Sedimentologists*) described how ripples were formed and their migration produced ("ripple drift") cross-lamination, and his explanation was independently rediscovered in America. George Darwin (1883) studied current ripples experimentally, and recognized the importance of flow separation. De la Beche and others had earlier described cross-bedding, but early attempts to explain its origin (by micro-delta growth and truncation) by Sorby (1852) and W.M. Davis (1890) were less successful. Eolian cross-bedding was well-known, but the connection between subaqueous cross-bedding and dune migration was not made until much later. The earliest observations on the orientation of grains and fossils were made by Hall, Miller, Gressly, and Ruedemann (see Potter and Pettijohn, 1973).

Observations made in several different disciplines advanced our understanding of hydraulics and sediment transport (see Miall, 1978; Dooge, 1987, for references in this paragraph). Brahm (1753) had already developed the "sixth-power law" (relating the weight of a grain to the sixth power of the velocity needed to move it in water) and it was rediscovered independently by Airy (1834). Humphreys and Abbott (1861) produced a major study of the hydraulics of the Mississippi River (used by Lyell in later editions of the *Principles*). Sternberg (1875) described the exponential decline downstream of the weight of pebbles in some rivers, and Daubrée (1879) studied attrition (abrasion) of particles experimentally. Du Boys (1879) developed the first theory of bed-load movement, and Kennedy (1895) proposed a regime theory for Indian canals.

The first work to draw together the many scattered observations on modern sediments, to mark out clearly the stages of the sedimentary cycle (weathering, transportation and abrasion, deposition, and diagenesis; see Dunoyer de Segonzac, 1968), and to document the actualistic method as the basis for a specific science of sedimentary rocks ("comparative lithology") was Johannes Walther's *Introduction to Geology as Historical Science* (1893–1894; see *Sedimentologists: Walther*). The method was demonstrated by major investigations, including Walther's own studies of deserts, studies of coral reefs including the report of the Royal Society of London's expedition to Funafuti (Bonney, 1904), and, most important of all, publication by Murray and Renard of the sediment studies made by the *Challenger* expedition to the deep seas (1872–1876; see *Sedimentologists: Murray*).

This period was also the "heroic age" of geomorphology, which established not only the significance of glacial action (thus solving a long-standing problem posed by the peculiar properties of "drift"), but also the effectiveness of fluvial, rather than marine, processes for erosion and sediment transport (Tinkler, 1985, chapters 4–8). Notable contributions were by G.K. Gilbert (on the Henry Mountains and the concept of *grade*, 1877, and on Lake Bonneville, and its deltas and beaches, 1890; see *Sedimentologists: Gilbert*), and by W.M. Davis (1884, 1889; see Chorley *et al.*, 1973) on geomorphic

models and the "cycle of erosion." These studies established a process, and/or model-based approach that changed the nature of sedimentological studies and provided a firm foundation for future work (Loewinson-Lessing, 1954; for contemporary views see Cross, 1902; Teall, 1902). Thus, 1894, the date of publication of the third volume of Walther's work, a volume prophetically titled *Modern Lithogenesis*, seems an appropriate one to choose as the beginning of a systematic science of sedimentology.

Third period (1894–1931)

This period was marked by the further development of lines of investigation established during the previous period. Investigations of modern sediments continued, and were summarized in the *Treatise on Sedimentation* (edited by Twenhofel, 1926; revised 1932), and in *Recent Marine Sediments* (edited by Trask, 1939). Both volumes were produced under the sponsorship of the US National Research Council, which set up a Committee on Sedimentation in 1920. Important works applying actualistic methods to the sedimentary record were published by Sorby, C. Schuchert (*Paleogeography of North America*, 1910), J. Barrell (see *Sedimentologists: Barrell*), and A.W. Grabau (*Principles of Stratigraphy*, 1913—dedicated to Johannes Walther). Other manifestations of the power of the actualistic method were the development of soil science and from it the study of paleosols (see Retallack, 1990), and the development of taphonomy and therefore of the processes of fossilization and bioturbation (see Cadée, 1991, and *Sedimentologists: Richter*).

The major new techniques developed were size analysis (by Udden, Wentworth, and Atterberg (see *Sedimentologists: Udden*; Krumbein and Pettijohn, 1938); and shape analysis (by Wentworth, Waddell, and Zingg). The petrographic approach developed in the previous period by Sorby, was continued mainly by Lucien Cayeux in France (see *Sedimentologists: Cayeux*). It was extended to include the study of accessory minerals by separation using heavy liquids (a technique pioneered by Thoulet, 1881), and applied by many investigators early in the nineteenth century (see Milner, 1962; Luepke, *Heavy Minerals*, in Good, 1998). The value of heavy minerals to the study of provenance was early demonstrated by Thomas (1902), Brammall and Harwood (1923) then by many others (see Milner, 1962). Only in the 1920s did such studies become popular in the petroleum industry, in the (misguided) hope that heavy minerals would be useful for correlating oil sands.

The foundations of coal petrology (coal types, the distinction between macerals and phyterals) were established using thin and polished section techniques by White and Thiessen (1913) in America, Winter (1913) in Germany, and Stopes (1919) in England (see Van Krevelen, 1961, appendix) and an international agreement on petrographic nomenclature was reached at the Heerlen conference in 1935.

A German tradition of chemical studies, already established toward the end of the previous period by K.G. Bischoff, J. Roth and others, was continued by the monumental studies of J.H. Van't Hoff on the evaporation of seawater (see Eugster, in Ginsburg, 1973; and Kirkland and Evans, 1973).

Physical experimentation was carried to new levels of sophistication in the use of flumes by a German school including Engels (from 1898; see Rouse and Ince, 1957), Kramer (1932) and Shields (1936; see Dooge, 1987; Buffington,

1999). Gilbert's work in 1914 (see *Sedimentologists: Gilbert*) was stimulated by his interest in the physiographic activity of rivers and in the environmental problems produced by hydraulic gold-mining in California, and was carried out in a large, open-air flume on the Berkeley campus—these studies together produced his distinctions between saltation and suspension, and between the competence and capacity of flows. They also led to his formulation of flow regimes, with “dunes,” formed in a lower regime, separated from plane bed and antidunes, in an upper regime. Unfortunately, the flume was not quite large enough to make clear the distinction, eventually discovered in the 1960s, between ripples and true subaqueous dunes.

Perhaps the main characteristic of the period, however, is not to be found in the investigations themselves, so much as in a tendency to define sedimentology as a distinct discipline within geology. This process of professionalization can be traced through the appearance of textbooks, journals, societies, and research institutes; and it took place in America, Russia, and to varying degrees, in England and Germany at about the same time, during the 1920s and 1930s. A convenient date is 1931, making the appearance of the first journal devoted exclusively to sedimentology, the *Journal of Sedimentary Petrology*. This journal was published by the Society of Economic Paleontologists and Mineralogists, founded in 1927 as an offshoot of the American Association of Petroleum Geologists (see Russell, 1970; for more recent history, see Clinton, 2001). The first American textbooks were by Krumbein and Pettijohn (1938) and Twenhofel (1939).

In Russia, the influence of the *Challenger* reports and Walther's work was strong. Strakhov (1970) dates the “independence of lithology as a scientific discipline” from 1923, the date when Y.V. Semoilov clearly expressed the “endeavour to systematically develop lithology as a science. . .” The main period of professionalization, however, was during the 1920s and 1930s (Anonymous, 1967). The first textbooks on sedimentology in Russian were produced by Nalivkin in 1932, and by Shvetsov in 1934. National lithological conferences were not held until 1952, and it was not until 1963 that there appeared *Lithology and Mineral Resources*, a journal devoted exclusively to sediments and sedimentary rocks.

In Germany, there were many early sedimentological studies (reviewed in Brinkmann, 1948). Marine institutes existed in Naples (Italy), Helgoland, and Kiel, but most of their work was biological. In 1929 Rudolph Richter (see *Sedimentologists: Richter*) established the Senckenberg am Meer as an institute for the study of modern shallow-marine sediments, to aid in the study of sedimentary rocks. In 1937, Erich Wasmund established a marine geological station at Kiel. In 1918, Richter had begun publication of a journal *Senckenbergiana*, in which most of the sedimentological work carried out at the marine institute was published. But there is still no separate national sedimentological journal or society of sedimentologists in Germany.

The European countries were active in founding the International Association of Sedimentologists, and the first Congress was held in Belgium in 1946. The IAS journal *Sedimentology*, appeared for the first time in 1962. The first major French textbooks were by Cayeux (1916; see *Sedimentologists: Cayeux*), Carozzi (1953), and Vatan (1954). The first German textbook, after Walther, was by Correns (1939; see *Sedimentologists: Correns*), and this was followed, in 1964–1973, by a

major three-volume work by Von Engelhardt, Müller and Füchtbauer.

An active group of sedimentologists existed in Great Britain at the beginning of the twentieth century, and the first textbooks were by Hatch and Rastall (1913), Milner (1922; see Milner, 1962), Marr (1929), and Boswell (1933). In the 1920s and 1930s, however, heavy mineral studies predominated, the Sorby tradition was neglected in favor of classificatory biostratigraphy, and the professionalization of sedimentology had to wait upon the founding of IAS.

For developments in Japan, see *Sedimentology: History in Japan*.

In summary, the professionalization of sedimentology took place first in the USA in the 1920s and 1930s. The first results, particularly the new journal and the two NRC-sponsored symposia (which included many contributions from outside the United States), exerted a profound influence on the development of sedimentology elsewhere.

Fourth period (1931–1950)

The early professional period was characterized by the revival of studies pioneered earlier (petrography, diagenesis) and the development of new techniques (x-ray methods, particularly for clay mineralogy, statistical methods, coring techniques). Techniques were standardized for routine sedimentological analysis, particularly of modern sediments. These techniques and the dissemination of sedimentological observations and ideas through the publication of the many books that appeared at the close of the period (particularly Pettijohn, 1949) set the stage for the rapid progress in and growth of sedimentology in the next period.

An example is the book by Shrock (1948), devoted to the use of sedimentary structures for “way-up” determination. There were numerous scattered early references to such techniques, as far back as the work of Ganly (1856) on the use of cross-bedding (see *Sedimentary Structures as Way-up Indicators*) but the technique itself was not widely used until the 1930s and the literature was not fully known until Shrock's book was published. The book had a much wider impact: it was the first to give a systematic description and discussion of a wide range of structures, and it did this by making extensive use of block diagrams, which had rarely been used earlier for this purpose. Their first application to sedimentary structures was perhaps by Knight in 1929, though the technique itself has a much longer history in the earth sciences (see Howarth, 1999).

Though Sorby was aware of the potential of measuring the preferred orientation of structures to determine paleocurrents, the first systematic basin studies using this technique were begun by R. Brinkmann and E. Cloos in Germany in the 1930s (see Pettijohn, 1962). Statistical techniques to handle this type of data were described by Reiche, Shotton, Brinkmann and others, before being fully developed by R.A. Fisher (see Potter and Pettijohn, 1963; Howarth, 1999). In England and America, attention had earlier been focused mainly on paleogeography (by Jukes-Browne and Schuchert; see Schuchert, 1910), but shifted under Twenhofel's influence to the recognition of sedimentary environments. The key concept of facies (*q.v.*) long neglected by English-speaking geologists, was rediscovered in America, and popularized at a meeting of the Geological Society of America held in 1948.

The concept of geosynclines, though originated by Hall (1859) and Dana in America (Dott, 1974, 1978) was developed

after that mainly in Europe (see Hsu, in Ginsburg, 1973), along with concepts of “tecto-facies” such as flysch and molasse, until interest in geosynclines was revived in America by Kay (1951). Further interest in the tectonic control of sedimentation was stimulated by the revival of sedimentary petrology in the broad sense, as opposed to heavy mineral studies. The broader studies had been continued in the previous period mainly by Cayeux (see Taylor, 1950). Shvetsov and others in Russia developed theories of the control of sedimentary mineralogy by tectonics, and these theories were further developed and popularized in America by P.D. Krynine (see *Sedimentologists: Krynine*), E.C. Dapples, W.C. Krumbein (see *Sedimentologists: Krumbein*) and L.L. Sloss, who later became better known as one of the founders of sequence stratigraphy (Miall and Miall, 2001).

X-ray techniques established the crystalline nature of even the finest clay fractions beginning with the work of L. Pauling in 1930 on kaolin, chlorite and talc and a complete summary of such studies was first published by G.W. Brindley in 1951 (for other contributors, see Grim, 1942; and *Sedimentologists: Correns*). Clay mineralogists rapidly formed a separate discipline, with their own societies and journals (*Clay Mineral Bulletin*—later, *Clay Minerals*, 1947; *Clays and Clay Minerals*, 1952; also see Volume 34, number 1 of *Clay Minerals* for historical papers celebrating the fiftieth anniversary of the Clay Minerals Group). The sedimentological significance of this work was elucidated by Millot (1964, summarizing work from the 1940s and 1950s; see Carozzi, 1975, 162–165 for a brief history of this, largely French, series of environmental studies).

Statistical techniques were developed for the processing of petrographic and particularly grain-size data (see *Sedimentologists: Krumbein: Statistics Applied to Sediments*). Heavy mineral and insoluble residue studies continued but began to wane in popularity, as their use in the petroleum industry was replaced by geophysical logging techniques.

Studies of physical processes of sedimentation were carried out mainly by hydraulic engineers, using the boundary layer concepts developed at the beginning of the twentieth century by Prandtl and Von Karman (e.g., Shields, 1936; Rouse, 1937; Einstein, 1937; Vanoni, 1946; see Middleton and Southard, 1984 for references), but most of these studies were not well-known to geologists. Exceptions were the work of Rubey (e.g., 1933, 1938; see Ernst, 1978), Hjulström (1935, summarized by him in Trask, 1939), and particularly the work of Bagnold on wind-blown sand (see *Sedimentologists: Bagnold*).

Fifth period (1950–1977)

A number of books appeared at the close of the fourth period (Shrock, 1948; Shepard, 1948; Pettijohn, 1949; Twenhofel, 1950; Trask 1950; Kuenen, 1950; Krumbein and Sloss, 1953), and a re-reading of these books is a simple way of establishing the “state of the art” just before the beginning of the major expansion of sedimentological studies in the 1950s and 1960s. During this period, courses entitled “sedimentology” became widespread in university curricula (many of them using Pettijohn’s book as a text), and many new staff were hired specifically to teach sedimentology, rather than stratigraphy. By the late 1970s, probably “sedimentologists” outnumbered “stratigraphers” in university geology departments. Many sedimentologists were also hired by oil company research laboratories. For some “personal perspectives” of this period, see Pettijohn (1984), Van Houten (1989), Picard (1989) and

Friedman (1998). The influence of Pettijohn’s book, strongly oriented toward sedimentary rocks, rather than processes, continued until the appearance of a new, more process- and facies-oriented text by Blatt *et al.* (1972) and the classic text by Bathurst (1975) on carbonate rocks (see *Sedimentologists: Bathurst*).

The first major change in this period was the great expansion in the number and scale of investigations of modern sediments, due partly to the interests of petroleum companies, partly to the spectacular growth in oceanography (stimulated by submarine warfare in World War II), and partly to the renewed interest in facies. For example, the American Petroleum Institute project on the Gulf Coast, and most of H.N. Fisk’s work on the Mississippi alluvial plain and delta postdate 1950.

L.V. Illing’s work on the Bahama Banks in 1954 was the first of many investigations of modern carbonate sediments in the Caribbean and Persian Gulf. These investigations and a renewed interest in carbonate petrography had a revolutionary effect on the study of ancient limestones, dolomites, and evaporites. Notable advances included the first modern classifications of limestones by Folk and Dunham (see Ham, 1962; Folk, in Ginsburg, 1973; and Morse and Mackenzie, 1990, p.599–602, for the historical background to modern carbonate studies), the discovery of modern, early-diagenetic dolomites (see Pray and Murray, 1965), and the discovery of sabkha gypsum and anhydrite (see Kirkland and Evans, 1973). Concepts derived from these studies strongly influenced the interpretation of ancient carbonates and evaporites.

The second major change was in both the techniques and theory of sedimentary geochemistry. Analytical advances included electromagnetic and centrifugal techniques for mineral separation, flame photometry, colorimetric analysis, optical emission spectroscopy and atomic absorption spectroscopy, for both trace and major element analysis, all of which became widespread in geology in the 1950s (see summaries in Smales and Wager, 1960; and for later developments, particularly ICPMS developed in the 1980s, see Gill, 1997). The electron microscope was another powerful tool, first applied in sedimentology to clays and cherts (see *Sedimentologists: Folk*), and, after the development of scanning electron microscopy, to microfossils and grain surface textures (see *Surface Textures of Grains*). X-ray fluorescence spectroscopy developed rapidly and led in the 1960s to the electron microprobe. Radioactivation analysis allowed analysis of trace elements in the ppb range. Carbon-14 dating, developed by Libby (beginning in 1949; see Taylor, 2000) allowed accurate dating of sediments up to about 50,000 years BP, and in the 1980s, use of accelerator mass spectrometry allowed the sample size to be reduced. Mass-spectrometric methods were applied to radioactive elements (e.g., K–Ar dating, and later Ar–Ar dating) present in sedimentary minerals such as illite and glauconite, and in the 1980s, the Uranium series method has been developed to fill the gap in dating between K–Ar and Carbon-14. The most important applications of mass spectroscopy in sedimentology, however, were on the natural distributions of the stable isotopes of hydrogen, carbon, oxygen and sulfur (see Epstein, 1997; *Isotopic Methods in Sedimentology*). The first modern review of the analytical geochemistry of sediment was published by Degens in 1965.

Mason’s paper on oxidation and reduction, in 1949, and Krumbein and Garrel’s paper of 1952 on the use of Eh and pH set the stage for many subsequent theoretical, experimental

and field studies of weathering, chemical sedimentation and diagenesis under low-temperature, aqueous conditions (see Garrels and Christ, 1965; Eugster, in Ginsburg, 1973; Berner, 1971; Morse and Mackenzie, 1990).

The third major change was a conceptual one: the experimental development of the hypothesis of high-density turbidity currents by Kuenen in 1948 (see Walker, in Ginsburg, 1973). This was the first entirely new theory of sediment transport and deposition developed since the glacial theory, and it revolutionized the study of flysch sediments, and made possible a deep-water interpretation of sands and gravels previously thought to be necessarily deposited in shallow water, because they were too coarse to be carried by wave-action into deep water. It also made possible an interpretation of submarine canyons, which had been a long-standing enigma since their discovery in the nineteenth century. Since the hypothesis could not be tested by direct observation, it also stimulated the observation, explanation, classification, and mapping of sedimentary structures, and the further development of basin analysis using paleocurrent techniques (Bouma, 1962; Potter and Pettijohn, 1963; Pettijohn and Potter, 1964; Conybeare and Crook, 1968; Ricci Lucchi, 1970).

The fourth major change was the revival in tectonic control of sediment types, and the use of sedimentary mineralogy to determine provenance, brought about by the development of plate tectonics in 1963–1967 (see *Provenance*). Plate tectonics also led to the Deep Sea Drilling Project, begun in 1968, which led to greatly increased understanding of the deposition and diagenesis of deep-sea calcareous and siliceous sediments (see Warme *et al.*, 1981) and threw new light on the old controversy about the depth of ancient evaporite basins (see Cita, in Müller *et al.*, 1991).

The fifth major change was that experimental work on sediment transport and bed forms, carried out largely by engineers since the 1930s, was reintroduced to geologists at an SEPM symposium on sedimentary structures (Middleton, 1965; and Middleton, 1977 for later developments). The revolution in understanding of cross-bedding, in particular, began earlier in Germany with work that finally recognized the link between dune migration and cross-bedding (based in part on observations of intertidal dunes; see Hülsemann, 1955), but in the English speaking world it was largely due to work carried out by US Geological Survey hydraulicians in a newly constructed large flume in Colorado (see Simons, in Middleton, 1965). After this, there was a rapid increase in the number of experimental studies carried out by geological sedimentologists, and more recently by geomorphologists. New theoretical and experiment studies of sediment transport were published in the 1950s by Bagnold (see *Physics of Sediment Transport: the Contributions of R.A. Bagnold*). Re-education of sedimentologists in fluid mechanics was promoted by Allen (1968, 1985) and Middleton and Southard (1978, 1984), and the application to sedimentary structures was exhaustively reviewed by Allen (1982).

Finally, toward the end of this period there was a major change in interest from textural or mineralogical studies of sediments (“sedimentary petrology”) toward the recognition and explanation of sedimentary facies in terms of their environment of deposition (Reineck and Singh, 1973); these studies were further organized into a number of models (see *Facies Models*), based largely on concepts dating back to Walther’s “comparative sedimentology.” Crucial works included Van Straaten (1955) and others on tidal sediments (see

Middleton, 1991), Bernard, LeBlanc and Major (1962, on the Brazos River and Gulf Coast barriers); De Raaf, Reading and Walker (1965, on Pennsylvanian cycles), and the work by Shearman (1965, on modern evaporites). This work was systematized by Walker (1976; see 1979) and Reading (1978, and later editions: which may be consulted for detailed references). By the time that Walker and coauthors came to revise their volume in 1989, the influence of the new “sequence stratigraphy” was strongly felt, to the point that an entirely new volume was thought necessary (Walker and James, 1992; and see Moore, 2001).

Final period (1977–present)

This period is too recent to be reviewed as history, but its characteristics will become apparent, I hope, from the articles contained in this encyclopedia. For the history of sequence stratigraphy see Miall and Miall (2001).

 Sedimentology: History in Japan

SEDIMENTOLOGY: HISTORY IN JAPAN

The study of sediments and sedimentary rocks in Japan started with the introduction of Geology in the 1870s shortly after the Meiji Restoration in 1867 which modernized Japanese society. Since then, the study of sediments and sedimentary rocks developed rapidly. The study of sedimentology in Japan was reviewed by Shoji (1966), Shoji *et al.* (1968) and Okada (1998, 2002).

The history of the development of sedimentology in Japan can be divided into six stages.

Stage 1 (before 1930)

Immediately after the Restoration, the Japanese government invited European and American scientists to establish modern science and technology in Japan. Among them, an American geologist Benjamin S. Lyman (1835–1920) and a German specialist Edmund Naumann (1854–1927) became the founders of geology in Japan. In 1873 Lyman conducted a geological survey of Hokkaido mainly for developing coal resources and published the first geologic map of Hokkaido in 1876. Naumann was appointed as the first professor of geology (1877–1879) at the University of Tokyo, founded the Geological Survey of Japan in 1878, and determined the tectonic and stratigraphic framework of the Japanese Islands. The Geological Survey of Japan, by systematic mapping, quickly developed the study of regional stratigraphy and sedimentary rocks over the whole country. The geology department of the University of Tokyo, prepared a number of able stratigraphers, and contributed to the establishment of many other geology departments and institutions as places for the study of stratigraphy and sedimentary rocks. In 1893 the Geological Society of Japan was founded to support and enhance the quality of geological science in Japan.

Stage 2 (1930–1950)

In the young stage of Japanese geology, the study of sedimentary rocks was called *chiso-gaku* (lithology in English), under the influence of classic text-books with the same title by Hanjiro Imamura (1931) and Masao Minato (1953), meaning the science of all aspects of sediments and sedimentary rocks. In this period, Jun-ichi Takahashi and Tsugio Yagi made significant contributions to petroleum geology and the study of authigenic minerals such as glauconite (Takahashi, 1935; Takahashi and Yagi, 1929). It is worthy of special mention that Yagi (1933) introduced a new term “*taiseki-gaku*” (sedimentology in English) in his study of Miocene oil-bearing sediments in Northeast Japan as early as H. Wadell's (1932) proposal of sedimentology. The word “sedimentology”, however, had not been commonly used before 1950.

Stage 3 (1950–1960)

The new discipline of sedimentology quickly became popular and grew into an important field of geology in Japan. This trend in Japan was much earlier than in the international community, in which sedimentology seems to have become established in the early 1960s, and the study of sedimentary facies, sedimentation and sedimentary environments became prominent among stratigraphers and paleontologists. In 1951,

the Sedimentology Subcommittee was established under the Science Council of Japan in order to promote sedimentological studies in Japan. It continues to the present and liaises with the International Association of Sedimentologists (IAS). With the support of the Sedimentology Subcommittee, systematic collaborative studies of the recent sediments of the Matsukawa-ura Estuary near Sendai in northeastern Japan and of the bottom sediments of Tokyo Bay were carried out in 1953 and 1955, respectively. On the other hand, the Sedimentology Research Group founded the Association of Japanese Sedimentologists in 1957 and published a journal called "*Sedimentology Research*" in mimeograph. Sedimentological studies, mainly on the petrology of sandstones and heavy mineral analysis, were active at Tokyo, Tohoku, Nagoya, Kyoto, and Kyushu Universities.

Stage 4 (1960–1980)

In 1961, the Science Council of Japan requested the Sedimentology Subcommittee to discuss the creation of a National Institute of Experimental Sedimentology in order to promote long term basic science in Japan. A proposal for a new institute comprising seven research sections (dynamics, physical, mineralogical, chemical, biochemical, lithological, and mathematical studies), was submitted to the government in 1967 (Omori, 1968), but unfortunately it was not adopted. Instead, however, the Ocean Research Institute was established in 1963 at the University of Tokyo, and the Marine Geology Department of the Geological Survey of Japan started in 1974, both of which have contributed much to create a collaborative system of research on submarine sediments and have greatly encouraged sedimentological studies in Japan. In particular, the official participation of Japan in the International Phase of Ocean Drilling (IPOD) in 1971 provided a large boost to the further development of Japanese sedimentology.

Additionally, a very successful symposium on "Some Problems in Sedimentology" held in Nagoya University in 1967 made a deep impact on many geologists and sedimentologists (Shoji *et al.*, 1967). In 1971 the Sedimentology Research Group reorganized the Association of Japanese Sedimentologists into the Sedimentological Society of Japan, but its journal remained unimproved.

Many sedimentologists in this period studied the flysch and turbidites of the so-called geosynclines of various ages from Paleozoic to Tertiary, particularly of the Shimanto Belt in southwestern Japan. Though the new concept of plate tectonics or new global tectonics was being applied to Japanese geology in the 1970s, it then had not been widely accepted.

Stage 5 (1980–1990)

A remarkable feature of Japanese sedimentology in this stage was the diversity of interests of young sedimentologists many of whom came to occupy important positions at universities, institutions and the councils of the Geological Society of Japan. Their activities included facies analysis, sedimentary petrology, mathematical sedimentology, experimental sedimentology, sequence stratigraphy, and chemical sedimentology; many of them attaining international levels in quality.

Sedimentological studies of accretionary complexes were improved remarkably not only because the new paradigm of plate tectonics became firmly established in Japanese geology,

but also because stratigraphical and chronological studies of these highly deformed strata were developed rapidly through the successful application of radiolarian biostratigraphy.

Stage 6 (1990–)

The Sedimentological Society of Japan was reformed in 1994 with a stimulating and high-quality biannual journal entitled "*Journal of the Sedimentological Society of Japan*". Papers from India, Korea, Russia and USA were also included in the journal. The Society has about 600 members and holds scientific meetings twice a year. Another important activity of the Society was the bench-mark publication of "*The Encyclopedia of Sedimentology*" in 1998.

Special mentions should be made of the recent progress in the study of sequence stratigraphy in Japan (Saito *et al.*, 1995) and of the provenance study of siliciclastic rocks mainly from their chemical aspects (Kumon *et al.*, 2000), in which an effective provenance indicator, Basicity Index, was proposed.

In the 21st century, it is suggested that Japanese sedimentology should contribute more to environmental sedimentology, and achieve greater internationalization through links with the International Association of Sedimentologists.

SEDIMENTOLOGY—ORGANIZATIONS, MEETINGS, PUBLICATIONS

Organizations

Scientific organizations, “societies”, play a key role in the intellectual vitality and growth of the discipline by providing the means for scientists to communicate with each other, learn new ideas, methods and skills, as well as attract new scientists to the profession, particularly students. Societies act as locus of activity in the form of published journals, special topic volumes and memoirs; field trips and field conferences; meetings featuring talks, posters, short courses, and workshops; awards, i.e., recognition for outstanding scientific accomplishments; research grants; and general social and scientific networking through newsletters and the internet. In addition, societies contribute to educational programs at all levels (K-12, college, and continuing education) and provide the important connection between the scientific community and general public via outreach (e.g., public lectures). Societies are also a valuable resource of scientific information for local and national government personnel developing public policy.

Originally sedimentology and paleontology were included within large broad-based geological societies, along with the closely associated discipline of stratigraphy. But, during the early part of the 20th century the scientific needs of the fossil fuel industry raised the profiles of sedimentology and paleontology as separate entities and spawned the formation of the first scientific organization for them in 1926, the Society of Economic Paleontologists and Mineralogists (SEPM), a division of the American Association of Petroleum Geologists (AAPG). SEPM became an independent society in 1986 and has since changed its name to SEPM Society for Sedimentary Geology. It is now the largest society in the world (4500 members) focused on sedimentary geology.

At the beginning of the 21st century the nature and practice of the discipline of sedimentology is clearly different from what it was a few decades ago. It is more broad based and diverse with less focus strictly on sediments themselves, i.e., physical and chemical processes and deposits. A sedimentologist now may work with seismic data, study aquifer characteristics, interpret paleoclimate from stable isotopes, or consider the impact of biological processes on weathering or diagenesis. Sedimentologists like other disciplines are becoming more interdisciplinary; however, the need for organizations, meetings, and publications remains strong.

There are easily dozens of regional societies dedicated to sedimentology and/or sedimentary rocks in various countries around the world. No single listing of them exists, however, and there is little communication among them. Activity in the English-speaking realm is focused in a few large organizations:

SEPM Society for Sedimentary Geology (4,500 members); International Association of Sedimentologists (IAS), (~2,000 members); Sedimentary Geology Division (~1,500 members) of the Geological Society of America (GSA); the British Sedimentological Research Group, BSRG, (~500 members); and Indian Association of Sedimentologists. The sedimentological communities in Canada, South Africa, Hong Kong, New Zealand and Australia meet as specialty groups or Divisions within the larger geological societies. The Sedimentological Society of Japan (550 members) publishes in Japanese (with English abstracts); and societies in National Republic of China communicate only in Chinese.

Meetings

Meetings bring scientists together, usually annually, to provide a forum for exchanging ideas, presenting research results, and educating in the form of field trips, short courses, and workshops. Meetings also provide a means for helping members with professional development, such as retooling for a career change, or offering courses for students on writing resumes, grant proposals, or applying for employment. Social activities and networking contribute to the health of the profession by establishing long term bonds and making new connections.

Meetings also fulfill the growing need for utilizing interdisciplinary and multidisciplinary research to address scientific questions that fall between the natural boundaries of existing disciplines. Small societies find a logistical and economical advantage to hold meetings with other societies. For examples, the Mineralogical Society, Paleontological Society, Society of Economic Geologists, and Geochemical Society all have potential for interacting with sedimentologists and sparking new ideas and new approaches to answering questions that cannot be addressed by any group alone.

Publications

There are three major journals devoted to sedimentology. Two are sponsored by scientific societies and are based on volunteer efforts of the community, *Journal of Sedimentary Research* (SEPM) and *Sedimentology* (IAS), whereas *Sedimentary Geology* is published commercially by Elsevier Publishers. All three have sedimentologists as Editor-in-Chiefs and Associate Editors and they draw from the sedimentological community for reviews of the manuscripts. Papers based substantially on sedimentology may also be published in broad-based journals such as *Nature*, *Science*, and *Geology* and in specialty journals such as *Marine Geology*, *Journal of Coastal Research*, *American Association of Petroleum Geologists (AAPG) Bulletin*, *Geochronology*, *Quaternary Research*, and *Earth Surface Processes and Landforms*.

Specialty volumes are a published collection of papers on a related topic often spawned from a symposium or conference. SEPM and IAS regularly produce 2–5 topical volumes a year. GSA and The Geological Society (of London) frequently create “special publications” that focus on sedimentology and are sold to geological community. As a group of papers focused on a relatively narrow topic and placed between two covers, these publications are valued resources and preferred alternatives to widely decimated papers appearing in a number of journals over several years.

At the beginning of the new millennium, the publishing of sedimentological journals, as all scientific journals, is in a stage of gradual transition between paper and electronic format. Problems of permanent archival have yet to be worked out, but the continuous flow of paperbound journals into and filling of libraries is definitely a thing of the past. Visions of electronic publishing involving papers electronically linked to maps, references cited, and even animation will likely become reality.

RALPH ALGER BAGNOLD (1896–1990)

Ralph Alger Bagnold was born on April 3rd, 1896 in Davenport, England. He was commissioned as an officer in the Royal Engineers in 1915 and served in France and Flanders during World War I, subsequently taking leave from the Army to earn an honors degree in engineering at the University of Cambridge. Rejoining the army, official service took Bagnold to Egypt, from where he began exploring the Libyan Sand Sea with fellow bachelor officers, using Model T Ford motor cars. Weekend trips evolved into serious geographical exploration and mapping and Bagnold developed specialized techniques for taking these simple automobiles deep into the desert without getting completely stuck or lost.

Bagnold became fascinated by the movement of sand by wind and wished to understand the physics of the processes responsible for the formation of desert dunes. He retired from the army in 1935 to devote all his time and energy to the study of sand movement, but still found time to write *Libyan Sands*, an exciting chronicle of his desert expeditions (Bagnold, 1935). The results of his pre-war research were published in *The Physics of Blown Sand and Desert Dunes* (Bagnold, 1941).

Returning to Cairo in 1939 at the outbreak of World War II, he established and led the Long Range Desert Group (LRDG). Operating deep behind enemy lines, the LRDG scouted and reported troop movements, mapped enemy positions, collected intelligence and created havoc through lightning raids on forts, convoys and airfields. So important were the achievements of the LRDG that Bagnold was promoted to the rank of Brigadier and awarded the Order of the British Empire (military). A good account of the exploits of the LRDG may be found in Bagnold's autobiography (Bagnold, 1990).

Bagnold again retired from the army in 1944 and, after a short period as Director of Research for Shell, he decided to pursue fundamental research full time. His primary goal remained the elimination of the empiricism that had long dominated study of the movement of granular materials by flowing fluids. His approach rested on the application of

theory to identify key variables and formulate relationships between them, supported by carefully conceived and executed experiments to elucidate and quantify physical constants and material properties. The conception and construction of innovative experimental apparatus and instrumentation was incidental to his work.

Bagnold's post-war work produced hallmark papers on the morphology and sedimentology of near-shore zones, beaches, submarine density currents, and meandering rivers. He also introduced two of the most significant concepts underpinning our understanding of the sediment transport process: "dispersive stress" and "stream power". A collection of his finest papers was published by the American Society of Civil Engineers in 1988 (Thorne *et al.*, 1988).

Bagnold's achievements as an explorer won him the 1934 Gold Medal of the Royal Geographical Society and his contribution to the engineering profession earned him the Telford Premium of the Institution of Civil Engineers in 1940 (repeated in 1946). His calibre as a scientist was marked by his election as a Fellow of the Royal Society in 1944. His post-war work brought numerous awards, medals and honorary degrees.

Recent advances in fluid mechanics, boundary layer theory and the sophistication of instrumentation have supported new findings that, to some extent, supersede Bagnold's work, which were necessary based on incomplete knowledge of the nature of turbulent flow structures. However, his contributions to science and engineering form essential components of progress in sedimentology and the study of sediment transport during the twentieth century.

Brigadier Bagnold was married to Dorothy Alice Plank (who died 1989) in 1946. They had two children, Stephen (born in 1947) and Jane (born in 1948). He died peacefully following a short illness on May 28th, 1990.

JOSEPH BARRELL (1869–1919)

American geologist Joseph Barrell was a pioneer in integrating tectonics, denudation, and climate for the understanding of sedimentation. Barrell graduated from Lehigh University in

1892 with high honors and promptly earned two advanced degrees (EM, 1893; MS, 1897). Joseph then accepted an instructorship at Lehigh for four more years to teach mining, metallurgy, mechanical drawing, and mine surveying. Recognizing Barrell's exceptional potential, one of his professors urged him to take more advanced work at Yale. While studying at Yale, he worked during the summers for the US Geological Survey in Montana mining districts. In 1900, he received the PhD and returned to Lehigh as a professor of geology and biology. In 1903, Barrell was called to Yale to be the professor of dynamic and structural geology.

Joseph Barrell's early publications dealt with mining and regional geology. Next they emphasized erosion, sedimentation, ancient climate, and paleogeography. His later ones treated the strength of the earth's crust, isostasy, the origin and genesis of the earth, and radioactivity and geologic time. He also wrote and spoke on epistemology and the transition from a qualitative to a more quantitative geology. Barrell perfected a talent for generalization from the work of others and in constructing his syntheses, he was an ardent exponent of multiple working hypotheses. In sedimentary geology, Barrell early concerned himself with criteria for distinguishing ancient non-marine from marine sediments by giving close attention to sedimentary structures, and in doing so he refined criteria of paleogeography and paleoclimate and destroyed the ruling dogma that practically all of the ancient stratigraphic record was marine. Barrell was a devotee of William Morris Davis's idealized evolution of landscapes through cycles of erosion, to which he added the idea of complementary cycles of deposition related to changing base level. He explicated his views in two papers on ancient deltas (1912 and 1913–1914). As a river passes through its cycle from youth to maturity to old age, its sediments must change, too, with one part of the depositional cycle being a delta stage. In 1916 he combined his knowledge of the Devonian Catskill delta complex of the Appalachian region with published work on the contemporaneous fluvial Old Red Sandstone of Britain. From these Devonian researches, Barrell later suggested that environmental factors, especially climate, had influenced the evolution of the first air-breathing animals; drying of climate stimulated the evolution of amphibians from river fishes. Similarly, he suggested that the vicissitudes of Pleistocene climate had contributed to the appearance of the human species.

Barrell's most important contribution to sedimentary geology was a long article, "Rhythms and the measurements of geologic time," published in 1917 two years before he died unexpectedly from pneumonia and meningitis. His thesis was that "Nature vibrates with rhythms, climatic and diastrophic." He first discussed rhythms of denudation, arguing that erosion is pulsatory; the Davis erosion cycle represents a single rhythm, but small, partial cycles can be superimposed on larger ones. Next he argued that sedimentation is also discontinuous, resulting in a stratigraphic record riddled with breaks of varying durations. Barrell coined the term diastem for the lesser but numerous breaks in contrast with the longer but rarer breaks known as disconformities. His figure 5 (p. 796) so effectively illustrated this concept that it has been reproduced many times; figure 6 (p. 800) and the accompanying discussion illustrates that he already understood the implications of climbing dune forms for time equivalences of the cross laminae and diastems produced by migrating dunes, thus anticipating important revelations in eolian sedimentology during the 1970s–1980s. Finally, by invoking estimates of

rates of erosion and sedimentation along with the loss of primeval earth heat, Barrell estimated geologic time spans and then compared these with the measurement of geologic time by radioactivity, which was still in its infancy. He concluded that the two approaches converged upon the conclusion that between 550 million years and 700 million years had elapsed since the beginning of Cambrian time, a remarkably modern figure!

ROBIN G.C. BATHURST (1920–)

Bathurst was born in Chelsea, London, on March 21, 1920. His undergraduate studies in geology, begun at the Chelsea Polytechnic in 1939, were interrupted by World War II and continued at Imperial College, London where he earned his B.Sc. in 1948. After this he spent three years at Cambridge studying Wealden sands with Percy Allen. He was appointed to teach sedimentology at University of Liverpool, retired from teaching in 1982, but remained there as a Senior Research Fellow until 1987.

His work at Liverpool shifted from siliciclastic sediments to carbonate rocks, and particularly their diagenesis. In this field, he was largely self-taught, though influenced by the work of H.C. Sorby (*q.v.*), Maurice Black, and especially Bruno Sander. Sander's work on Triassic carbonates, originally published in German in 1936, was at that time largely unknown in the English-speaking world (it was translated into English in 1951). In 1958 and 1959 Bathurst published three papers dealing with limestone diagenesis, all of which are now classics that have had an immense influence on the study of carbonate diagenesis. The earliest paper, published in the *Liverpool and Manchester Geological Journal*, was the first (in English) to develop criteria distinguishing carbonate cavity-filling cements from calcite mosaics formed by recrystallization. It was not only important scientifically but also had significant applications to understanding the diagenetic evolution of limestones and their pore systems, which at that time had become very important in the scientific community and the petroleum industry. His interest in these topics persisted

throughout his career (Bathurst, 1986, 1993). Later contributions include documenting the importance of interpenetration of sediment grains ("fitted fabric"), dissolution-seams, and stylolites in the development of rhythmic limestone bedding (Bathurst, 1991).

In 1971, Bathurst published the first edition of his book *Carbonate Sediments and their Diagenesis* (revised in 1975) which remained the standard reference work for many years. Bathurst travelled widely, working with many of the leading carbonate petrologists in many other countries. In 1959 he began a series of research seminars on carbonates at Liverpool, which inspired a generation of sedimentologists in the United Kingdom and professional colleagues in the international community: out of this developed the meeting, held every four years, now known as the Bathurst Meeting of Carbonate Sedimentologists. He received the Lyell Medal (1978) from the Geological Society of London, the Twenhofel Medal (1983) from SEPM, and the Sorby Medal (1986) from the International Association of Sedimentologists.

LUCIEN CAYEUX (1864–1944)

Cayeux's long academic career culminated with his appointment in 1912 to the chair of geology at the Collège de France in Paris. He spent the next thirty years developing the investigation and the teaching of sedimentary petrography, a field in which he is considered one of its founders. In his doctoral dissertation (1897) on the chalk and certain Mesozoic and Cenozoic siliceous rocks of the Paris basin, Cayeux gave the first outline of his outstanding analytical method of investigation. For a given sedimentary rock, he first described its detrital and authigenic components, the microfossils, and finally the interstitial matrix or cement. The textural relationships between all the constituents combined with chemical

analysis led to a synthesis attempting to establish the original characters of the sediment, the provenance of the components, and the post-depositional diagenetic modifications. Cayeux's avant garde techniques of 1897 became increasingly sophisticated with time and for him, the science of sedimentary rocks was essentially the complete and comparative natural history of ancient and recent sediments.

Following his investigation of the chalk in which he demonstrated that, in spite of apparent similarities with the recent deep-sea Globigerina ooze, it was a shallow-water deposit, Cayeux undertook a series of comprehensive and well-illustrated monographs on the sedimentary rocks of France and its colonies. He successively investigated the Tertiary sandstones of the Paris basin (1906); Paleozoic and Mesozoic oolitic iron ores (1909, 1922); banded and nodular siliceous rocks (1929); carbonate rocks: limestones and dolomites (1935), and phosphates (1939, 1941a, 1950 [posthumous]). Although Cayeux's interpretation of the oolitic iron ores remained controversial, his synthetic views on the deposition and diagenesis of siliceous rocks, phosphates and carbonates show an unusually modern character. Particularly in carbonate rocks, he anticipated many modern trends concerning early diagenetic processes such as cementation, recrystallization, and dolomitization.

During his years of teaching at the Collège de France, Cayeux realized the need for an introductory book to the field of sedimentary petrography through the use of high-quality extensive illustrations of mineral constituents, microstructures of skeletal remains, and depositional-diagenetic textures. The result was his *Introduction à l'étude pétrographique des roches sédimentaires*, in 2 volumes, a precursor of the numerous atlases of microfacies published half-a-century later to meet the needs of an expanding oil exploration. It was published in 1916, out of print in 1927, and reprinted in 1931.

Cayeux's philosophical approach to geology developed from his studies on iron ores, siliceous rocks, phosphates, and mostly carbonates. He concluded that many fundamental features of these deposits had been generated contemporaneously or penecontemporaneously with deposition by extensive submarine processes of reworking, cementation, recrystallization, and replacement. He felt that most of these processes, so clearly displayed in ancient sediments, were inactive or incipiently active in present-day marine environments. This led to his last book (1941b) *Causes Anciennes et Causes Actuelles en Géologie* in which he concluded that serious consideration should be given to the dual concept of past and present causes in geology. This controversial challenge to uniformitarianism has not yet been fully answered.

CARL WILHELM CORRENS (1893–1980)

C.W. Correns was born on May 19, 1893 at Tuebingen (Germany), the son of the botanist, Carl Correns, who rediscovered Mendel's laws of heredity. After World War I, Correns started as a field geologist mapping several areas of the Rheno-Hercynian belt in the Variscan orogen in Germany. Shales are a major constituent of this belt and were the only abundant rock type of which the mineral composition was unknown in those days. This fact was not accepted by Correns' supervisors in the Prussian Geological Survey. They claimed that clay minerals are the fraction of fine grained sediments, soluble in sulfuric and hydrochloric acid. Correns' statement about the unknown nature of clay minerals was confirmed by chemists investigating colloidal systems at the Kaiser Wilhelm Institute of Physical Chemistry in Berlin. They offered him a part-time position to study the adsorption of certain metals on kaolinite. He became increasingly interested in the composition of Recent sediments and was invited to join the scientific party in one of the first extended oceanographic expeditions. From July 1926 to June 1927 he participated in two traverses through the equatorial Atlantic Ocean by the German research vessel "Meteor." On this cruise a primitive piston corer was used to sample the upper few decimeters of sediments at more than 100 stations between South America and Africa.

On returning from this introduction to practical oceanography, Correns was appointed to the chair of geology at the University of Rostock, close to the shore of the Baltic Sea. He arrived with his valuable collection of "red clay," "blue mud" and "globigerina ooze" from the bottom of the equatorial

Atlantic. Correns anticipated that X-ray investigation of the clays was required to recognize their distinctive minerals. Simple X-ray cameras and high-voltage equipment were available 15 years after M. von Laue's discovery of X-ray diffraction by crystal lattices. Correns and his coworkers then systematically investigated a selection of Atlantic pelagic clays, as well as shales of Pleistocene to Jurassic age from northeast Germany, using the microscope, X-ray diffraction and chemical analysis. By studying separate grain-size fractions, they discovered that even the smallest consists of crystalline rather than amorphous substances. The latter result was earlier claimed by many scientists. Correns and coworkers observed that the grain size distributions were comparable in both Recent pelagic clays and ancient shales. Mica was the most abundant mineral of these pelites.

Crystallographic studies revealed that mica as well as the other clay minerals are sheet silicates. In the 1930s Correns (1937) compiled the results of the Rostock laboratory on the grain size, and mineral and (partial) chemical composition of the pelagic clays and foraminiferal oozes from the "Meteor" expedition in the Atlantic. At about the same time he revised the old-fashioned textbooks on sediment formation and composition. Correns (1939) presented the state of the art on sedimentary petrology ("Die Sedimentgesteine") condensed to 146 pages in a unique international book on the origin of rocks. His coauthors were Tom Barth (magmatic rocks) and Pentti Escola (metamorphic rocks).

At the beginning of World War II, most of the copies of this book were lost during the bombing of Leipzig. This event, and the fact that the book was written in German, precluded a wide international readership, so it is worth quoting the main headings of the part on sedimentary rocks: mechanical weathering, chemical weathering, transport and deposition of clastic sediments, fabrics and constituents of clastic sediments, chemical and biogenic sediments, and diagenesis.

Because of gaps in knowledge revealed by his second book, Correns turned his attention to the experimental investigation of the solubility, as a function of pH, of simple compounds such as quartz and aluminum oxide. Next came experimental weathering of feldspar, mica and other minerals, as well as glass, in open systems. In 1939 Correns was appointed to the chair of sedimentary petrology, and later to that of mineralogy, at the University of Goettingen. By the time the book "Die Entstehung der Gesteine" was reprinted (1960), Correns had already turned his interest toward geochemistry, investigating the crustal distribution of the halogens and titanium. He became cofounder of *Geochimica et Cosmochimica Acta* and of *Contributions to Mineralogy and Petrology*.

Correns died on August 29, 1980, and is known as one of the pioneers of sedimentary petrology, based on generalizations from carefully observed details.

ROBERT LOUIS FOLK (1925–)

Robert Louis (“Luigi”) Folk has an unusual and exceptional record as a geologic educator, researcher, and author of articles on sedimentary rocks. His teaching and published contributions on sandstone, limestone, dolomite, shale, and chert during a 50-year career have earned him numerous accolades, including the two highest honors for research in sedimentary geology: the W. H. Twenhofel Gold Medal from the SEPM (Society for Sedimentary Geology) in 1979 and the H.C. Sorby Medal from the International Association of Sedimentologists in 1990. He also received the Penrose Medal, the premier medal for research, from the Geological Society of America in 2000.

Bob was born in September 1925 in Shaker Heights, Ohio. He earned all his degrees—BS, MS, and PhD, the PhD in 1952—from Pennsylvania State College. His mentor at Penn State was Paul D. Krynine, legendary at the time as a leader in the emerging field of sedimentary rocks. Bob did not own a car when he was a graduate student, so topics for his Master’s thesis and PhD dissertation were determined by the rocks that he could reach by bus from his apartment in State College, prefacing later expeditions by train and bus to localities in Italy. His dissertation was on Cambro-Ordovician carbonate rocks in the vicinity of Penn State. Unraveling the primary and diagenetic textures of these beds led to the first comprehensive carbonate classification scheme in English. Publication of the classification in the *Bulletin of the American Association of Petroleum Geologists* led to the best paper of the year award; it was a preview of Bob’s subsequent outstanding research.

Bob worked two years for the Gulf Oil Company before joining the University of Texas at Austin in 1952, retiring in 1988. At the University of Texas-Austin he supervised 26 Master’s and 14 PhD students. His teaching style would now be considered unusual—use of an Aboriginal wadi stick as a pointer, lab exercises dominated by rocks, extensive reviews of the literature, random-walk field trips, and so on. He repeatedly earned local and national awards, including the Neil Miner Award of the National Association of Geology Teachers (1989) and the Distinguished Educator Award of the AAPG (1998). He also has served as a visiting professor at the Australian National University, University of Milano, and Tongji University (PRC). At the University of Texas at Austin he served as the J. Nalle Gregory Professor in Sedimentary Geology from 1977–1982; and from 1982 until retirement in 1988 as the Dave P. Carleton Professor. He presently holds the title of Carleton Professor Emeritus.

Most of Bob’s major contributions are based on observations at the hand-specimen or thin-section scale, although in the last 10 years the scanning electron microscope has become a research instrument of choice. Repeatedly he has seen textures in rocks that other people overlooked or paid no attention to, in the process arriving at new and novel

interpretations of features. Bob has made fundamental contributions on the classification of sandstone, limestone, and mudrock and codified such common parameters as textural maturity, grain-size statistics, rock color, grain roundness, grain shape, identifying and naming architectural components of sandstone, limestone, dolomite, mudrock, and chert. His *Petrology of Sedimentary Rocks*, a soft-bound locally published semi-text, which first appeared in 1957, and was revised periodically until 1980; sold for little more than production costs. The 1980 version is available “on line”; it remains a fundamental resource of sedimentary petrologists. His curiosity-generated projects outside mainstream sedimentary geology have led to publications on the petrology of avian urine, the petrography of roofing tiles, enhanced stereo vision using two hands, black phytokarst from Hell, shape development on Tahiti, a unit of scuffle abrasion on stone steps, vitrified rat feces of aragonite, and a challenge to the concept that the pyramids of Egypt are made of epoxy-cemented crushed stone. His citation index is off the chart when compared with most other academicians; this reflects the fundamental importance of his contributions over the years. His research has been accomplished with almost no external funding.

Not all of Bob’s contributions have been widely accepted. His ideas on sediment transport, as he says, sank like a stone. His suggestion that ultra-small bacteria (<0.1 μm), called nannobacteria, are directly or indirectly responsible for the precipitation of many carbonate, silicate, oxide, sulfide, and possibly other minerals has been rejected by most microbiologists and questioned by many geologists. However, there is also strong support for his hypothesis. The verdict on this issue has not been rendered, but the research illustrates once again how Bob recognized textural elements in SEM images of rocks that had been ignored or overlooked by other workers.

In 1972, when Bob was a visiting professor at the University of Milano, he fell in love with Italy. This led to his admiring most things Italian and Italian rocks became a major research focus. His nickname now is Luigi rather than Bob.

Earle F. McBride

GROVE KARL GILBERT (1843–1918)

One of the greatest American geologists of the nineteenth century—a man who should be ranked with Lyell, Agassiz, and Smith—is Grove Karl Gilbert, born May 6, 1843 in Rochester, NY, and who died May 1, 1918 while preparing for another field season in Utah. His intellectual contributions were theoretical and institutional, ranging from the concept of dynamic equilibrium of landscapes to founding member and Chief Geologist of the United States Geological Survey. He was one of the premier scientific explorers of the American West and it is not coincidental that his lifetime is called the heroic age of American geology.

Born the son of a self-taught portrait painter, Gilbert was the youngest of three children. He received a classical education studying at home and from the University of Rochester where he emphasized Greek and Latin; he took but

one geology course. After a failed attempt at teaching school on the Michigan frontier, he landed a job at Cosmos Hall, the famous distributor of natural history artifacts run by Henry A. Ward. This in turn led to a position with the Ohio Geological Survey as a volunteer, where he came under the tutelage of John Strong Newberry. Two years later Newberry recommended him for the position of geologist on the US Army's Geographical Survey West of the 100th Meridian. He remained an employee of the US Government for the rest of his life, joining the Powell Survey in 1875, and the fledgling United State Geological Survey in 1879.

Gilbert's principal contributions to sedimentology are contained in his four great monographs: *Report on the Geology of the Henry Mountains* in 1877; *Lake Bonneville*, 1890; *The Transportation of Debris by Running Water*, 1914; and *Hydraulic-Mining Debris in the Sierra Nevada*, 1917. In the third and final part of the Henry Mountains report he erected the foundations of modern geomorphology. Conceiving of a stream as an engine which performs work and applying the laws of conservation of energy and least action, he codified three laws of land sculpture and invented the fruitful concept of dynamic equilibrium of landscapes and its derivative, the graded stream. He also presented the concept of bed-load as a corrosion tool in bedrock streams and articulated for the first time the conditions under which streams will form lateral planation surfaces.

In his Lake Bonneville studies the objective was twofold: "the discovery of the local Pleistocene history and the discovery of the processes by which the changes constituting that history were wrought." Here is the first description of the origin of coastal features such as spits, bars, and wave-cut terraces as a product of the balance between wave energy and sediment supply as it affects littoral drift and the first sedimentologic description of the delta type which still bears his name. Its everlasting contribution however, was primarily methodological. In this one quarto volume Gilbert showed how sedimentary processes could be deduced from geomorphic forms using the proper application of mechanical laws.

Gilbert's monograph on bed-load transport (with E. C. Murphy) is a seminal document in experimental sedimentology. It is the first systematic attempt to formulate the functional relationships between bed-load flux and flow energetics, the only exception possibly being the work of C. Lechalas in 1871. The experiments were conducted in four flumes of varying sizes. In each, the capacity of the flow was measured as a function of seven variables: discharge, slope, fineness of debris, depth, width, and to a lesser extent, mean velocity and channel curvature. Although Gilbert was never able to reduce the data to a rational theory of bed-load transport, he succeeded in formulating the basic questions and concepts. Besides providing practical formulae relating capacity to discharge, slope, and width/depth ratio, he described the particle dynamics of the moving bedlayer, the threshold of motion as a function of grain diameter, and the role played by fines in increasing the capacity of the coarse fraction in bimodal mixtures. While others, especially French engineers, had conducted flume experiments before Gilbert, his methodology, mathematical formulations, and physical explanations were unrivaled. The experimental design was so well conceived and the observations so meticulously taken, the data are still used today.

In his last monograph Gilbert applied these flume results to address the natural and man-made problems arising from

excess sediment supply to the Sacramento River system. Using his idea of a graded stream, he predicted the effectiveness of various engineering structures to control flooding along its course. And in a final rhetorical flourish he predicted that the tidal bar at the mouth of the Golden Gate would move inland as a consequence of reduction in tidal prism as the bay was filled by mining debris and agricultural sediment runoff. The power of this work was not in the social change it effected, but in the template it provided for subsequent conservation literature.

In separate contributions he published on the origin of bedforms, in particular ripples marks, ripple drift lamination, and "giant wave" ripples, from which he attempted to deduce ancient water wave heights.

AMADEUS WILLIAM GRABAU (1870–1946)

Born of German heritage in Cedarburgh, Wisconsin, January 9, 1870, the young Grabau was raised in a bilingual family. His fluency in German proved later to be an asset in his drive to bring advanced concepts in sedimentology and stratigraphy to American classrooms. In particular, Grabau was strongly influenced by the German geologist Johannes Walther (*q.v.*), to whom in 1913 he dedicated his textbook, *Principles of Stratigraphy*. A correspondence course in mineralogy from the Massachusetts Institute of Technology started Grabau's formal education in geology. He graduated from that institution with a BS degree in 1896. Grabau earned his MS and DSc degrees from Harvard University in 1896 and 1900, respectively. His subsequent career may be divided into an American phase from 1900–1919, when he was associated principally with Columbia University, and a Chinese phase from 1920–1946, when he held joint appointments at the National University of Peking (now Beijing University) and the Geological Survey of China. Grabau remained in China during the Second World War and died in Peking, March 20, 1946. His gravesite and memorial is located on the campus of Beijing University.

Regarded overall as a stratigrapher and paleontologist, Grabau's impact on sedimentology came during his early career through various attempts to devise a comprehensive classification scheme for sedimentary rocks. The most detailed treatment occurs in *Principles of Stratigraphy* in a single 30-page chapter out of a total text of 1,185 pages in 32 chapters. Grabau divided all rocks into two groups: exogenetic as opposed to endogenetic. He defined exogenetic rocks as those formed by agents acting from the outside to break down pre-existing materials. Endogenetic rocks were classified as those formed by agents acting from within, for example precipitation of minerals from solutions. Essentially, his dichotomy

corresponds to clastic and nonclastic rocks. In an earlier 1911 paper, Grabau stressed that after the question of origin, texture was the next most important consideration. He applied the terms rudaceous, arenaceous, and lutaceous to clastic particles that range in size from boulders to clay. Other terms coined by Grabau, such as calcirudytes, calcarenytes, and calcilutytes still are used for various grades of bioliths, or limestones. Derivation of new terms from classical roots was a proclivity of Grabau's. In a state of mild exasperation, Joseph Barrell (*q.v.*) offered a written response to an abstract by Grabau on the classification of marine deposits, suggesting that English terms "perfectly clear and quite as sharp" might be used in place of those derived from Greek. As an example, Barrell preferred "shallow-sea deposits" for the "Thalassigenous deposits" proclaimed by Grabau (1913).

Grabau's lasting influence was as a compiler with an encyclopedic mastery of materials and concepts. To regard his massive *Principles of Stratigraphy* as a textbook devoted strictly to the study of layered rocks would be a gross underestimation. His command of the topic was expansive, as indicated by the array of contents in separate sections on the atmosphere, hydrosphere, lithosphere, pyrosphere (on volcanism), and centrosphere (on internal earth dynamics). Grabau's outlook was entirely holistic and careful examination of the contents of *Principles of Stratigraphy* reveals that well over half the book is devoted to topics closely allied with sedimentology. Individual chapters, for example, deal with evaporites, eolian deposits, fluvial deposits, swamp deposits, reef and algal deposits, and deep-sea deposits. His handling of stratigraphy in the broadest sense, was thus prescient of contemporary texts that combine the studies of sedimentary environments and stratigraphy. Grabau (1917) may have shown his ultimate passion, however, with the prediction that "In future, the study of lithogenesis must go hand in hand with the study of paleogeography."

AMANZ GRESSLY (1814–1865)

Gressly was born in Switzerland, and became interested in geology while a medical student in Strasbourg. In 1838, he

published in French "Geological observations on the Soleurois Jura." This work was carried out under the direction of Jules Thurmann, and contains the analysis of facies that is generally considered to be Gressly's main contribution to geology. The paper, and his extensive collections of fossils, led to his appointment as an assistant to Louis Agassiz: when Agassiz left for America in 1846 he took many of Gressly's fossils with him, but left Gressly and his other assistants (Eduard Desor and Carl Vogt) behind. Gressly was then employed in engineering studies for railroads in Switzerland, but found time to explore ecological zones on the Mediterranean coast (Schneer, 1972).

The parts of Gressly's 1838 paper related to facies have been reprinted, with a critical commentary by Wegmann (1963) and discussed by many other authors, most recently by Cross and Homewood (1997). Gressly explained how he was led to develop the concept of facies:

"In the regions that I have studied, perhaps more than anywhere else, very variable modifications, both petrographic and paleontologic, everywhere interrupt the universal uniformity that, up until now, has been maintained for different stratigraphic units ("terrains" in the original French) in different countries. They even reappear successively in many stratigraphic units and astonish the geologist who wishes to study the nature of our Jurassic ranges..."

"There are two principal points that always characterize the group of modifications that I call *facies* or *aspects of stratigraphic units*: one is that a similar petrographic aspect of any unit necessarily implies, wherever it is found, the same paleontological assemblage; the other, that a similar paleontological assemblage rigorously excludes the general and species of fossils frequent in other facies." (Gressly, 1838, pp. 10–11, translated from the French: the emphasis is Gressly's own.)

WILLIAM CHRISTIAN KRUMBEIN (1902–1979)

William Christian Krumbein, father of computer geology, pioneer in application of statistical techniques to sediments and sedimentary rocks, and innovator of sediment analyzes, was born in Beaver Falls, Pennsylvania on January 28, 1902 and died of a heart attack in Los Angeles, California on August 18, 1979. His specialties were the study of physical properties of sediments, application of statistics to sedimentology, dynamics of sedimentary processes, and regional sedimentary analysis. His degrees included a PhB in business administration (1926), and a MS in geology (1930) and PhD (1932) both from the University of Chicago, and a DSc

(honora causa) from Syracuse University in 1979. He advanced through the academic ranks from assistant to associate professor at the University of Chicago and after working for the Beach Erosion Board of the US Corp of Engineers during WWII and a short stint with Gulf Research and Development Company (1945–1946), joined Northwestern University as a full professor in 1946, later made William Deering Professor of Geological Sciences, retiring in 1970.

His first papers in 1932 were on the mechanical analysis of fine-grained sediments and his last was on probabilistic modeling in 1978. (He was senior author posthumously on, *CORSURF: a Covariance-Matrix Trend Analysis Program*, published in *Computers & Geosciences* in 1995.) He explored sampling, textures, size distribution, diagenesis, transport, properties, and classification of modern and ancient sediments. He was one of the early workers to apply quantitative techniques, including descriptive statistics, Latin square experiments, regression analysis, Markov chains, and probabilistic modeling, extensively to geological problems.

With introduction of the computer in the mid 1950s, he transferred his statistical analyzes from the calculator to the computer; in 1958, he published (with L.L. Sloss) the first geologically oriented computer program (in SOAP). His last publications were philosophical in nature as he explored the directions and influences of quantification on sedimentology. He had an uncanny analytical mind and could cut through the extraneous material directly to the problem.

He carefully formulated and presented his ideas in his 130+ publications including 5 books. His manual with Francis Pettijohn, *Manual of Sedimentary Petrography* (1938), was a standard text for several decades as was his book with Larry Sloss on *Stratigraphy and Sedimentation* (1951, 1963). However, it was his book in collaboration with Frank Graybill in 1965, *An Introduction to Statistical Models*, that put him in the forefront of quantitative sedimentology. Krumbein co-authored several papers with leading statisticians of the day including John Tukey, Geoff Watson, Frank Graybill, Ron Shreve, and Mike Dacey.

He was a founding member of the International Association for Mathematical Geology (IAMG), was elected the first Past-President of the Association, and their premier award was named the William Christian Krumbein Medal in his honor; these tributes indicate the esteem held for him by his peers. He was a fellow of GSA, AAAS, and ASA; member of SEPM (President in 1950), SEG, AAPG, and AGU. He received a Guggenheim Fellowship, was a Fulbright Lecturer, and a President's Fellow at Northwestern University.

Statistical Analysis of Sediments and Sedimentary Rocks

PAUL DIMITRI KRYNINE (1902–1964)

Paul D. Krynine was born in Siberia, the son of Dimitri P. Krynine, an engineer who travelled with his family to Argentina (1909–1917), then back to Moscow, where Paul graduated with a BSc in geology in 1924. Paul then emigrated to the United States, obtained a second bachelor's degree in geology at Berkeley (1927), and worked for Standard Oil of California for three years in Mexico. At this time his father also left Russia and became professor of soils engineering at Yale; Paul moved to Yale in 1931, and completed his doctorate there in 1936. He then accepted a teaching position at Penn State University where he remained until his death in 1964.

Krynine's doctoral thesis was a detailed study of the Triassic of the Connecticut Basin, a study which set new standards for sedimentary petrographic work in America (publication was delayed by the Second World War until 1950). Krynine made use of his experience in Mexico to argue that arkoses were not necessarily, or even most probably, deposited in arid climates. Humid climates, combined with active tectonic uplift of suitably feldspar-rich source rocks, and burial in a rapidly subsiding basin, was the most probable explanation. He also noted that red soils, which he considered important in the deposition of red arkosic beds, were confined to humid climates (his study of red beds in Mexico was, however, flawed by inadequate field work). These views started a long fruitful debate about the relative importance of tectonics, climate, and diagenesis in controlling the major mineralogy of sandstones (with most sedimentologists now inclined to the opinion that Krynine underestimated the importance of diagenesis).

In Pennsylvania, Krynine produced petrographic studies of the Third Bradford Sand, a major Devonian oil reservoir, and

a sandstone with many “low rank metamorphic” rock fragments, and the Oriskany Sandstone, a pure quartz sandstone. Out of these, and other studies came Krynine’s famous “megascopic” classification of sandstones into four main types: arkoses (with few fine-grained rock fragments), low and high rank greywackes (rich in fine grained rock fragments, and either poor—low rank, or rich—high rank, in feldspar), and the Orthoquartzites that were derived from them by much sedimentary recycling. Krynine presented these ideas in 1948 with the aid of the first triangular diagram used in sedimentary petrology: the classification was designed to be used for *field* classification using a hand-lens, so exact numerical boundaries between petrographic fields were never specified. This work, and Krynine’s earlier ideas about tectonic control, were presented at meetings but published, if at all, only in obscure conference proceedings (Folk and Ferm, 1966, give a complete bibliography, and an exposition of some of his obscure publications: see also Bates and Griffiths, 1971). Nevertheless, Krynine’s ideas were very influential, focused attention on refined petrographic interpretation of the major (light) constituents of sandstones (not just the heavy minerals, which were the focus of much attention in earlier decades), and set off many other attempts at sandstone classification. Krynine did not neglect heavy minerals, either and was one of the first since Sorby to expose the wealth of information that can be obtained by studying the compositional and textural *varieties* of key minerals, particularly stable minerals such as quartz and tourmaline. His basic concepts were extended by Robert L. Folk (one of his doctoral students) to produce the first generally accepted classification of limestones.

Krynine was an eccentric personality, no field geologist (he was almost blind), but a highly perceptive petrologist and an extraordinarily effective teacher. His teaching style and influence have been amply documented by his students (Folk, Ferm, Williams) and contemporaries (Griffiths, van Houten): together he and Griffiths made Penn State one of the three major schools for sedimentology in America in the 1940s and 1950s (the others were Chicago, with Pettijohn and Krumbein, and Northwestern with Dapples, Sloss, and Krumbein after he left Chicago). These were the decades when sedimentology came to maturity in the United States.

Sedimentologists: Robert L. Folk, Francis J. Pettijohn

PHILIP HENRY KUENEN (1902–1976)

Philip Kuenen was born in Scotland. His father was a Dutch physicist and his mother was English: they moved to Leiden in 1907, where Kuenen received all his education (including his doctorate in economic geology in 1925). He served as geologist on the *Snellius* expedition in 1929–1930. In 1934 he was appointed lecturer in Groningen, and remained there until his retirement in 1972.

Kuenen made major contributions in three main areas: experimental geology, marine geology, and sedimentology. In experimental geology, his main studies of sedimentological interest were: (1) a long series of experiments on the attrition of grains by sediment transport both in air (using a wind-tunnel) and in water, using a horizontal “racetrack” flume with the flow driven by a paddle wheel; (2) experiments on sedimentary structures, including ripples, plane lamination, and load structures (“pseudonodules”); and (3) studies of turbidity currents and their deposits (see below).

His paper of 1965 defends the experimental approach, and gives a summary of many of the results. He was himself an excellent experimentalist, with a fine physical intuition, but with almost no knowledge of mathematics or theoretical mechanics. His studies on attrition established that aqueous transport, even for long distances, was incapable of producing major changes in the size and shape of resistant mineral sand grains, such as quartz: thus well-rounded quartz grains must have undergone at least one cycle of wind transport. Earlier studies, using tumbling mills, did not duplicate natural processes, and so gave an exaggerated estimate of the attrition resulting from transport in water.

Kuenen’s interest in marine geology dated from his experience as geologist on the *Snellius* expedition and included studies of coral reefs, eustatic changes of sea level, and calculations of the total mass of sediments in the oceans based on geological–geochemical cycles. His views were summarized in his influential textbook *Marine Geology*, published in 1950. Later he collaborated with his colleague L.M.J.U. van Straaten in series of studies of sediment transport and deposition on Dutch tidal flats (see *Sediment transport by Tides*).

Kuenen is undoubtedly best known for his development of the turbidity current theory for the origin of graded sand beds. The studies began as an experimental attempt (1937) to test Daly’s hypothesis that muddy density flows were responsible for the erosion of submarine canyons. Experimental work continued during the war, while Kuenen was confined to the laboratory. The emphasis soon changed to the ability of turbidity currents (a term suggested by Johnson) to transport and deposit sand in deep water. The results were first presented at the International Geological Congress in London in 1948, and led immediately to collaborative papers with Migliorini, who had been studying graded beds in the field in the Apennines, and with Natland, a micropaleontologist who had faunal evidence that many of the sands and conglomerates in the Cenozoic Ventura Basin in California had been deposited in deep water. Natland organized a symposium at the SEPM meeting in Chicago in 1950, and he and Kuenen carried out field work together in California. The symposium volume was published in 1951. A detailed history of the period has been

given by Walker (1973). Kuenen's work, together with that of coworkers and that of Heezen and other marine geologists at Lamont undoubtedly changed the way that geologists interpreted thick series of graded beds, previously thought to have been deposited somehow in shallow water, even though they did not display many of the structures (e.g., cross-bedding) thought to be typical for sands deposited in shallow environments.

Following the war, Kuenen was a strong advocate of turbidity currents and conducted field studies in many different regions. He recognized, described and explained many of the structures typical of such deposits, and helped to develop the growing field of paleocurrent studies in the 1960s and 1970s. One result from these studies was the discovery that in many sedimentary basins, sediment derived from the sides or end of the basin was transported mainly longitudinally, along the basin floor.

JOHN MURRAY (1841–1914) AND THE CHALLENGER EXPEDITION

The voyage of HMS Challenger (1872–1876) was a major event in the history of oceanography and in the knowledge of the deep sea. It was initiated and led by C. Wyville Thomson, but after his stroke he was forced to resign the Directorship, and turn over the publication of the results to John Murray. Murray oversaw the publication of 50 volumes in the years from 1880 to 1895: five of the volumes he coauthored himself, including one on the *Deep-sea Deposits* (1891).

John Murray was born in Cobourg, Ontario and attended school there until 1868, when he moved to Scotland, living with his grandfather, and attending Stirling High School, and then the University of Edinburgh. Though it was originally intended that he should become a medical doctor, he followed an irregular course of study, earning himself a reputation as a "chronic student," and never graduated. Besides some medical courses, he studied physics with Tait, and geology with Geikie. He also participated in a voyage to Spitsbergen, when he became interested in marine biology. By chance, one of the assistant naturalists appointed to the *Challenger* expedition was forced to resign, and, at Tait's recommendation, Thomson appointed Murray to replace him.

Murray's interests remained very broad, but on the *Challenger* he was assigned the bottom sediments as his main responsibility. A preliminary report, sent to the Royal Society from Valparaiso, and published in the *Proceedings* in 1875, already recognized "Shore deposits," "*Globigerina* ooze," "Radiolarian ooze," "Diatomaceous ooze," and "Red and Green clays." The *Challenger* travelled 110,000 km in the Atlantic and Pacific Oceans, and took soundings, dredgings, and bottom samples at 362 stations, thus achieving a major advance in knowledge of the biology and sediments of the deep sea. The final report, written with the Abbé Alphonse Renard, of the Brussels Museum, was not restricted to the *Challenger* samples, but also used comparative material from many other sources. It provided, for the first time, a classification and detailed description of deep-sea sediments (including also "Pteropod ooze" and iron-manganese nodules), which could be compared with sediments in the geological record.

The shallow-water nature of most sedimentary rocks was rarely questioned in America, but many European authors believed that some geosynclinal sediments, notably radiolarian cherts were deposited in the deep sea (e.g., Neumayer in 1876; Haug in 1900; and Steinmann in 1905). Though this interpretation remains controversial, plate tectonics suggests that some radiolarian sediments, associated with ophiolites, may in fact have been deposited at great depths. At first the Cretaceous cherts of Europe were compared with *Globigerina* ooze, but more detailed comparison with the *Challenger* samples soon showed significant differences. Undoubted deep-sea deposits were, however, described by Gregory in 1889 from Barbados and by Guppy in 1892 from Trinidad.

Besides his work on deep-sea sediments, Murray became a leading authority on coral reefs, opposing Darwin's subsidence theory of atolls and barrier reefs. The controversy was in part responsible for the drillings (1896–1898) on Funafuti commissioned by the Royal Society. The results, reported in 1904, remained inconclusive. After discovering a sample of phosphate rock from Christmas Island (in the Indian Ocean) in collections made for comparison with *Challenger* material, Murray first persuaded the British Government to annex this uninhabited island, and then organized a company to explore and ultimately exploit this resource. The population reached 1,500 inhabitants, and Murray claimed that the government received much more in royalties and taxes than the entire cost of the *Challenger* expedition! He used his own profits to finance further oceanographic research.

Late in life, Murray participated in several other expeditions, including investigations of Scottish fjords and lochs, and a four-month cruise (1905) of the Norwegian ship *Michael Sars*, together with Johan Hjort. The results were later included in their book *The Depths of the Ocean* (1912). Three years later Murray published a popular book on oceanography. He remained active until he died in 1914 as a result of an automobile accident.

FRANCIS J. PETTIJOHN (1904–1999)

His life, 1904–1999, spanned most of the 20th century and he influenced many. By the time he finished high school, Francis Pettijohn knew he wanted to be a geologist. All his academic training was at the University of Minnesota (BA, 1924; MA, 1925; and PhD, 1930), where Professor Grout was his advisor and the Precambrian of Minnesota was the great center of geologic interest, which was studied through fieldwork, thin sections, and a few wet chemical analyzes. He taught briefly as a graduate student at nearby Macalester College, but spent 1925–1927 at Oberlin College in Ohio. His article “Geology at Oberlin a Half Century Ago,” published in the Oberlin alumni magazine in 1980, is a fine insight to a small Midwestern geology department in the late 1920’s. Francis developed his teaching skills and studied the beaches of Lake Erie, but he spent some of his summers in the North Woods. In 1927–1928 he was a Fellow at the University of California, where he became acquainted with Andrew E. Lawson from whom he learned much.

In 1929, Francis moved to the University of Chicago and started a program in sedimentary rocks with two sedimentology courses. He and W. C. Krumbein published *A Manual of Sedimentary Petrology* in 1938, a landmark book that was recently reprinted, and *Sedimentary Rocks* (1949), which established his reputation worldwide. His most famous paper at that time was “Archean Sedimentation” published in the GSA Bulletin in 1943. During these Chicago years he spent nearly every summer in field studies in the Lake Superior region for the Michigan and US Geological Surveys and the Geological Survey of Canada. During these prewar Chicago years he was active with the National Research Council in Washington, the forerunner of today’s National Science Foundation, and often commented on how stimulating these small meetings were. Someone would bring along a puzzling rock and a wild discussion would break out. Later he edited the *Journal of Geology* for six years and traveled abroad, mostly to international meetings.

When he was 48 years old, Francis moved to The Johns Hopkins University in Baltimore in 1952, where he remained for the rest of his life, becoming emeritus in 1973. He left Chicago because fieldwork was considered old fashioned. At Johns Hopkins, Francis discovered the Appalachians, had new colleagues and had the most productive part of his career. He published *Paleocurrents and Basin Analysis* (1963) and *Sand and Sandstone* (1972), later translated into Russian and Chinese, and he revised *Sedimentary Rocks* (1976) for the third time. He also published *Atlas and Glossary of Sedimentary Structures* (1964) and *Memoirs of an Unrepentant Field Geologist* (1988), and helped edit *Studies of Appalachian Geology, Central*

and Southern (1970), and wrote *A Century of Geology, 1884–1984*, at the Johns Hopkins University (1988). While at Johns Hopkins, he received many foreign visiting geologists who came to the United States at the invitation of the US Geological Survey. With all of these activities, Francis had time to be a Councilor of the Geological Society of America and to serve on several advisory boards.

The following special qualities and viewpoints were typical of Francis and served him well throughout a spectacularly successful, long life. He had sufficient self-confidence that he could fully appreciate and easily work with talented people and learn from them. He had the ability to read an article critically (thanks to Andrew Lawson). He persuaded with good observations, rationality, and tact. Conversely, even though Prof. Pettijohn had some strong opinions, he was conservative in his expression of them. Francis followed the rule, “Clarity of expression is best achieved by simplicity of expression.” His favorite short and simple rule was, “Only outcrops keep geologists honest,” which goes far to explain the common-sense attitudes seen in his writing.

Francis’s influence on the profession was great and extended worldwide. Even as late as 1998, 25 years after he retired, his publications were cited 57 times; from 1990 to 1998, they were cited 497 times. His influence was transmitted through his books, his key articles, and his many students and visitors. Many of his students became prominent in the US geological and Canadian Geological Surveys, the petroleum industry, and university teaching. Many people had the opportunity to work with him and watch how he approached and resolved geologic problems—by asking questions that could be answered by the direct logical study of rocks or sediments rather than questions based on broad physical, chemical, or geological principles. Right or wrong, his analysis of a problem always employed a strong internal logical consistence and a full review of the prior literature.

Paul E. Potter

RUDOLF RICHTER (1881–1957), AND THE SENCKENBERG LABORATORY

Rudolf Richter (Figure S20(A)) was born on November 7, 1881 at Glatz in Silesia and studied at the Universities of Munich and Marburg. Richter worked under the tutelage of Emanuel Kayser and completed his doctorate at Marburg in 1909, his doctoral dissertation was published under the title “Beitraege zur Kenntnis devonischer Trilobiten aus dem Rheinischen Schiefergebirge” (Contributions to the knowledge of Devonian trilobites from the Rheinische Schiefergebirge). Richter is generally regarded as having been one of the most influential geologists of his time, his influence reaching far beyond the boundaries of Germany. Biographical works include Stubblefield (1957), Kegel (1957), Schmidt (1982), and Burghard Flemming (personal communication) provided insights on both Richter and the Senckenberg Laboratory.

After leaving Marburg Richter earned his living as a high school teacher in Frankfurt, his scientific work being carried out in his spare time. In 1908 he joined the Senckenberische

Figure S20 The Richters; (A) Rudolf Richter 1881–1957; and (B) Emma Richter 1888–1956. (Photographs courtesy of the University of Frankfurt.)

Naturforschende Gesellschaft and in 1919 he launched the journal *Senckenbergiana* to mark the centenary of the society. Richter maintained the editorship of that journal until his death in 1957. He also founded and edited its popular magazine *Natur und Museum*. In 1920 Richter was appointed Privat Dozent in Geology and Paleontology at the Johann Wolfgang Goethe University in Frankfurt; in 1925 he became Extraordinary professor, and in 1934 Ordinary Professor and Director of the Geological and Paleontological Institute a position he held until his retirement in 1949. In 1932 Richter took control of the Society and in 1933 was named “Leiter” and also took over the directorship of the Natur-Museum at Frankfurt.

Richter married Emma Hüther (Figure S20(B)) in 1913 and they enjoyed a remarkable collaboration. Emma was a skilled artist and was invaluable in their joint work on trilobites and the series of ichnological papers. The papers on animal-sediment relationships were fundamental in establishing basic principles on how organisms affect the substrate. Their ichnological work also established the zoological affinities of many trace fossils and became the corner stone for further work in actiupaleontology and actuoichnology. Emma died on November 15, 1956.

In 1929 with the support of the Senckenberg Society and the German Navy Richter established the Senckenberg Vorschungstelle für Meeresgeologie und Meerespaläontologie at Wilhelmshaven which was subsequently known as “Senckenberg am Meer” (Senckenberg by the Sea). The institute is presently housed in a building named after him, the “Rudolf Richter Haus”. Richter’s interest in the modern marine environment was documented as early as 1920 when he gave an inaugural lecture at Frankfurt University entitled “Die Erscheinungen des Wattenmeers in ihrer Bedeutung für die Geologie” (The manifestations of the Wadden Sea and their significance for geology). The station was founded with the specific aim of studying animal-sediment relationships in the intertidal environment in the Wadden Sea. It was the first institution founded with the specific aim of actively applying the actualistic concepts of Charles Lyell, following the principle “the present is the key to the past”. The Wadden Sea has been the enormously successful hunting grounds of well-known Senckenbergian researchers such as Walther Häntzschel, Wilhelm Schäfer, and Hans-Erich Reineck. It

was instrumental in establishing Germany as the home of ichnological research and shallow water marine sedimentology. The Senckenberg Lab has been used as the model for other facilities around the world including the Sapelo Island Marine Institute in Georgia. In fact these two institutes had very close ties in the 1970s and did joint work on the sedimentology and animal-sediment relationships of modern shoreface and estuarine environments (see Howard *et al.*, 1972 and Howard and Frey, 1975). Today the station houses the Marine Science Division of the Senckenberg Institute and the legacy of excellence left by Richter, Häntzschel, Schäfer and Reineck continues.

Richter received many honors including honorary membership in the Société belge de Géologie, Paléontologie et d’Hydrogéologie, the Paläontologische Gesellschaft and the Paleontology Society of America. He was also the recipient of the Gold Medal of the Paläontologische Gesellschaft and the Hans Stille Medal given by the Deutsche Geologische Gesellschaft. To celebrate his seventieth birthday former students and friends put together a special Festschrift volume published by the Senckenbergische Naturforschende Gesellschaft. Rudolf Richter passed away at Frankfurt on January 5, 1957.

HENRY CLIFTON SORBY (1826–1908)

Henry Clifton Sorby lived all his life in Sheffield, England. He never married, and inherited enough money from his father to pursue a life of independent scholarship and scientific research. He made major contributions to microscopy applying the newly discovered polarized light technique to the study of rocks, meteorites and metals, earning the titles “Father of Petrography” and “Founder of Metallography”. Later he worked on spectrum analysis, and coastal marine biology, using his own 35-ton vessel.

Sorby never attended university: his main forum for the exchange of ideas was the local Literary and Philosophical Society, though from the beginning of his active research career (in 1851) he presented papers to the Geological Society of London, the British Association for the Advancement of

Science, and other well-known societies. Later in life he helped found the Royal Microscopical Society (1874) and the Mineralogical Society (1876: he was the first president), and was active in the Geological Society, becoming president in 1878–1880.

Sorby's first petrographic study was of a "Calcareous Grit," and he went on to make major discoveries about the nature of calcareous rocks and their diagenesis: many of these were summarized in his Presidential Address to the Geological Society (1879). He distinguished the different types of grains making up limestones, and described the mineralogy and textures of bioclasts, and their influence on resistance to mechanical attrition and chemical alteration. He demonstrated the original calcitic nature of Paleozoic corals, as opposed to the aragonitic nature of most later corals. He described oolites, and proposed a mechanical "snowball" origin, followed by recrystallization, and recognized that some ancient oolites were originally aragonitic, while others were calcitic. His petrographic studies were soon extended to minerals found in other rocks, particularly sandstones (1877, 1880), and he paid particular attention to the mineral and fluid inclusions found within mineral grains (1858), showing experimentally how fluid inclusions could be used to deduce the temperature and pressure at which the minerals had originally formed. His combination of microscopic and experimental studies also provided the first clear evidence that slaty cleavage was formed by deformation under anisotropic stress (1853).

Sorby was also interested in the hydraulics of sediment transport and structure formation. He observed in a small stream how ripples formed soon after sediment began to move, but were washed away leaving a plane bed at higher flow intensities. He observed ripple cross-lamination and attributed it to "ripple drift" and described climbing sets (1859). He proposed that cross-bedding ("drift bedding") formed by migration of microdeltas. He also systematically recorded the orientation of ripples and cross-bedding and proposed that they be used to study paleocurrents, long before this became standard practice.

In retrospect it seems strange that Sorby's work did not inspire similar studies by his contemporaries. The work on limestones lay fallow (with rare exceptions, such as Cullis' study of the Funafuti cores, and Cayeux's work in France) until the revival of carbonate petrology in the 1950s. The textural and mineralogical study of sands fared better, but the main emphasis was on the "heavy minerals" and on mineral inclusions. Sorby's work on ripples and cross-bedding remained largely unknown, even after the revival of interest in America, due to the work of Gilbert, Kindle, and Bucher, until rediscovered in the 1960s. Paleocurrent techniques were developed in Germany (Brinkmann and others) and America, before being taken up again in Sorby's homeland.

Sedimentology, History

WILLIAM H. TWENHOFEL (1875–1957)

William H. Twenhofel was prominent in the emergence during the 1920s–1930s of a new specialty called sedimentation, which became known as sedimentology during the 1950s. He was born on a northern Kentucky farm to German immigrant parents. Twenhofel's formal education began in public country schools and a private secondary school. For eight years, he taught grade school and studied at a normal (teachers) college until he qualified for a position at East Texas Normal College. After three years at Commerce, Texas, he entered Yale University at the age of 32, where he earned AB, MA, and PhD degrees within four years. He had intended to pursue mathematics, which he had been teaching, but an emergency assignment to teach geology showed him his true calling. At Yale, Professor Charles Schuchert suggested a dissertation on fossils of the Ordovician–Silurian boundary in Maritime Canada, which became the foundation for his first career, paleontology and stratigraphy. But also at Yale, Joseph Barrell had planted interests in weathering, erosion and sedimentation, which would blossom into Twenhofel's later and more famous sedimentation career. In his presidential address to the Paleontological Society in 1931, Twenhofel blended the two with a talk about the importance of sedimentary environments to paleoecology.

After six years at the University of Kansas, Twenhofel joined the University of Wisconsin in 1916. His sedimentological career began in 1919 with appointment to the National Research Council's Committee on Sedimentation. As chair of the Committee (1923–1931), he was the principal author of *A Treatise on Sedimentation*, a 661 page synthesis published in 1926, which defined the new specialty. In that same year, he was also a co-founder of the Society of Economic Paleontologists and Mineralogists (SEPM), the first professional society for sedimentology. From 1933 to 1946, he was editor of the first journal in the discipline. *The Journal of Sedimentary Petrology*, which was published by SEPM. After the *Treatise* appeared, the National Research Council capitalized upon his unusual talents by enlisting him to organize a Committee on Stratigraphy and another on Paleocology.

Like many sedimentary geologists of his day, Twenhofel's early publications were chiefly on stratigraphy and paleontology. Later he contributed papers on a very wide range of sedimentary topics, which included the origin of black shales, Cambrian glauconitic greensands and their potential as a source of potash fertilizer, marine conglomerates and unconformities, deep-sea sediments, reefs, and black beach sands.

In 1939 Twenhofel published the important text book, *Principles of Sedimentation*. He is also remembered for emphasizing the environments of deposition and paleoecology of sediments, for pioneering the study of temperate lake sediments, and for stressing the geology of soils and the importance of soil conservation.

As an educator, Twenhofel inspired countless introductory geology students as well as many post-graduate students; he was also active in public outreach. Twenhofel's importance to sedimentology was recognized by the creation in 1973 of the Twenhofel Medal as SEPM's highest honor. Other recognitions included an honorary doctorate from Belgium's University of Louvain awarded to him in 1947.

JOHAN AUGUST UDDEN (1859–1932)

Johan August Udden was the “father of sedimentology” in North America, although during his 49-year career he made contributions in stratigraphy, areal geology, eolian processes, till in the upper Mississippi valley, and other topics. He was born at Lekasa, Sweden, March 19, 1859, and in 1861 moved with his parents to Carver, Minnesota. He attended Augustana College in Rock Island, Illinois, and received a bachelor's degree in 1881, a master's degree in 1889, an honorary PhD degree in 1900, and an honorary Doctor of Laws in 1929. He taught natural science and other courses at Bethany College, Lindsborg, Kansas, from 1881 to 1888 as the first teacher of an institution established to enhance the education of Swedish emigrants to Kansas. Udden returned to Augustana College as the Oscar II Professor of Geology and Natural History and taught geology, botany, zoology, meteorology, astronomy, physiology between 1888 and 1911. Even with this crushing teaching load he published 46 papers. In 1911, Udden joined the Bureau of Economic Geology and Technology of the University of Texas and served as its director from 1915 until his death. Prior to moving to Texas he worked short periods for the Iowa Geological Survey, University of Texas Mineral Survey, and US Geological Survey.

Udden is best remembered as the originator of the Udden grain-size scale for sediments published in 1898 and 1914. In order to document the eolian origin of loess, which influential geologists, including J.D. Dana disputed, he collected till, glacial outwash, and wind-blown sediment around the Mississippi River valley and analyzed their grain

size distributions. He rejected a partially geometric scale used by soil scientists in favor of a totally geometric scale. He devised sieves to determine grain size distributions for gravel and sand to 0.06 mm and laboriously measured the diameter of finer particles, which he called dust, down to 4 μm under the microscope. He used histograms to help visualize his data. Chester Wentworth later changed some of the grain-size terms to establish the Udden-Wentworth scale that we use today. Udden was inventive in collecting eolian sediment. In addition to cylindrical sediment traps, he used glycerin-coated cloth attached to flagpoles, collected dust from melted snow, and swept sediment from the clothes of train passengers and from tree and corn leaves. After years of collecting sediment from various environments, in 1914 he published the first sediment grain-size database of 337 samples.

Udden's contributions extend far beyond grain-size analyzes. In 1905, he flew a model helicopter of his design. Using a horse, he studied the geology within 30 miles of Rock Island in great detail. He compiled a detailed picture of the artesian groundwater system in the area and used well cuttings and driller's logs to establish the subsurface stratigraphy. He recognized the potential value of well cuttings in a variety of geological endeavors and demonstrated this to the oil industry by establishing the first subsurface geology laboratory when he assumed directorship of the Texas Bureau of Economic Geology. In 1914, from a study of cuttings from a deep well in West Texas, he demonstrated the occurrence of extensive deposits of potash salts in the Permian basin. In 1916, on the basis of theoretical reasons and fieldwork done years previously, Udden advised the regents of the University of Texas of the likely occurrence of oil and gas on university lands in Reagan County, Texas. This led to the discovery of the first deep giant oil field in Texas and led to the development of the West Texas and eastern New Mexico oil province. Oil and gas revenues from university lands generated the permanent endowment of the Texas state university system. Udden's early work on the Permian in the Glass Mountains led to the establishment of that area as the type marine Permian of the world.

According to Charles Laurence Baker, a colleague of Udden in Texas, Udden's success can be attributed to his mastery of the basic natural sciences chiefly through his teaching, his ingenuity, and his ability to rely on his own powers of observation and reasoning. His ingenuity is exemplified by his invention of one of the earliest successful adding machines, and his ability to accomplish important results with cheap and simple devices. Udden early came to the conclusion that the best contributions he could make, given the limited opportunities available to him, was in fields neglected by others. In 1911, Udden was awarded the Swedish Order of the North Star by the king of Sweden.

T. WAYLAND VAUGHAN (1870–1952)

Thomas Wayland Vaughan, (born Jonesville, Texas, September 20, 1870—died Bethesda, Maryland, January 16, 1952) entered Tulane University in 1885, receiving a BS in Physical Sciences in 1889. From 1889 to 1892 he taught physics and chemistry at Mount Lebanon, Louisiana, where he encountered Eocene fossils, and became especially interested in corals. In 1892, Vaughan published his first two scientific papers (his bibliography lists about 350 titles until his last paper in 1946). The same year he enrolled in Harvard University and received a BA (1893) and a MA (1894). His PhD (1903) thesis was on Eocene and Oligocene corals.

Vaughan was a US Geological Survey, Assistant Geologist, 1894–1903; 1907–1923 he was geologist in charge of the Coastal Plain Subsection. Attending the 1897 International Geological Congress allowed him to examine European fossil coral collections and meeting Sir John Murray sparked his interest in oceanography. Two major Federal projects, resulting in more than 100 papers, occupied him between 1901 and 1923. First was Caribbean geologic and paleontologic studies. Vaughan assisted in Cuba in 1901, and in 1911 worked in the Panama Canal Zone. In 1914 he led an expedition to islands north of Guadalupe and west of Puerto Rico. In 1919 he examined strata in the Virgin Islands and eastern Puerto Rico. From 1919 to 1921 he directed reconnaissance geological studies in Dominica and Haiti. His second major effort concerned Atlantic and Gulf Coast coastal plain investigations, ranging from Mexico north to Cape Cod. In addition to these duties, with support from the Carnegie Institution of Washington, Vaughan studied recent and fossil corals and coral reefs in the Florida Keys and in the Bahamas from 1908 to 1915. He is reputed to have published more papers on corals than any of his predecessors or contemporaries. In 1922 he also began the study of larger Foraminifera, which subsequently became particularly important for stratigraphic dating in the Pacific Islands.

During his early days, stratigraphy and paleontology for correlation were mainstays of the geologic community. The first world war and the need for petroleum began to focus attention on rocks as such and sedimentation started to develop as a discrete discipline. The formation of the National Research Council in 1915 and its subsequent war efforts, served as a national focus for comprehensive geological investigations. Vaughan was member of the NRC, Division of Geology and Geography, 1919–1926 and chairman of the Committee on Sedimentation, 1919–1923. This committee laid the foundation for the classic “Treatise on Sedimentation” compiled by W. H. Twenhofel (1926). Vaughan wrote few papers directly on sedimentation, but it was his vision which led this work. He then went on to organize the Committee on Submarine Configuration and was its chairman, 1922–1932. Prior to the advent of the second world war, this committee

stimulated what little American investigation there was of the oceanic sedimentation.

February 1, 1924, Vaughan moved to California, though he continued as a nominal member of the USGS, with the title of senior geologist (1924–1928) and principal scientist (1928–1939). His new position was Director of the Scripps Institution for Biological Research which shortly became the Institution of Oceanography. Vaughan made the place into a world leader in the growing field of ocean investigations, and remained its head until 1936. Biological work continued, but Vaughan instituted programs in dynamic and physical oceanography, as well as chemical and geological oceanography. As a member of the National Academy of Sciences, in 1927 Vaughan was appointed to the Committee on Oceanography. In large measure this committee was responsible for the founding of Woods Hole Oceanographic Institution and the Oceanographic Laboratories of the University of Washington. The 1926 Pan-Pacific Congress formed an International Committee on Oceanography of the Pacific. Vaughan served as its chairman for a decade. Thus, a significant portion of our present understanding of the oceans can be traced to his influence; his 1924 paper on oceanography is noteworthy. Simultaneously with his directorship, Vaughan was Professor of Oceanography; upon his retirement in 1936, he was appointed professor emeritus.

In retirement, Vaughan returned to the Natural History Museum in Washington. He continued his studies of Cenozoic fossil corals and foraminifers until 1947 when pneumonia led to failing eyesight which curtailed his scientific efforts. “His interest remained unabated to the end, and his circle of close friends kept him in close contact with current developments in his many fields of interest to the day of his death on January 16, 1952” (Wells, 1952, p.1495).

Just as Vaughan fused his combined interests in stratigraphy and paleontology into formalizing sedimentation at the NRC, he also sparked studies of the allied discipline of paleoecology. Indeed drawing a sharp line between these two may be difficult. The efforts of the Committee on Ecology and Paleocology took longer to crystalize than did that on Sedimentation. It is sufficient to note that both volumes of “Treatise on Ecology and Paleocology” (Geological Society of America Memoir, 67) are dedicated to him.

Vaughan’s outstanding efforts were recognized by his peers and in 1915 he was president of the Geological Society of America, among other organizations. He was awarded the Agassiz Medal (1935) and the Mary Clark Thompson Medal (1945) of the National Academy of Sciences, and the Penrose Medal (1946) of the Geological Society of America, along with many honorary memberships, degrees, and other honors. In the last year of his life, Scripps Institution dedicated a new building to him in appreciation of his manifold activities.

JOHANNES WALTHER (1860–1937)

Biographical data

Johannes Walther was one of the pioneers in sedimentology combining lithological and ecological aspects. He was born July 20, 1860 in Neustadt/Orla, Germany and died May 4, 1937 in Hofgastein. After his studies of zoology in Jena (PhD 1882) he studied geology more intensely in Leipzig and Munich. In 1886, he became lecturer in Jena; in 1894 associate “Haeckel-Professor” and from 1906 until his retirement 1928 he held the post of director of the Geological Institute in Halle. He received honorary degrees in Perth and Melbourne (1914!) and in 1928 he was guest professor at the John Hopkins University; from 1924 to 1931 he served as president of the Academy “Leopoldina” in Halle. (for biography and bibliography, see I. Seibold, 1992).

At the time when Walther wrote his principal works, paleontology, stratigraphy and tectonics played a leading role in geology. Walther took little interest in them but followed his line of “dynamic geology”. His scientific thinking was deeply influenced by the famous zoologist Ernst Haeckel, the German apostle for Darwin whose thoughts thus shaped Walther’s view on geology. He looked at the *processes* causing the formation of rocks and not only at their characteristics. He wanted to revive Lyell’s uniformitarianism, but he showed critically that some phenomena of the past are not occurring today. On his travels he tried to study as many different geological conditions as possible. His topics were:

Shallow marine sediments

In 1884, 1885 and 1910, Walther went to the Zoological Station in Naples to carry out investigations of the recent seabottom. The 1910 study on the sediments of the “Taubenbank”, a shoal in the Gulf of Naples, became classic for its quantitative and experimental approaches to sedimentology (e.g., ashes of Mt. Vesuvius) and biogeology (e.g., bioturbation). For instance, he kept crawfish together with mussels in an aquarium to find out how long the former would need to work the shells into detritus.

Reefs

In the Sinai Peninsula (1886), Walther studied recent and fossil coral reefs, their growth, subsidence, tectonic uplift and diagenetic processes. He completed his investigations 1888 in India (see R.N. Ginsburg *et al.*, 1994, for commented translations).

Deserts

His main desert voyages in the Sinai and Egypt (1886), USA (1891) and Central Asia (1897) revealed to him the importance of the eolian erosion, which had hitherto found less recognition. After a first publication in 1892, his desert book of 1900 went through four editions (English edition by E. Gischler and K.W. Glennie, 1997) and made him widely known as the “Desert-Walther”. Besides a vast material of observations about erosion and sedimentation he dealt also with fossil deserts and the shift of climatic zones. His theory of the origin

of salt deposits in desert basins stands against Ochsenius’ bar theory.

Lithogenesis

Finally, his name became worldwide linked with the “Law of the Facies” originally expressed by A. Gressly (1839) but explained in detail in volume III (“Lithogenesis of the present”) of Walther’s principal work “Einleitung in die Geologie als historische Wissenschaft” (1893/94). Historical geology had previously been treated almost exclusively under its paleontological aspects. He pointed to the priority of lithological research in connection, of course, with paleontological findings. One can regret that he published only few case studies to illustrate his ideas. In his time, this inspiring work received only limited attention in Anglo-American circles, though Amadeus Grabau welcomed it with enthusiasm (1913). Yet Walther’s impact on Russian geology (including translations of his main works) was remarkable.

Since the 1970s his work found renewed attention by the facies research in the oil industry. Middleton (1973), dealt with the Law of facies. The recent English translations of his works will make him better known as a forerunner of modern biogeology.

SEDIMENTS PRODUCED BY IMPACT

Impact cratering is now recognized to be a very important (if not *the* most important) surface-modifying process in the planetary system. The reason for this becomes clear if one takes a look at the Moon, or peruses spacecraft images of the surfaces of Mercury, Venus, Mars, the asteroids, and the moons of the outer gas planets. On Earth, the situation seems to be different. Lunar-like craters are not an obvious or common landform, and impact cratering is not described as an important process in textbooks on terrestrial geology. There are a number of reasons for this deficiency, as impacts happen on Earth just as they do on other planets, but endogenic forces cover or obliterate their traces. This would explain why impact cratering, on first glance, does not seem to be a particularly important geological process on Earth and why it has been ignored by generations of earth scientists.

One of the most important driving forces for impact research in the past decades was the study of rocks from the *Cretaceous–Tertiary (K–T) boundary*. At the beginning of this important development was a serendipitous discovery. Alvarez and colleagues were trying to use the concentration of the extraterrestrial tracer element iridium (Ir) as a proxy for the sedimentation rate of Cretaceous and Tertiary age limestones in Italy. It turned out that Ir was not useful as such a tracer because the abundances were too low, but they found that the concentrations of the rare platinum group elements (PGEs; Ru, Rh, Pd, Os, Ir, and Pt) and of other siderophile elements (e.g., Co, Ni) in the thin clay layer that marks the K–T boundary are considerably enriched compared to those found in adjacent Cretaceous and Tertiary rocks. These significant enrichments (up to four orders of magnitude) and the characteristic interelement ratios were interpreted by Alvarez *et al.* (1980) to be the result of a large asteroid or comet impact, which also caused extreme environmental stress. There are several excellent overviews of this discovery and its implications for the earth sciences (e.g., Glen, 1994; Alvarez, 1997; Powell, 1998). Subsequently, shock-metamorphosed minerals (quartz, feldspar, etc.) were found in K–T boundary layer samples from all over the world (e.g., Bohor *et al.*, 1984, 1987), which confirmed the impact origin of the K–T boundary layer and, thus, that a large-scale impact event was responsible for the end-Cretaceous mass extinctions. Details on shock metamorphism can be found in Features Indicating Impact and Shock Metamorphism, and other reviews (e.g., Melosh, 1989; Stöffler and Langenhorst, 1994; Grieve *et al.*, 1996; French, 1998; Montanari and Koeberl, 2000; Koeberl, 2001).

An important result of K–T boundary studies is the demonstration how the various types of distal ejecta can be correlated with proximal ejecta and, eventually, an impact structure. The determination of the enrichment in the concentration of the element iridium, a specific marker of extraterrestrial material, in the sediments from the K–T boundary provided the first direct evidence for a large impact event at the end of the Cretaceous. This led, in turn, to the theory that the mass extinction of the end of the Cretaceous was caused by a huge asteroid or comet impact. Studies of the K–T boundary event provided data that helped with the understanding of the origin and significance of other, possibly impact-related, boundaries and exotic layers in the stratigraphic record (*cf.* Montanari and Koeberl, 2000; Peucker-Ehrenbrink and Schmitz, 2001). As such, K–T boundary research played several important roles: to increase the visibility and acceptance of impact research, and to provide applications for decades of impact-related research.

An important basic concept is the definition of *proximal and distal ejecta*. Proximal ejecta are those that are found in the immediate vicinity of an impact crater, within <5 crater radii from the rim. In contrast, distal ejecta are those ejecta that occur at considerable distances from the source crater (>5 crater radii from the crater rim; see, e.g., Melosh, 1989). Distal ejecta commonly consist of (usually fine-grained) rock and mineral fragments or of glassy spherules or fragments. Whereas it is often not possible to right away recognize their connection to a specific impact structure, distal ejecta can act as a guide to major impact events and even lead to the discovery of large impact structures. During crater formation, at the end of the excavation stage, about 90 percent of all material ejected (excavated) from the crater is deposited as proximal ejecta. This conclusion has been obtained from

impact experiments, simulation calculations, and comparison with nuclear and chemical explosions. The mass of the ejecta decreases outward: about half of the ejected material can be found within about one crater radius from the rim. At greater distances the ejecta blankets become increasingly thinner and discontinuous. The presence of an atmosphere significantly influences the ejection and distribution mechanisms. On an airless planet, ejecta will be emplaced ballistically. Calculations and experiments show that not only the total ejecta mass decreases with increasing distance from the crater, but also the average particle size. Ejection of material from a crater is a complicated, multistage process. Some material is ejected early on during the contact and compression stage at very high velocities, but most material is ejected during the excavation phase. The material seems to be ejected at relatively low angles, with very little material being thrown out at angles of more than 45° (Oberbeck, 1975). On Earth (or another planet with an atmosphere), ejecta near the crater can also be deposited in a base surge, which is a gravity-driven density current (composed of air and dust entrained by the fireball) that flows down (and outward) from the expanding mushroom-shaped cloud.

Material launched early in the crater formation will still be in flight after the crater is completely excavated and after the more massive local ejecta have been deposited to form the continuous deposits around the crater (Oberbeck, 1975). Late during the crater formation (when the shock wave has already decayed somewhat), material is ejected at lower velocities and will be deposited close to the crater rim, whereas material that was ejected early and at higher velocities is deposited at greater distances from the crater. The low velocity ejecta deposited at the crater rim often preserve the initial stratigraphic relationship, which leads to the inverted stratigraphy (the overturned flap) at the crater rim (because material from greater depth at the target is deposited last on the rim). This can well be seen in the field at, for example, the famous Meteor Crater in Arizona. In general, material from greater stratigraphic depth at a crater location is, thus, deposited closer to the crater compared to distal ejecta, which more commonly consist of the uppermost stratigraphic layers of the target. The higher energies available early in the crater formation sequence make it also more likely that the earliest ejecta are molten or at least strongly shocked, while the later ejecta may only be slightly shocked or not at all. Examples of molten distal ejecta include tektites (see below). On Earth the interaction with the atmosphere complicates matters somewhat. Early ejecta may also be entrained in the rapidly expanding fireball and, if the event is large enough, they will be ejected outside of the atmosphere, leading to a global distribution. Size sorting will result in larger particles settling out first and finer dust being deposited later.

There are several empirically derived equations that describe the thickness of ejecta blankets with distance from the crater (*cf.* Melosh, 1989, p. 90). One of the most commonly used ones gives a power law for the ejecta blanket thickness t as a function of distance r from the crater center:

$$t = 0.14R^{0.74}(r/R)^{-3.0} \text{ for } r \geq R \quad (\text{Eq. 1})$$

where R is the radius of the transient cavity and dimensions are in meters. The exact values for the function of R are debated, and Melosh (1989) proposed a more general version in which the term $0.14R^{0.74}$ is replaced by $f(R)$, a poorly defined function that depends on a variety of parameters.

From the study of the distribution of microtektites (see below) in the Australasian strewn field, Glass and Pizzuto (1994) derived the following equation:

$$t = 0.02 R(r/R)^{-4.4 \pm 0.3} \quad (\text{Eq. 2})$$

which can be rewritten as a function of the distance alone:

$$t = 10^{24.0 \pm 0.4} r^{-4.4 \pm 0.3} \quad (\text{Eq. 3})$$

This relation seems to be valid not only for proximal, but also for distal ejecta, such as tektites and microtektites.

Impact ejecta are found in Archean and Proterozoic rocks sequences in Australia and South Africa. Investigations of these layers are still in progress (see chapter by Koeberl, this volume). However, the study of the K–T boundary ejecta provided the most influence for the discussion about the importance of impact events. It is easy to detect the K–T boundary layer in the field, where it appears as a distinct break in lithology, with a thin (usually up to 1 or 2 cm thick) layer commonly composed of clay or claystone. A detailed description of the field occurrences of various K–T boundary layers relations was recently given by Smit (1999), and references therein. Information on a variety of aspects of the study of the K–T boundary, the K–T impact event, and its implications can be found, for example, in the “Snowbird” series of conference proceedings (Silver and Schultz, 1982; Sharpton and Ward, 1990; Ryder *et al.*, 1996; Koeberl and MacLeod, 2002). From the sedimentological perspective, K–T boundary layers in marine and terrestrial sections have a somewhat different appearance. Terrestrial K–T boundaries (e.g., in the Western Interior of North America) are characterized by an up to 3-cm-thick dual layer, whereas in most marine sections it does not display a dual-layered nature. At the Western Interior locations, the lower layer is mainly kaolinitic with some smectite; it contains hollow spheres up to 1 mm in diameter, that are most often also composed of (and filled by) kaolinite, but at some sites (e.g., in Wyoming) they are composed of goyazite (a hydrous aluminophosphate; an alteration product). Bohor and Glass (1995) give a detailed description of the formation and alteration of these spherules. The upper (thinner) layer is commonly laminated and consists of smectite and kaolinite clay with variable amounts of organic matter, giving it a dark gray to black appearance (Bohor, 1990). Most of the shocked minerals and the siderophile element anomaly (see below) are restricted to the upper layer; it has been called the “fireball” layer (e.g., Bohor, 1990). However, the composition and internal structure of the K/T boundary layer varies with distance from the source and depositional environment (e.g., Smit, 1999). In marine sites in Italy, for example, a cm-thick clay layer occurs within well-bedded limestones (Figure S21). Besides high contents of the PGEs and the presence of shocked minerals, evidence for impact in the various K–T boundary layers includes also the presence of osmium and chromium with extraterrestrial isotope ratios, fragments of the original bolide, impact-related diamonds, high-pressure polymorphs of quartz (coesite, stishovite), and impact glass. In the early 1990s, the 200-km-diameter Chicxulub structure in Mexico (Yucatan Peninsula) was confirmed as an impact structure of K–T boundary age. Thus, the source crater of the K–T boundary impact was found.

There are several other cases where impact craters were identified after careful studies of distal ejecta layers. For example, Gostin *et al.* (1986) reported on the discovery of an

Figure S21 The Cretaceous-Tertiary boundary layer at Frontale, Umbria–Marche sequence, central Italy. The grayish clay layer is about 1.5 cm thick and situated within limestones. End-Cretaceous rocks are marked with a K, and earliest Tertiary rocks are marked with a T.

impactoclastic layer within late Precambrian shales of the 590 Ma Bunyeroo Formation in the Adelaide geosyncline, South Australia. This layer was found to contain abundant shocked quartz grains, zircons, shattered mineral grains, and small shatter cones (e.g., Wallace *et al.*, 1996). The ejecta were found in outcrops and drill cores over several hundred kilometers in south-central Australia. Around the same time, Williams (1986) identified the Acraman structure in South Australia as an impact structure, which was rapidly confirmed as the source crater of the Bunyeroo impact ejecta layer. Gostin *et al.* (1989) and Wallace *et al.* (1990) detected enrichments of the PGEs in the ejecta layer; however, post-formational redistribution had altered the PGE patterns. The diameter of the deeply eroded Acraman structure is probably about 90 km. Impact ejecta have been found at distances of up to 450 km from the Acraman structure (i.e., about 10 crater radii), making this a true distal ejecta layer.

Another important group of distal impact ejecta are *tektites* and *microtektites*. They are a group of natural glasses that have been known for several centuries by now, which earlier had been interpreted to represent glassy meteorites or ejecta from terrestrial or lunar volcanoes. Mainly due to chemical studies, it is now commonly accepted that tektites are the product of melting and quenching of terrestrial rocks during hypervelocity impact on the Earth. The chemistry of tektites is in many respects identical to the composition of upper crustal material. Tektites are currently known to occur in four strewn fields of Cenozoic age on the surface of the Earth. Strewn fields can be defined as geographically extended areas over which tektite material is found. The four strewn fields are: the North American, Central European (moldavite), Ivory Coast, and Australasian strewn fields. Tektites found within each strewn field have the same age and similar petrological, physical, and chemical properties.

In addition to the (macroscopic) tektites found on land, microtektites were found in three of the four strewn fields. Microtektites occur in deep-sea cores, within layers that correspond in stratigraphic age to the radiogenic age of tektites on land, are generally less than 1 mm in diameter, and show a somewhat wider variation in chemical composition

than tektites on land, but with an average composition that is very close to that of "normal" tektites. Microtektites have been very important for defining the extent of the strewn fields, as well as for constraining the stratigraphic age of tektites, and to provide evidence regarding the location of possible source craters. For details see Koeberl (1994) and Montanari and Koeberl (2000).

Tektites are chemically homogeneous, often spherically symmetric natural glasses, with most being a few centimeters in size. Those found on land have commonly been classified into three groups (see, e.g., O'Keefe, 1963): (1) normal or splash-form tektites; (2) aerodynamically shaped tektites; and (3) Muong Nong-type tektites (sometimes also called layered tektites). The aerodynamic ablation results from partial remelting of glass during atmospheric re-entry after it was ejected outside the terrestrial atmosphere and solidified through quenching. The shapes of splash-form tektites include spheres, droplets, teardrops, dumbbells, etc., or fragments of such shapes. These are not to be confused with aerodynamical forms. Muong Nong-type tektites were named after the type-locality in Laos. They are usually considerably larger than normal tektites and are of chunky, blocky appearance. Muong Nong-type tektites show a layered structure with abundant vesicles. These tektites are less depleted in volatile elements than the splash-form tektites.

Microtektites are, by definition, less than 1 mm in size, and show a variety of shapes, ranging from spherical to dumbbell, disc, oval, and teardrop. In color they range from colorless and transparent to yellowish and pale brown. They often contain bubbles and lechatelierite inclusions. Microtektites occur in the stratigraphic layers of the deep-sea sediments that correspond in age to the radiometrically determined ages of the tektites found on land. Thus, they are distal ejecta and represent an impact marker. For example, in deep sea sediments in the Indian Ocean and Pacific Ocean in the general vicinity of Australia and Indochina they have a stratigraphic occurrence near the Brunhes–Matuyama boundary; this and their composition indicate that they are indeed part of the Australasian strewn field.

The geographical distribution of microtektite-bearing cores defines the extent of the respective strewn fields, as tektite occurrences on land are much more restricted. Furthermore, microtektites have been found together with melt fragments, high-pressure phases, and shocked minerals (e.g., Glass, 1989; Glass and Wu, 1993) and, therefore, provide confirming evidence for the association of tektites with an impact event. The variation of the microtektite concentrations in deep-sea sediments with location increases toward the assumed or known impact location. Glass and Pizzuto (1994) determined the geographic variation in abundance of Australasian microtektites (ranging from <1 to 3,255 microtektites per cm² in the >125 μm size range), and found that the abundances increased toward Indochina; and deduced a possible source region in Cambodia.

Within the past few decades the impact origin of tektites was established, raising the question regarding their source craters. Since then, numerous suggestions and educated guesses have been made regarding the location of the possible source craters for the tektite strewn fields. Relatively reliable links between craters and tektite strewn fields have been established between the Bosumtwi (Ghana) and the Ries (Germany) craters, and the Ivory Coast and the Central European fields, respectively. Only recently, a plausible link was established between the

newly discovered Chesapeake Bay crater and the North American strewn field. No large crater with a compatible age has yet been identified for the Australasian strewn field. The exact process of tektite formation is still not quite clear, although from chemical and isotopic studies it is fairly well established that tektites have formed from the immediate surface layers of the target rocks (*cf.* Koeberl, 1994).

Distal ejecta ("impactoclastic layers") can be used as markers for impact events in the stratigraphic record. "Impact markers" can be described as all chemical, isotopic, and mineralogical species derived from the encounter of cosmic bodies (such as cometary nuclei or asteroids) with the Earth, as discussed in more detail by Montanari and Koeberl (2000). Such markers are quite important in the detection and study of accretionary events in the sedimentary record, to identify their origin, and to evaluate their possible role in global change and on the Earth's biotic and climatic evolution throughout geological time. Distal ejecta layers can be used to study a possible relationship between biotic changes and impact events, because it is possible to study such a relationship in the same outcrops, whereas correlation with radiometric ages of a distant impact structure is always associated with larger errors. Impactoclastic layers are composed of distal ejecta. For example, microtektites occur in well-defined and thin layers in deep-sea sediments and provide an excellent time marker. The sedimentology of impactoclastic layers can provide important information not only on source craters and impact processes, but also on the effects (local, regional, or global) of the related impact events.

Extraterrestrial Material in Sediments
Features Indicating Impact and Shock Metamorphism

SEPTARIAN CONCRETIONS

Septarian structures are former cracks, often filled with cement and are most commonly found in concretions hosted in

mudrocks, although rare occurrences are known from siltstones and sandstones. Septarian structures occur in concretions or concretionary sheets, which may be chemically and mineralogically the same as non-septarian concretions in the same mudrock. The host concretions are most commonly calcite, dolomite or siderite dominated, although rare occurrences have been interpreted from silica concretions. Septarian concretions are predominantly a pre-Pleistocene phenomenon, although a potential “proto” version has been described from the late Pleistocene (Duck, 1995).

Crack morphology

Septarian structures were initially formed as open fractures, and are most often concentrated in the central regions of concretions and reduce in width and frequency toward the outer parts of the concretion, which may or may not be cracked. The fractures take a variety of forms, from lenticular cracks, which are widest toward the center of the concretion, to straight-sided cracks, to dense networks of hairline cracks. The orientation of the cracks can be diverse, but always include cracks which are predominantly sub-vertical to the bedding plane. Some sub-vertical cracks in sections perpendicular to the bedding plane may appear inclined, which is often due to the low angle intersection of the crack and section. Cracks can also be sub-horizontal or curved, sometimes reflecting the shape of the concretion (Figure S22A). Within horizontal sections the cracks often demarcate approximately equidimensional blocks of the concretion (Figure S22B). Multiple generations of cracks are apparent in some septarian concretions, cross cutting earlier formed cracks. Cracks are mostly displacive and may cut body fossils, or occasionally cracks may show a component of shear displacement.

Crack filling cements

Cracks may range from largely unfilled to fully cement filled, often with a variety of distinctively colored spar cements. The fills may also include geopetal sediment, or sediment injected from the surrounding mudrocks, through cracks that reached the concretion surface. The cements grew on the fracture walls within a pore-fluid filled crack. This is evident by the preservation of partially unfilled cracks displaying crystal terminations in the voids. The cracks are usually filled with calcite, but sometimes include other carbonates, sulfide, sulfates or clay minerals, sometimes quite different to the mineralogy of the concretion body. In most occurrences the volume of the cracks make up less than 20 percent of the volume of the concretion body, although in rare occurrences the cement-filled cracks may constitute up to ~70 percent of the concretion body.

Timing of crack formation

The timing of the crack formation relative to the formation of the concretion body is indicated by the geochemistry of the body and crack cements. Detailed carbon and oxygen isotopic studies (see *Isotopic Methods in Sedimentology*) indicate the central region of the concretion body generally formed first. The outside of the concretion body may have a similar cement chemistry to the earlier formed crack cements, hence for some concretions the outer part of the concretion formed at the same time as the inner cracks fills. The fracturing of some of

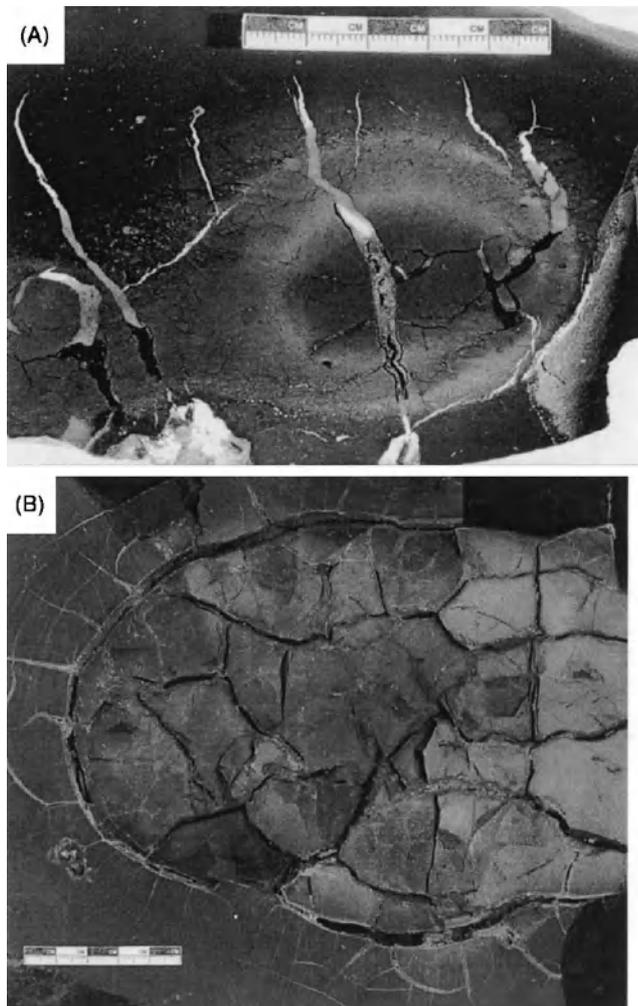

Figure S22 (A) vertical section through a compound calcite (pale central part) and siderite (dark outer) septarian concretion. The lenticular and parallel-sided cement-filled cracks are mostly vertical to bedding. Three generations of cement fill occur a clear calcite spar (dark) in the calcite concretion (large and small cracks), a pale brown spar (pale gray) and a barite (white), which mostly fills the later tapering terminations to cracks. Some crack voids are preserved in the inner calcite concretion (Ironstone Shales, Lower Jurassic, UK). (B) horizontal section through dolomitic septarian concretion with septarian cracks partially filled by dolomite (Lower Carboniferous of Berwickshire, Scotland).

the early cement fills by later cracking, and subsequent filling by later cements has indicated that some concretions have a repeated history of cracking and successive crack fills. The linkage of cement chemistry to likely changes in pore-fluid chemistry with sediment burial (see *Diagenesis*), has also indicated that in some septarian concretions the crack-fills formed later than the concretion body.

Depth of formation

Estimates of the depth of formation of septarian cracks are closely linked to the origin of the body of the concretion. There are three main clues to the depth of formation. Firstly, the

variation in the amount of cement in the concretion body has been used as a relative indicator of burial depth, through its assumed passive filling of the early sediment pore-space. This is not without its problems, due to the possible displacive or replacive growth of some concretion body cements. Secondly, the isotope geochemistry of the crack and body cements, linked to models of organic matter stimulated diagenesis (see *Diagenesis*) has suggested estimates of likely burial depth, based on typical present-day depths of pore-water chemical boundaries. Thirdly, occurrences of septarian concretions exhumed at unconformities and subsequently re-buried, in which estimates of the amount of sediment removed can be ascertained (Hesselbo and Palmer, 1992). These three estimates suggest that some septarian cracking was initiated at a minimum of a few meters to a few 10s of meters depth. Maximum cracking depths are often not well constrained, but may extend to several kms of burial, or occur during uplift.

Origin of cracks

Septarian structures have attracted debate since the late 19th Century, when the accepted hypothesis was that they formed by shrinkage of the interior parts of the concretion. This idea has attracted many proponents since that time involving increasingly more complicated growth models (Pratt, 2001). However, a plausible model that explains this shrinkage process in firm physical terms has largely eluded its proponents. The physical process that may provide a comparable analogue for the shrinkage hypothesis is the production of syneresis cracks (see *Syneresis*). The shrinkage model is also deficient in explaining the physical and chemical nature of the cementing medium which shrinks in the early-formed parts of the concretion, and deficiencies pertaining to the textural and geochemistry data about the relative timing of textural features (Astin, 1986). More recent hypotheses suggest the cracks are generated by tensional failure, either through stresses produced by excess pore pressure (see *Compaction*; Astin, 1986; Hounslow, 1997) or shaking motions produced by earthquakes (Pratt, 2001). The essential differences between these models are that the Astin and Pratt models implicate formation-wide stresses, which are through unknown processes, localized to the concretion body. Without a process of tensional failure localization, both the Astin and Pratt models would also produce septarian cracks in rocks other than the concretion. The Hounslow model implicates stresses localized to the cementing concretion, whose cementation is the cause of the tensional stress. The driving motivation for tensional fracture models is the realization that large instantaneous tensional forces are needed to fracture rigid body fossils and the concretion body in its consolidated state. Tensional stresses applied over a long period of time (sub-critical crack growth) appear to provide a solution in lowering the threshold for fracture growth, and partially cemented concretions, as implicated in some growth models, may lower the tensional strength of the concretion body. A deficiency in the tensional fracture models are that in some concretions the tensional strains implied by the large volumes of crack-filling cement are far in excess of what could be expected. Hence, a hybrid shrinkage- tensional fracture model may be appropriate for some septarian concretions (Pratt, 2001).

Ultimately the origin of septarian cracks is tied to the debate about the origin of concretion bodies. One of the problems is the lower number of case studies linking the timing of

concretion body and septarian cement formation, which utilize integrated and detailed geochemical, textural and mineralogical data. Study of hiatus septarian concretions could be a fruitful avenue for further study, since exhumation provides a relative timing and depth indicator (Hesselbo and Palmer, 1992). A second gap in knowledge is the physical properties of concretions when they first form, which is fundamental in dictating the likely processes of septarian crack formation. The absence of a present day analogue for septarian concretions either suggests the formation processes are absent or very rare at the present day, or that they take longer to form than current understanding suggests.

SILCRETE

Silcretes or siliceous duricrusts are defined by Summerfield (1983) as the indurate products of surficial and penesurficial (near-surface) silica accumulation. They are formed by cementation and/or low-temperature replacement of bedrocks, weathering deposits, unconsolidated sediments, soil or other materials. Summerfield proposes silcretes should contain at least 85 percent silica, however some silcretes may not contain this percentage as they retain parts of the parent material. Silcretes form nodular, columnar and/or massive layers in outcrops. In hand specimens they show many different features inherited from the parent material or acquired during silica accumulation and afterward in silica diagenesis. Silcrete horizons usually vary from several cm to 3 m, but can occasionally exceed this thickness. Although silcretes exist globally, the principal studies on them have been carried out in Australia and Africa.

Once the petrology of a silcrete is known, any further discussion of its formation needs to explain: (1) the source of silica; (2) the silica transfer from the source to the site of

accumulation; (3) the conditions and mechanisms that give rise to silica precipitation; and (4) their relation to the climate and paleosurfaces.

Mineralogical composition and petrology

The main SiO₂ minerals deposited during silcrete formation are: quartz, moganite (silica polymorph with a crystal structure closely related to that of quartz), opal CT (stacked sequences of cristobalite/tridymite and occasionally Opal A (amorphous silica)). These silica phases display many fabrics and textures, depending on the parent material, chemical composition of the pore fluids, and whether the mineral formation process is replacement or cementation. Consequently the petrography of silcretes is highly complex.

Common crystalline quartz of different sizes is frequently associated with several varieties of chalcedony. Chalcedony is fibrous microcrystalline quartz and different varieties (with distinct names in French and English) can be observed using a polarizing microscope. These are: calcedonite (length-fast chalcedony, in which the elongation of the fibers is perpendicular to the crystallographic *c*-axis), quartzine (length-slow chalcedony, in which the elongation is parallel), lutecite (another type of length slow, in which the fiber axis is inclined by approximately 30°) and helicoidal calcedonite or zebraic chalcedony (systematic helical twisting of the fiber axes around the crystallographic *c*-axis). The varieties of chalcedony allow the definition of formation environments as acid or nonsulfate (length-fast) or basic or sulfate/magnesium rich-environments (length-slow) (see review in Hesse, 1991). Unfortunately, there are exceptions to these rules and rigid application of these criteria can lead to error in interpretation.

The microscopic characteristics of moganite have not yet been studied in depth, but it is generally described as uniformly flaky or fibrous (length-slow). Moganite, in amounts of over 20 percent, is considered indicative of special evaporitic environments which have still not been clearly determined (Heaney, 1995).

The opal in silcretes is generally opal CT and appears throughout the rock as massive or glaeubular. Glaebules are concentric rings of silica and matrix components and are usually less than one centimeter in diameter, although they can occasionally reach several centimeters. The opaline cements are fibrous and named lussatite (length-slow) or lussatine (length-fast). Opal A is not common, but of great interest, because in some cases its existence propitiates the formation of opaline gemstones. The opaline phases in silcretes appear where the parent material is mudstone or the silica concentration of the pore fluids is very high (120 ppm of silica for amorphous silica and 89 ppm for opal CT). These opaline phases can recrystallize to quartz (aging). In the case of silcretes, temperature and time, the two main factors favoring aging, are not always necessary.

The major silcrete types and genesis

Parent materials determine the majority of the mineralogical and micromorphological characteristics of silcretes and as there are many parent materials, there are many varieties of silcretes. It is therefore difficult to find a universally acceptable petrographic classification of silcrete. Summerfield's classification (1983) has been commonly used, although this classification is not appropriate for silcretes formed from nondetrital

parent materials. Thiry and Milnes (1991) developed a general genetic classification of silcretes, which subdivided them into pedogenic and groundwater types. Pedogenic silcretes are the result of silica precipitation within the soil profile. The structures and fabric of the parent materials are disturbed or destroyed during silcrete formation being substituted by others more typical of paleosols. Intermittent and repetitive leaching, infiltration and illuviation alternate with evaporation, which causes the precipitation of silica minerals. This occurs in areas with alternating wet and dry periods.

Groundwater silcretes are massive, with sharp upper and lower boundaries, and lack pedogenic features such as nodules and columns. The structures and fabrics of the parent material are retained in the silcrete. They probably represent silicification on or close to the water table and are related to the position of the paleowater table. The silica is imported either by infiltration through the upper part of the profile or by lateral groundwater flow. The mixing zone between meteoric ground water and saline waters from a lake or the sea facilitates silicification processes and the silica rocks formed there are considered to be silcretes by some authors. Characteristics of the two types of silcretes, vadose and groundwater, sometimes appear together because silicification might have commenced with groundwater and continued into the unsaturated zone (Bustillo and Bustillo, 2000). Generally the silica precipitation is dependent upon geochemical parameters at the microscale and the pore water movement at the mesoscale. The movement of water is largely conditioned by geomorphological and hydrological controls, and to climatically influenced water-table fluctuations.

Silcretes and climate

Varied studies of silcretes in Australia (Langford-Smith, 1978) revealed these occur in two geological contexts: (1) associated with deep-weathering profiles where their formation is attributed to wetter conditions; and (2) arid/semiarid or alkaline conditions. In the first context silcretes can coexist with ferricretes and laterites and in the second with calcretes, dolocretes and gypcretes. Within deep weathering profiles, chemical alteration breaks the silicate minerals down and releases the silica. The mechanism of silica precipitation is unclear but sufficiently sluggish drainage could lead to silica precipitation. In arid/semiarid conditions, the source of silica is sometimes a consequence of the high amount of silica liberated when other duricrusts (calcretes, dolocretes, and gypcretes) are formed on a silicate parent material. The dissolution of opaline particles (phytolites, diatoms...) and eolic quartz sands and silica-rich groundwaters are other sources. Silica precipitation mainly occurs in response to concentration through evaporation or by a localized decrease in pH.

The existence of two distinct climatic formation environments, does not mean all silcretes should be assigned to them. Moreover, efficient geochemical and petrological tools capable of definitively assigning a silcrete to one of these two contexts have not yet been developed. After many years use, criteria such as the amount of TiO₂ or some petrographic characteristics, are not now considered acceptable (Nash *et al.*, 1994).

Oxygen isotopic studies of the quartz that forms silcretes may yield environmental information, including variations in temperature (Knauth, 1992). The opaline phases and to a lesser extent, the chalcedonic quartz, are not appropriate for the isotopic studies due mainly to bound/included water. Once

we know the oxygen isotopic composition of the quartz, the oxygen isotopic composition of fluids from which it precipitated can be calculated if the temperature range can be established. For this calculation, a fractionation formula can be used. Webb and Golding (1998) consider the Knauth and Epstein formula gives more realistic results under near surface conditions, which is where silcretes are formed. Detailed geochemical and oxygen isotopic studies of a silcrete and its parent material can shed light upon the mechanism of silcrete formation and if evaporation is a major factor in silcrete formation (Webb and Golding, 1998). Silcrete formation depends on a complex interaction between climate and silica supply and needs tectonic stability.

Siliceous Sediments

SILICEOUS SEDIMENTS

Introduction

Siliceous sediments are composed of silica that has actually precipitated at or near the site of deposition or has replaced pre-existing sediments. They are distinguished from clastic or terrigenous sediments which are made of grains derived from rocks elsewhere and physically transported to the site of deposition. In today's oceans, the dominant examples of siliceous sediments are oozes composed of microscopic silica particles precipitated biologically by diatoms and, to a lesser

extent, by radiolarians, sponges, and silicoflagellates. Diatom silica is precipitated on a colossal scale in surface waters and slowly settles to the ocean floor to produce diatomaceous oozes. Although most of the opaline tests dissolve in transit, a small percentage survive and accumulate in thicknesses up to hundreds of meters. The purity of the ooze is greatest for depths below the carbonate compensation depth and in areas far removed from landmasses that can supply abundant clays. Siliceous oozes are regularly encountered on the deep ocean floor and in deep-sea drill cores. Locally, radiolarians and silica sponges are so abundant that oozes of radiolarian skeletons and opaline spicules can also accumulate.

Diatomites, porcelanites, and bedded cherts

Along the coast of California, the Miocene Monterey Formation has been uplifted to produce superb exposures of diatomaceous layers displaying every gradation from pure, unconsolidated diatomite to porcelain-like beds and even brittle, glass-like beds of chert. The diatomite is extensively mined for insulation, paint filler, filtration material, and a wide variety of other industrial uses (Figure S23). The classic study by Bramlette (1946) first demonstrated that the gradations in lithology represented various steps in the burial transformation of opaline diatoms into microcrystalline quartz. Uplifted exposures along coastal California allowed detailed examination of this process where it had been arrested in various states of progress. Subsequent mineralogic and isotopic studies revealed that the solution-resistant particles that had accumulated continued to resist dissolution during burial until elevated temperatures provoked an *in situ* solution-reprecipitation conversion into hard, porcelain-like beds (Figure S24) of hydrous opal with weak X-ray diffraction peaks of cristobalite and trydimite (opal-CT). Upon further burial, this opal-CT converted to α -quartz. Pore spaces and fractures that developed at various times during burial became filled directly with microcrystalline quartz or with fibrous quartz that grades outward into microcrystalline aggregates of single, well-formed crystals. The most recent studies (Behl and Garrison, 1994) suggest that much of the quartz in the Monterey Formation formed throughout the burial history rather than only at maximum burial as originally thought. At burial depths such that temperatures reach 80–100°C, all opal and opal-CT becomes transformed into microcrystalline quartz. Most of the great oil fields in California have developed where abundant organic matter in diatomite converted to oil and

accumulated in fractured masses of brittle porcelanite and chert.

The stepwise transformation so clearly displayed in the Monterey Formation apparently also operates during burial of all deep sea oozes and readily explains the lithologic/mineralogic variations of siliceous oozes encountered during deep-sea drilling. Diatoms have become particularly abundant in the last 30 million years and now dominate silica deposition in the oceans. Tertiary examples of Monterey-type diatomites, porcelanites, and cherts are particularly common in the circum-Pacific area and have received much attention. Examples of Eocene radiolarian oozes that transformed into porcelanite and bedded chert are also regularly encountered during deep drilling of the ocean floor.

Early observers noted peculiar regional beds of Paleozoic and Mesozoic strata composed of interlocking grains of microquartz that were clearly not clastic deposits. Examples include bedded cherts in the Alps (Gruneau, 1965) and the Devonian Arkansas/Caballos novaculite in Texas/Arkansas (Miser and Purdue, 1929; Folk and McBride, 1976). In many fold belts, the cherts display a distinctive “pinch and swell” texture and are known as “ribbon cherts”. Chemical etching of the microquartz now reveals radiolarian forms confirming prior inferences that most of these bedded cherts originated as radiolarian opal. The etched-out forms are distinct enough for assigning biostratigraphic ages useful in tectonic studies. Apparently, at times and in various places, radiolarians were abundant enough to accumulate as opaline oozes similar to the Tertiary diatomaceous examples. It is now inferred that these transformed into bedded cherts through the stepwise opal to opal-CT to quartz sequence so beautifully documented for the Miocene Monterey Formation.

Novaculite is a white radiolarian chert made almost exclusively of intergrown grains of microquartz and is famous for its widespread use as a whetstone. Other variations in color and texture of radiolarian cherts probably relate to the clay mineral content. The nature of the depositional basins combined with dilution effects of shale and calcareous plankton and possible diagenetic segregation of silica from shale (Murray *et al.*, 1992) may all play a role in determining

Figure S23 Quarry in Monterey Diatomite. Lompoc, California.

Figure S24 Transition of laminated organic-rich Monterey diatomite to opal-CT. Hammer head is on opal-CT horizons. Beach cliff at Pt. Pedernales, California.

the final lithologic character of the chert. Inasmuch as the mobile seafloor carries all sediments into accretionary wedges and subduction zones within about 100 million years, most of these older bedded cherts are today found in highly deformed and altered mountain belts.

Silicification

Silica is soluble in aqueous solution as H_4SiO_4 . At $\text{pH} > 9$, these units polymerize and solubility of all solid forms of silica increases dramatically. At lower pH and room temperature, solubility of quartz is about 6 ppm and opal is about 120 ppm. The solubility increases greatly with temperature, but because of the long times available, the low-temperature values are high enough to allow large-scale transfer of silica in the pore fluids of sediments prior to compaction. Supersaturation with respect to quartz is achieved if ground water moves through uncompacted sediment containing opal or grains of more soluble silica such as volcanic glass and/or clay minerals. Silicification can then occur if some other phase such as metastable aragonite/calcite shell fragment (or a tree trunk buried in volcanic ash) slowly dissolves or disintegrates and is transported away by the through-going, quartz-saturated ground water. Quartz can grow in the microscopic pore spaces so vacated and replacement can occur on such an incremental basis that extraordinary preservation of the precursor material is achieved. Even forms as small as bacteria can be preserved in this manner. Fibrous quartz and small quartz crystals can also grow in the larger void spaces from such saturated solutions. Quartz crystals up to $10\ \mu\text{m}$ have been grown in seawater at room temperature in 2 years in solutions with low silica concentration (MacKenzie and Gees, 1971). If dissolved silica concentrations are $> 120\ \text{ppm}$, silicification by opal can occur. The long time-scales required to achieve such incremental silica replacement preclude realistic laboratory simulations; the silicification process must be inferred from studies of the rock record.

Mineralogy

Silica occurs in sedimentary rocks as several varieties of opal and quartz. Opal is the most common form in Cenozoic deposits, but older strata are always composed of quartz. Amorphous, hydrous opal (opal-A) is today precipitated by diatoms, radiolarians, sponges, and silicoflagellates, and also forms inorganically in unusual depositional environments and in pore spaces during shallow burial. This material transforms to quartz with increased time, temperature, and/or depth of burial. Both nodular and bedded cherts are composed of microcrystalline quartz with individual grains ranging in size from about $8\text{--}20\ \mu\text{m}$ (Figure S25). The grains are thoroughly intergrown with each other and this makes chert one of the hardest of the sedimentary rocks. Each individual grain is crystallographically complex, with many lattice faults and up to 1 wt. percent OH and H_2O . Fibrous quartz is typically associated with the micro quartz (Figure S25) and has an even more complex internal structure. Coarser crystals of quartz with well-defined grain boundaries and more normal internal crystallographic ordering often occur together with fibrous and microcrystalline quartz and also form as recrystallization or annealing products of microquartz.

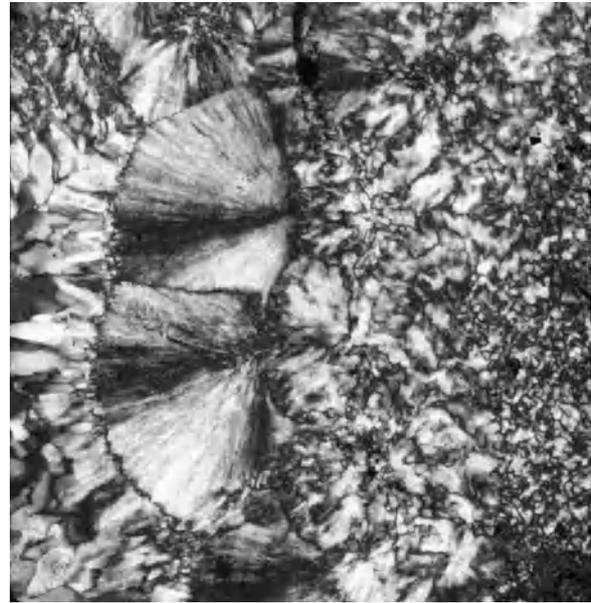

Figure S25 Thin-section of chert under crossed nicols. Microquartz on right half, 2 bundles of fibrous quartz grade to left to coarser individual crystals of quartz. From 2.7 Ga silicified stromatolite in Fortesque Group, W. Australia. Scale bar is $10\ \mu\text{m}$.

Nodular replacement cherts

The earliest examples of silica in sediments to be studied were the nodular cherts in limestones (Figure S26). Famous as the source rock for anthropological artifacts and widely used as flints for starting fires and igniting munitions (even used as cannonballs in one battle of the American Civil War), nodular cherts were originally interpreted as balls of opaline gel that rolled around on the seafloor and hardened into quartz during burial (Tarr, 1917). A long-standing debate started when Van Tuyl (1918) argued that the nodules were actually replacement features where zones of limestone had been incrementally replaced by silica precipitated from later diagenetic fluids moving through the sediment. Among others, Biggs (1957) provided thorough documentation for early replacement and the basic idea has not been challenged since.

Replacement of carbonate to produce nodular chert occurs during early sediment burial when shell fragments and other primary grains of carbonate undergo dissolution and re-precipitation into interlocking calcite and/or dolomite crystals to form limestone and/or dolostone (Knauth, 1979, 1994). In Phanerozoic rocks, the most common silica source is opaline sponge spicules which dissolve and re-precipitate as microquartz during this transformation of sediment into sedimentary rock. The amount of chert that forms depends on the abundance of the silica secreting sponges in the original depositional environment and the vagaries of hydrologic movement of pore fluids during stabilization. The nodules are often among the first stable phases to form, and cross-bedding, oolitic texture, and even organic-walled microfossils are often exquisitely preserved. Primary textures in the surrounding carbonate are typically degraded or obliterated during this early diagenetic “stabilization” event making cherts important “windows” to the original depositional

Figure S26 Nodular replacement chert in 1.2 Ga Bass Limestone, Grand Canyon, Arizona.

structures and fabrics that have been otherwise lost (Figure S27). This aspect of cherts has been generally underutilized and offers much potential in the investigation of carbonate depositional environments.

In addition to the prominent nodules, replacement chert also occurs as small blebs, thin stringers, silicified fossils, and disseminated patches throughout the parent carbonate mass. The color of the chert is black if unreplaced impurities are organic matter, gray if remnant carbonate, and red if iron oxide. The purer cherts are translucent and display conchoidal fracture (Figure S28). If pieces of such chert are reassembled, they often do not fit back together perfectly. Apparently, there is a slight flexing of the sample after breakage. Such pieces may also luminesce when rubbed together in the dark. Other cherts have splintery fracture and this usually indicates low-grade metamorphic recrystallization. Metamorphism can transform the purer cherts into interlocking grains of coarse quartz that are among the hardest known rocks. In thin section, cherts display a large range of petrographic textures that relate to the manner in which they formed and their subsequent burial and metamorphic history (Hesse, 1990; Carozzi, 1993)

While samples of chert from the geologic column may appear somewhat similar with regard to lithology and petrographic texture, the oxygen isotope variation in them is larger than for any other group of terrestrial rocks (Knauth, 1992). The $^{18}\text{O}/^{16}\text{O}$ ratio is determined by the temperature of quartz precipitation and by the $^{18}\text{O}/^{16}\text{O}$ ratio of the pore fluid. Because there are 2 variables, there has been much controversy over the origin of the enormous isotopic variation

Figure S27 Nodular cherts displaying primary pisolitic fabric which was largely obliterated in host dolostone by later neomorphism. Chuar Formation, Grand Canyon, Arizona.

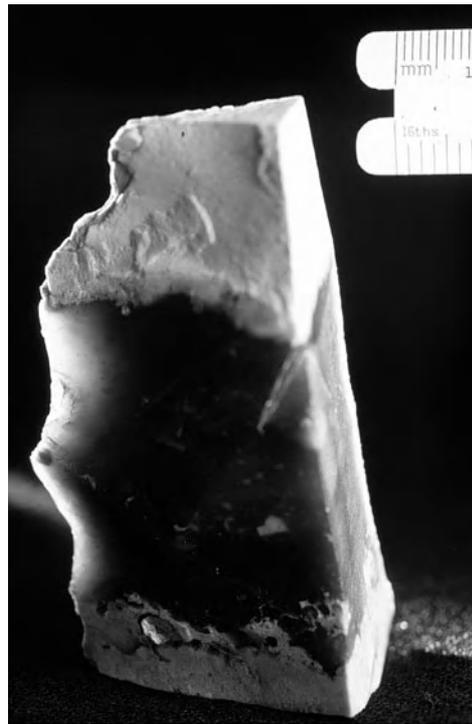

Figure S28 Dark nodular chert displaying translucence and conchoidal fracture typical of near 100% replacement of limestone with microquartz. Cretaceous Edwards Formation, Texas.

encountered in these rocks. One implication is that nodular cherts formed most abundantly in coastal environments where the transformation of primary metastable grains to stable crystals occurred in meteoric ground waters mixed with marine pore fluids. Archean examples are all enormously depleted in ^{18}O relative to Phanerozoic examples, and it has been argued that this indicates that the temperature of stabilization of initially deposited precipitates (and thus the climatic

temperature) was up to 40°C warmer in the Archean (Knauth and Lowe, 2003).

Replacement cherts are found in numerous Precambrian carbonates where they can display well-preserved microfossils. Fine laminations in many Precambrian limestones and dolostones are commonly defined by thin siliceous laminae composed of microquartz, clay, and detrital quartz. These are often classified as “stromatolitic” layers formed by trapping on biologic mats or precipitation of metastable carbonate grains which are subsequently stabilized as limestone, dolostone, or chert. The chert can form classic nodules, but more typically is arrayed as thin discontinuous bands, blebs, and coarse laminae (Figure S26). Black, dull-luster cherts in Precambrian stromatolites have provided much, if not most, of the Precambrian organic-walled microfossils that record the paleontologic record of early life. The silica source for these cherts remains problematic. Ocean water itself almost certainly had much higher dissolved silica in the absence of abundant silica secreting organisms to remove it and also due, possibly, to higher saturation values from much warmer climatic temperatures. It is also possible that some varieties of Precambrian bacteria precipitated silica (and carbonate) directly. In any case, pre-compaction silica diagenesis was extremely active, and distinct zones and laminae were often replaced with microquartz before bacteria could degrade or decompose.

Although nodular replacement cherts in carbonates are common in rocks older than mid-Tertiary, they have never been found forming anywhere today. The “disappearance” of the process of nodular chert formation is roughly coincident with the explosive radiation of diatoms in the mid-Tertiary and with the apparent reduction of silica sponge populations in shallow waters. Silica precipitation by diatoms is so prolific today that dissolved silica in surface and shallow waters is usually <5 ppm. Opaline sponge spicule debris is still produced in shallow waters in relatively minor amounts, but the spicules appear to quickly re-dissolve in the undersaturated, shallow seawater and do not contribute significant dissolved silica for diagenetic pore fluids. It seems that the advent of diatoms so reduced dissolved silica concentrations in shallow waters that opaline sponge spicules can no longer accumulate in shallow water carbonate depositional environments. The inability to observe cherts forming today means that all knowledge of replacement cherts must presently be based on inferences deduced from investigations of the rock record.

In addition to the nodular replacement cherts and the bedded cherts, there are numerous other examples of silica accumulations and replacements that occur during early diagenesis in sediments of all types. These included silicified fossils of everything from bacteria to trees, interbedded layers of chert and iron oxide (iron formations), silicified evaporites, silicified volcanoclastic materials, and vein/cavity in-fills in all types of sedimentary and volcanic rocks. The processes and timing of silica diagenesis in many of these examples remain poorly understood.

Silicified evaporites

Soluble evaporite minerals such as gypsum, anhydrite, and halite often occur in the supratidal facies of limestones and dolostones. These phases are the first to dissolve during early diagenesis when coastal ground waters containing a meteoric water component percolate through the original marine precipitates. Vugs and molds are thus encountered by

silica-saturated percolating groundwaters and can become filled with quartz, fibrous quartz, and/or microquartz. Small, cm-sized cauliflower-shaped nodules of chert that mimic the original morphology of gypsum/anhydrite masses are thus common in supratidal carbonates (Chowns and Elkins, 1974). The surrounding carbonate groundmass is subsequently dolomitized, but the distinctively shaped chert nodules provide instantaneous recognition of a probable supratidal depositional environment. Even in cases where chert nodules also replace the areas immediately surrounding evaporite crystals, coarse quartz in-fills of dove-tailed twins of gypsum or even halite cubes can be observed in petrographic thin-section. These examples of silicification provide powerful indicators of the supratidal environment in carbonate rocks so old that all traces of the primary evaporitic minerals have been removed by later dissolution.

Magadi cherts

The youngest cherts are probably those that formed in and around Pleistocene lakes in the rift valleys of East Africa. There, hydrous Na-silicates such as magadiite are precipitated in varve-like layers in alkaline lakes which undergo seasonal evaporation. Grid-work arrays of submicroscopic quartz crystals apparently replace the Na-silicate phases prior to compaction (Schubel and Simonson, 1990). Oxygen isotope studies suggest that the diagenetic fluids had become evaporatively enriched in dissolved silica. Silicification of trona and other lacustrine evaporite minerals are also evident. Several Tertiary examples of cherts that formed in this manner have been identified (Sheppard and Gude, 1986).

Precambrian cherts

Bedded cherts and silicified strata of all kinds are widespread in Archean Greenstone Belts. Silica was apparently vastly more mobile in these depositional environments and early silicification of sediments appears to have occurred on a scale not observed since. A possible explanation is that dissolved silica was fed into the deep oceans by hydrothermal vents on a vast scale and that silicification in the vent areas was intense. However, massive silicification does not appear to occur around modern examples and modern deep sea hydrothermal silica deposits are limited to local precipitation of opaline particles (“white smokers”) induced by the sudden encounter of silica-saturated hydrothermal water with cold ocean water. It is possible that the Archean climates were dramatically warmer and that the Archean oceans therefore had dramatically higher silica solubility. Silicification in hydrothermal cells is thereby facilitated as more silica-rich ocean water is circulated through the adjacent sediment pile. More extensive deposits of opaline flocs and particles around hydrothermal vents may have been widespread, and these would have converted to quartz chert during early diagenesis.

Also abundant in the Archean as well as in the early Paleoproterozoic are the famous and enigmatic “Banded Iron Formations” of interbedded chert and iron oxide. Peaking in abundance at prior to 2.0 Ga, these also formed on stable platforms in water shallow enough for stromatolites produced by photosynthetic cyanobacteria to occasionally accumulate. The iron in these deposits was apparently injected as Fe⁺² into deep anoxic ocean water from far-away hydrothermal vents. The dissolved Fe⁺² was oxidized in surface waters and/or in

shallow waters oxygenated by agitation or by cyanobacteria. It then accumulated either in pulses of deposition or else steadily amidst silica particles that were accumulating in such pulses because the deposits are beautifully banded with alternating layers of iron oxide (or iron carbonate) and chert. The nature of the original iron and silica precipitates is unknown, but both were likely hydrous, amorphous phases which underwent early diagenetic transformation to crystalline phases. The demise of iron formation deposition has been widely attributed to gradual oxygenation of the ocean, but this does not explain the disappearance of the associated silica deposition. One possibility is that climatic temperatures also declined with time which greatly reduced the amount of dissolved silica transported in the oceans. Numerous other types of silica-replaced sediments occur in the Archean. The silicification is often so extensive that the nature of the replaced sediments can be inferred only by study of petrographic fabrics and preserved sedimentary structures.

Evolution of siliceous sediments with time

For at least the past 540 million years, siliceous sediments have formed primarily by the deposition of biologically secreted opal particles that dissolve and reprecipitate as quartz beds and nodules during the compaction history of the sediments. Prior to this, there is no current fossil evidence that the sponges, radiolaria, and diatoms were present to supply biogenic silica to sediments. Cherts and silicified sediments are nevertheless widespread in Precambrian strata. In the Archean, it is possible that much higher ocean temperatures allowed greatly enhanced transport of dissolved silica and that large areas of the ocean floor were blanketed with opaline floes derived from intense weathering and from deep-ocean hydrothermal vents. It is also possible that bacterial precipitation of opal was widespread and produced equivalent amounts of silica as that produced by the Phanerozoic organisms. However introduced into sediments, silica diagenesis in the Archean must have been particularly vigorous to produce such extensive occurrences of bedded cherts and silicified sediments.

In the late Archean and early Proterozoic, interbedded cherts and iron oxides became common. Inasmuch as the iron is thought to have been exhaled from submarine hydrothermal vents, it is likely that much of the silica was also. However, the role of organisms and the mechanisms that produced rhythmic deposition of iron oxide and silica are still unknown. Large-scale siliceous sedimentation declined during the Proterozoic, but replacement cherts remained common in stromatolitic and other laminated carbonates throughout the Precambrian. Carbonates and associated evaporites were apparently replaced with microcrystalline quartz during early diagenetic stabilization via the same processes that produced Phanerozoic nodular cherts, but the silica source remains problematic. The amount of silica introduced into the Precambrian carbonates appears no different from the younger cases.

The evolution of sponges and radiolarians in the earliest Paleozoic was coincident with the evolution of prodigious numbers of carbonate-secreting organisms. Limestones and dolostones throughout the Paleozoic and Mesozoic are filled with nodular and disseminated replacement chert that resulted when opaline sponge spicules dissolved and reprecipitated during early diagenetic stabilization. Thick radiolarian oozes commonly accumulated in the deep sea and these were

transformed into great bedded chert sequences now displayed in deformed and uplifted accretionary wedges.

Silica secreting diatoms evolved within the last 100 million years and completely transformed the nature of siliceous sediments. These prolific photosynthesizers now dominate silica geochemistry in the ocean, lakes, rivers, streams, and soils. Silica is so efficiently extracted from water by these organisms that dissolved silica concentrations in surface seawater and virtually all fresh water environments are kept well below saturation for quartz and all forms of opal. Silica mobilization and re-precipitation in pore fluids has thus been arrested in sediments except for deep-sea diatomaceous oozes. Any biologic opal introduced into shallow marine carbonate sediments simply dissolves back into the sea; nodular replacement cherts have essentially stopped forming. Siliceous sedimentation is now mainly a case of diatom accumulation. The geologic history of siliceous sediments has thus undergone significant changes that provide another example of the profound influence of biologic evolution on the evolution of sedimentary rocks.

SLIDE AND SLUMP STRUCTURES

Slide and slump structures are common geological phenomena on subaerial and subaqueous slopes (Maltman, 1994). They range in size and volume from a few tens of centimeters to several thousand cubic kilometers (Jansen *et al.*, 1987; Martinsen, 1994), and encompass gliding unconsolidated sediments as well as lithified blocks (olistoliths). Slides and slumps are significant geological processes which have an important impact on human life, known from recent catastrophes (Maltman, 1994, and references therein). In addition, sliding and slumping can seriously affect the stability of offshore installations (Prior and Coleman, 1982), and generate

tsunamis (Driscoll *et al.*, 2000). Products of slides and slumps provide important information on the depositional setting of a sedimentary rock unit.

Basic characteristics and theory

Slumps and slides are downslope movements of sediments above a basal shear surface where there is, respectively, significant and insignificant internal distortion of the bedding (Stow, 1986). In slumps, the bedding should be recognizable, otherwise they classify as debris flows. There is a continuous transition between slides, slumps and debris flows, and some units may show characteristics of all three modes of transport depending on the internal deformation state (Martinsen, 1994).

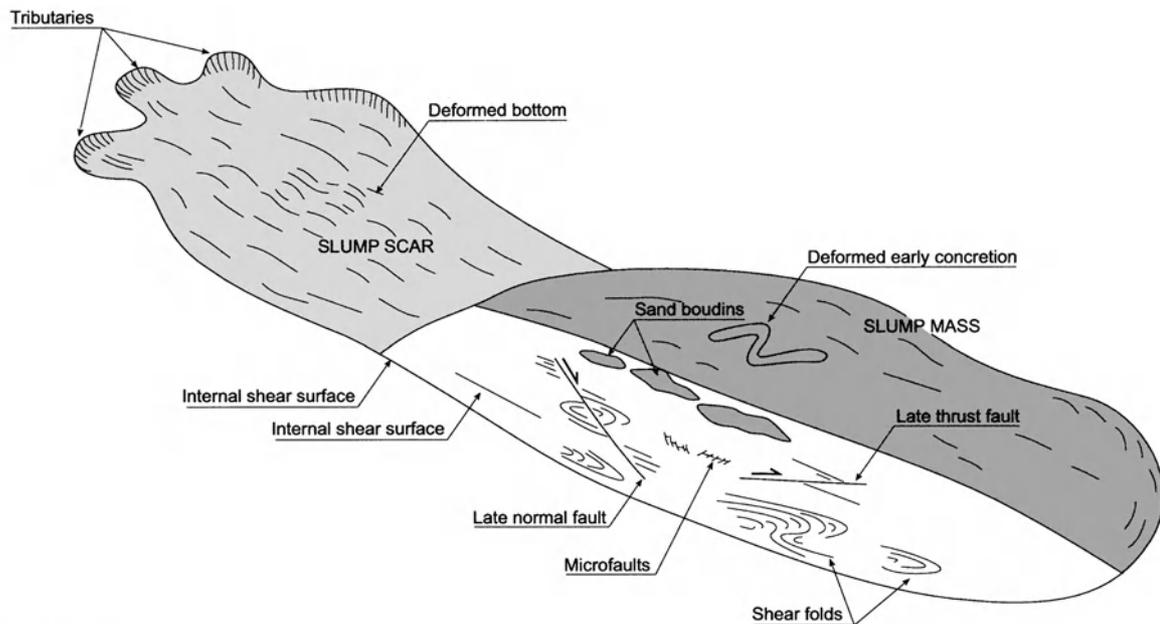

Slumping and sliding are common especially where there are significant fine-grained sediments. The structures form above a basal shear surface (Figures S29 and S30), the depth to which is decided mainly by the pressure gradient in the sediment. Where the pore pressure approaches or balances the normal stress induced by the weight of the overburden, the shear strength is sufficiently reduced to allow slippage along the basal shear surface, given a sufficiently high shear stress. These relationships are given by the equations:

$$\text{Shear strength } (\tau) = C + (\sigma - p)\tan \phi \quad (\text{Eq. 1; Hampton, 1979})$$

and

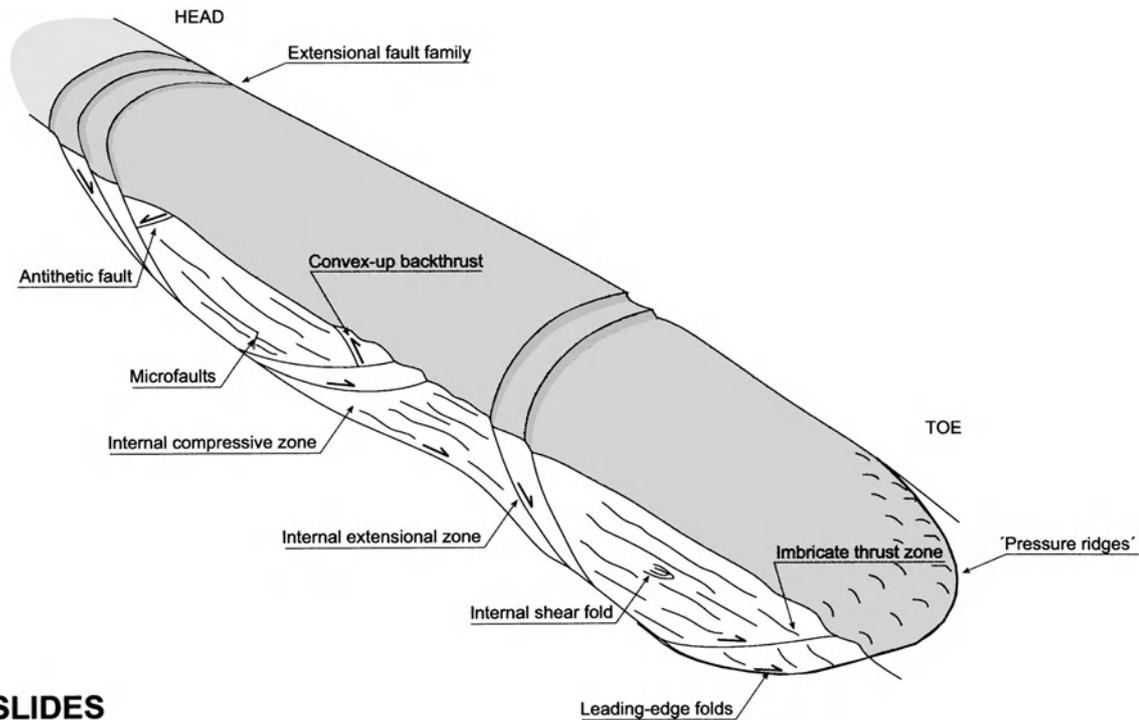

$$\text{Shear stress } (S) = \rho g s Y \tan \alpha \quad (\text{Eq. 2; Middleton and Southard, 1978})$$

where C is sediment cohesion, σ is normal stress (or weight of overburden), p is pore pressure, ϕ is the angle of internal friction, ρ is sediment density, g is acceleration due to gravity, s is solidity (or the complementary of porosity), Y is sediment thickness and α is slope angle.

SLUMPS

Figure S29 Idealized slump model. Modified from Martinsen (1994).

SLIDES

Figure S30 Idealized slide model. Modified from Martinsen (1994).

Once initiated, the slide or slump basal shear surface will propagate upslope in a radial fashion from its nucleation point (Williams and Chapman, 1983), leading to the formation of a scoop-shaped, concave-downslope depression or scar, often with an irregular outline with tributaries (Martinsen, 1994). The shear surface is probably initiated as a slope-parallel feature, but at some point steepens to intersect the sediment surface. The transition may occur at lithofacies boundaries, or at sites of pore pressure jumps where material strength contrasts are present (Crans *et al.*, 1980).

Slumps and slides are triggered by a variety of processes. Seismic triggering, cyclic wave-loading, high sedimentation rates and methane generation causing overpressuring, slope oversteepening, and tectonic movements are all possible initiators (Martinsen, 1994).

Slumps and slides form on low-gradient slopes, as little as 0.1° (Prior and Coleman, 1978). They range in thickness from 0.5 m (Martinsen, 1994), to several hundreds of meters on continental slopes (Jansen *et al.*, 1987).

Slump structures

Moving slumps deform intensely internally and produce a wide variety of deformational structures. Folds, boudins, micro-faults, internal shear surfaces and faults are common structures in slumps (Figure S29). These structures suggest that the slumps go through a main phase of plastic/ductile deformation whereby folds and boudins are formed. The ductile phase is followed by a late brittle phase where the faults form. It is common to see strain overprinting where early-formed folds are truncated by late faults (Figure S31).

Figure S31 Slump unit from the Upper Carboniferous Gull Island Formation, County Clare, Ireland. Note the internal distorted bedding of the unit in the near cliff, which is approximately 15 m high.

The slump folds are mainly sheath folds formed by simple shear (Figure S31; Martinsen, 1994), although buckle folds also occur (Woodcock, 1976). Faults can be extensional and contractional (Figure S29), related to local obstacles or shear surface irregularities. Models of slumps and slides (e.g., Allen, 1985) show a well-defined upper extensional zone and a downslope contractional zone. However, it is likely that a *lateral* compaction will occur when fine-grained slumps come to a halt, preventing development of toe contractional zones, leaving *open-ended zones* (Garfunkel, 1984).

Slump scars often show evidence of retrogressive failure, from footwall unloading (Martinsen, 1994). The slump scars are generally filled by fine-grained sediment, or expanded by

current erosion and filled by coarser-grained turbidity current deposits. In this case, it may be impossible to differentiate the slump scar from an erosional channel.

Slumps form hummocky sediment masses in plan view, particularly at their downslope ends if toe-zones are developed. The topography may be organized into lobate, convex-downslope ridges (Prior *et al.*, 1984) which are the surface manifestation of toe-zone thrust faults (Martinsen and Bakken, 1990).

Slide structures

Slides include bank collapse in river channels, subaerial mudslides, sediments displaced by delta-front growth faults, shelf-edge faults and submarine glide-blocks and olistoliths. Slides are either *rotational* or *translational* (Allen, 1985), depending on the thickness to movement distance ratio.

In their most simple form, slides are spoon-shaped features with a three-partite morphology of an extensional head region, a middle, translational, "rigid" zone and downslope, contractional toe zone (Figure S30; Brunsden, 1984). In rigid zones, there may internal slip between beds in the form of sheath folds or microfaults (Figure S31). The downslope toe region can be "open-ended" with no contractional structures developed because of lateral compaction (Garfunkel, 1984; see also above).

The head region usually develops a "family" of listric faults (Crans *et al.*, 1980) which soles out at a basal decollement. Antithetic extensional faults are common. Fault families in slides is an essential difference from slumps, where most faults are single faults. The margins of the slides are dominated by strike-slip deformation, but the width variability of the slide scar can cause both transpressional and transtensional movement if the slide scar narrows or widens.

Contractional deformation is most commonly expressed as thrust faults. The thrusts form classic duplex and imbricate zone geometries (Figure S31; Dingle, 1977). Three different types of contractional zones occur in slides (Martinsen and Bakken, 1990): (1) The thick package zones; similar to mountain belt thrust zones, but several orders of magnitude smaller; (2) Thin package zones developed at the frontal margin of heterogeneous slides; (3) Basal contractional zones related to obstacles such as ramps.

Toe zones of slides may be confused with contractional zones formed by *gravity spreading*. Gravity spreading forms in progradational settings (e.g., deltas) due to progressive sediment loading (Schack Pedersen, 1987).

SLOPE SEDIMENTS

The *slope* is a relatively steep transition zone between a low-gradient marine shelf (<1° gradient) and the deep seafloor. Mostly, slopes occupy the *bathyal zone* of the ocean basins (200–2000 m). Benthic macrofauna are rare, including thin-shelled bivalves, brachiopods, and echinoderms. Benthic foraminifera, where present, are useful in providing water-depth estimates along ancient slopes. Many slopes are located

at the edges of continents; others fringe volcanic islands or intracratonic basins on continental crust. Around the passive margins of the Atlantic Ocean, the *continental slope* extends from the *shelf-slope break* (~120 m average water depth) to the top of the *continental rise* (~2,400 m average depth; Emery and Uchupi, 1984). Along subduction margins, the base of the slope is much deeper at the landward edge of the trench. The depth of the *shelf-slope break* varies widely between 20–500 m (Fairbridge and Bourgeois, 1978), and may be within the photic zone along carbonate platform margins where reefs grow into the surf zone immediately landward of a precipitous upper-slope escarpment.

Basin slopes are distinguished from adjacent shelves by a steeper gradient and by a lack of significant wave and tidal-current action. Instead, *sediment gravity flows* predominate, sometimes associated with *thermohaline currents* which sweep the distal parts of some slopes. Gradients range from 3–6° or less on mud-dominated passive-margin slopes (Heezen, 1959), to 10–30° on erosional slopes flanking strike-slip basins like those along the North Anatolian Transform Fault of north-western Turkey (Aksu *et al.*, 2000), to local near-vertical escarpments seaward of variably cemented carbonate barrier reefs. The prodelta slopes of marine coarse-grained deltas commonly include sands and gravels transported by gravity currents and slope failures (Nemec, 1990).

Cementation, organic binding and reef development at carbonate platform margins may lead to the development of a very steep upper-slope segment (Coniglio and Dix, 1992). Carbonate slopes of this type are strongly concave in shape because the steep upper slope segment gives way in deeper water to a much gentler gradient. Some carbonate slopes can be steepened by erosion, which may cause the upper slope to retreat tens of kilometers (Jansa, 1981; Mullins *et al.*, 1986). Sandy carbonate sediments form steeper slopes than carbonate muds (30–40° versus <5°; Kenter, 1990).

A fraction of the sediment that moves across the shelf-slope break accumulates on the slope itself, leading to aggradation and progradation, or partial filling of slope basins along convergent continental margins. A greater portion, however, bypasses the slope to deeper water areas like the continental rise and abyssal plain (passive margins) or oceanic trenches (convergent margins). Seismic data provide considerable information on continental slopes. Various patterns of reflections, designated as *seismic facies*, have been recognized (e.g., Sangree *et al.*, 1978). These include: (1) mounded chaotic facies, the result of slumps, slides and other mass movements; (2) onlapping fill facies, due to infilling of slope irregularities by turbidity currents; (3) divergent and parallel-layered facies, a result of deposition from low-energy turbidity currents and hemipelagic sedimentation; and (4) sheet drape facies, resulting from blanketing of slope irregularities by hemipelagic sediments. Hemipelagic sediments accumulate sufficiently slowly that they are usually thoroughly bioturbated by representatives of the *Zoophycos* trace-fossil assemblage. Gravity-flow deposits and sediment slides are emplaced rapidly, so preserve physical structures (e.g., lamination formed by traction transport; deformation structures formed by shearing).

The gradients and morphologies of siliciclastic slopes are strongly controlled by tectonics, sediment supply, and salt or mud diapirism. On passive margins, gradients are low and the seabed may be quite featureless. Exceptions are erosional gullies and submarine canyons in the upper slope that funnel shelf-derived sediment seaward, and slide scars and

mound-shaped slide and slump deposits that characterize some slopes. In high latitudes, where continental ice sheets recently delivered sediment directly to the upper slope, gullies are replaced by widely separated, glacially cut transverse troughs, and the slope tends to be smooth, with or without down-to-the-basin listric faults (Aksu and Hiscott, 1989, 1992). During interglacial times, these glacially fed slopes may become extensively dissected by headward erosion of gullies and canyons (Hesse and Klauke, 1995).

The slopes along convergent plate boundaries lead from a narrow shelf, across an accretionary prism, to the floor of a deep-sea trench. Thrust faults and local mud diapirs in the accretionary prism produce a complex slope morphology (Figure S32) with intraslope basins that are elongated parallel to the plate boundary (Pickering *et al.*, 1995; Moore *et al.*, 2001). Turbidity currents travelling down the slope are diverted into these intraslope basins where they can become ponded.

On basin slopes seaward of major river deltas (e.g., Gulf of Mexico, Niger Delta area), loading of water-rich muds or deeply buried salt by a thick delta and slope succession leads to complex diapiric intrusions, thrust faulting, and down-to-the-basin growth faulting which can create a rugged seafloor characterized by intraslope basins and hills (e.g., Sigsbee Knolls on the Texas–Louisiana slope; Satterfield and Behrens, 1990).

Sedimentary processes and typical deposits

Particulate sediments are transported beyond the shelf-slope break by three main mechanisms: (1) bottom-hugging sediment gravity flows; (2) thermohaline bottom currents; and (3) surface wind-driven currents or river plumes that carry suspended sediment off the shelf. Tidal currents and surface waves are only locally important as transport agents on the upper parts of slopes and in the heads of some submarine canyons (Shepard *et al.*, 1979). Sediment gravity flows that develop on basin-margin slopes include *turbidity currents*, *liquefied flows*, and *debris flows*.

Where shelves are narrow (e.g., offshore California), plumes of suspended sediment from river deltas can extend beyond the

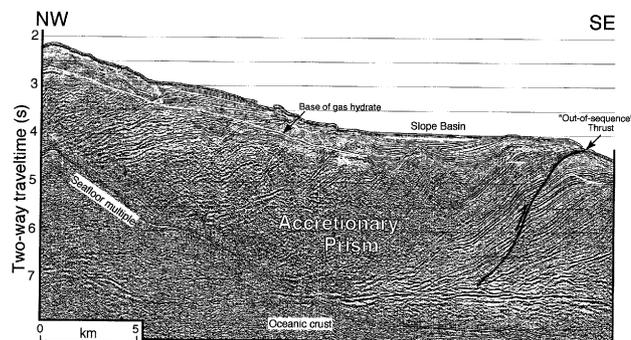

Figure S32 Multichannel seismic dip profile midway down the slope of the Nankai accretionary prism near longitude 134.5E, south of Japan (water depth ~3,000 m). A turbidite-filled *slope basin* has been created atop the stacked thrust sheets of the prism. The white line marks a bottom-simulating reflector, attributed to the presence of gas hydrates. Seismic profile discussed in Moore *et al.* (2001). Reproduced by permission of G.F. Moore.

shelf–slope break (Emery and Milliman, 1978; Thornton, 1981, 1984), directly contributing fine-grained sediments to the slope. In polar areas, sediment-laden spring meltwater may actually flow from the land across the surface of floating sea ice, to deposit its load directly onto the continental slope (Reimnitz and Bruder, 1972).

Mud that leaves the shelf either by high-level escape in river plumes, by dilute turbidity-current flow, or by movement along density interfaces in the water column over the slope eventually settles to the seafloor to form *hemipelagic deposits*. Deposition rates are on the order of 10–60 cm/1000 years (Krissek, 1984; Nelson and Stanley, 1984; Coniglio and Dix, 1992). Hemipelagic sediments contain a pelagic component (biogenic skeletons, volcanic and windblown dust, ice-rafted detritus), generally 5–50 percent but locally as much as 75 percent, with the remainder consisting of terrigenous mud supplied from the adjacent land mass. The finest particles are probably carried to the bottom as aggregates in the form of faecal pellets (Calvert, 1966; Schrader, 1971; Dunbar and Berger, 1981). Unlike turbidites, which fill low areas on the slope (Figure S32), hemipelagic deposits form even-thickness drapes (Figure S33).

Dilute low-concentration turbidity currents tend to travel at relatively low velocities, are potentially many tens of meters thick, and may be turned by the Coriolis Effect to flow oblique or parallel with the bottom contours before reaching the base of the slope (Hill, 1984). On carbonate slopes, the fine-grained material exported from the platform is referred to as *periplatform sediment* (Schlager and James, 1978; Coniglio and Dix, 1992). Suspended sediment concentrations in shelf areas may be quite high due to input of mud-laden river water, or stirring of the bottom by strong waves, tidal currents, or internal waves at density interfaces (Cacchione and Southard, 1974). This suspended sediment may be advected off the shelf by ambient currents, possibly wind-driven, or by transport in cascading cold water that may flow off the shelf in the winter months (McCave, 1972; McGrail and Carnes, 1983; Wilson and Roberts, 1995). Suspensions of fine-grained sediment may also leave the shelf as dilute turbidity currents (lutite flows),

moving along the bottom onto the lower slope and rise, or along density interfaces in the ocean water. These dilute suspensions may move down a smooth upper slope as unconfined sheet flows, or may be confined by gullies or canyons in which suspension is assisted by weak tidally-forced flows (Shepard *et al.*, 1979; Gorsline *et al.*, 1984). Most mud transported off the shelf by dilute turbidity currents (lutite flows) bypasses the slope, leading to maximum rates of accumulation on the continental rise (Nelson and Stanley, 1984). In carbonate settings, platform-derived sediment can be traced >100 km from the shelf edge (Heath and Mullins, 1984).

High-concentration turbidity currents carrying significant sand load are confined to gullies and larger canyons on the slope, permitting the sediment to *bypass* this area to accumulate in deeper water (base-of-slope fans, or on the abyssal plain). Komar (1971) argued that turbidity currents are likely to be *supercritical* (Froude number >1.0) on slopes greater than $\sim 0.5^\circ$. Such turbidity currents can effectively carry sand-sized detritus across basin-margin slopes without leaving a deposit: there may even be net erosion in these areas. For example, Weaver and Thomson (1993) demonstrated slope bypassing by large mud-rich turbidity currents entering the Madeira Abyssal Plain by examining their reworked coccolith assemblages. Such bypassing requires that the turbidity current be at the least self-sustaining on the slope, or while flowing through slope channels. This condition of *self maintenance* (Southard and Mackintosh, 1981) was named *autosuspension* by Bagnold (1962).

Gully margins and adjacent areas of the upper slope may be sites of sediment failures as coherent slides and internally folded and deformed slumps. The downslope component of gravity can cause sediment masses previously deposited on a slope to move by increments or during a single episode into deeper water. Slow downslope movement without slip along a single detachment surface, i.e., without failure, is referred to as *creep*. No structures in ancient successions have been unambiguously attributed to creep, although features in seismic profiles have been interpreted to have formed by this mechanism (Hill *et al.*, 1982; Mulder and Cochonat, 1996). More rapid downslope movements generate sediment slides and debris flows. Sediment slides can result in little-deformed to intensely folded, faulted and brecciated masses (Barnes and Lewis, 1991) that have translated downslope from the original site of deposition, leaving a headwall scarp and slide scar where the failure occurred. If the primary bedding is entirely destroyed by internal mixing, with soft muds and/or water mixed into the slide, then it may transform into a debris flow. The base of the slide mass is marked by an *intraformational truncation surface* and shear zones (Coniglio, 1986).

Initiation of slides in muddy terrigenous sediments depends on: (1) bottom slope (Moore, 1961); (2) sedimentation rates (Hein and Gorsline, 1981); and (3) the response of the sediment to cyclic stress produced by earthquake shaking (Morgenstern, 1967). Sedimentation rates on basin-margin slopes vary widely, but Hein and Gorsline (1981) conclude that a rate of 30 mg cm^{-2} per year must be attained before slope failures become common. For example, in the Santa Barbara Basin, California Borderland, sedimentation rates exceed 50 mg cm^{-2} per year, and debris flows are widespread on slopes of $<1^\circ$ (Hein and Gorsline, 1981). In many areas, sediment slides occur on very low slopes, suggesting the involvement of water-rich, rapidly deposited sediments.

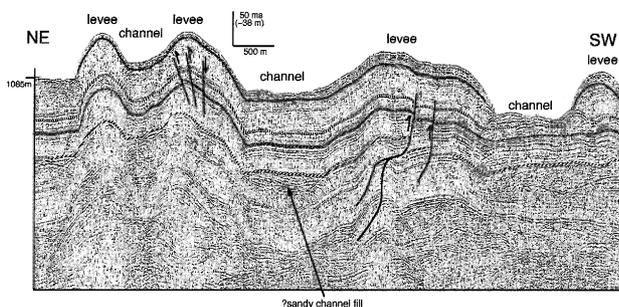

Figure S33 Single-channel seismic strike profile across the middle slope offshore Brunei, Borneo (Hiscott, in press). Water depth is $\sim 1,000$ m. The slope gradient, toward the reader, is $\sim 2^\circ$. A number of leveed channels have grown vertically during the Quaternary, principally through fallout of suspended load from the Baram Delta to form an even-thickness hemipelagic drape. The channel to the SW has been most recently active—levees have enhanced sediment thicknesses and the floor of the channel appears to have a central thalweg channel flanked by low, possibly sandy inner levees (cf. Piper *et al.*, 1999). The patterned lines mark reflections that can be widely traced across the Brunei shelf and upper slope.

The sedimentation rate effectively determines the water content and shear strength of the sediment, although shear strength is also a function of other variables such as content of organic matter (Keller, 1982) and generation of gas in the sediment by decay of organics or by decomposition of gas hydrates (Carpenter, 1981). According to Keller (1982, p.197), “cohesive sediments with greater than about 4–5 percent organic carbon [have]... (1) unusually high water content; (2) very high liquid and plastic limits; (3) unusually low wet bulk density; (4) high undisturbed shear strength; (5) high sensitivity; (6) high degrees of apparent overconsolidation; and (7) high potential for failure [by liquefaction] in situations of excess pore pressure”.

Slides and debris-flow deposits (*debrites*) are common slope sediments. In carbonate settings, the individual blocks in debrites may be larger in diameter than 100 m (Hiscott and James, 1985; Hine *et al.*, 1991). Single flow deposits can be many tens of meters thick (Figure S34), and taper to convex-upward *snouts* at their downslope and lateral margins (Hiscott and James, 1985; Hiscott and Aksu, 1994). Shingled, downslope-elongate debrites are common in high-latitude slopes (Aksu and Hiscott, 1992), where glaciers delivered large quantities of poorly sorted sediment directly to the upper slope during Quaternary glacial advances.

The deeper segments of slopes on the western sides of ocean basins are affected by geostrophic, thermohaline currents moving at mean speeds of 10–30 cm per second (McCave *et al.*, 1980; Hollister and McCave, 1984), with short “gusts” reaching about 70 cm per second (Richardson *et al.*, 1981). These currents follow bathymetric contours, and are known as *contour currents*. They carry a dilute suspended load, generally $< 0.1\text{--}0.2\text{ g m}^{-3}$, that forms the thick bottom *nepheloid layer* (Ewing and Thorndike, 1965; Biscaye and Eitrem, 1977). Concentrations may briefly exceed 12 g m^{-3} (Biscaye *et al.*,

1980, Gardner *et al.*, 1985). Most of the fine-grained suspended material is derived by winnowing of the seafloor; the rest is probably added to the current by cascades of cold shelf water or lutite flows originating at the shelf–slope break. The water depths to which thermohaline currents influence the seabed have changed from glacial to interglacial times in high-latitude oceans (Hillaire-Marcel *et al.*, 1994), in some cases shifting from the continental rise to the lower continental slope. It is reasonable to assume that similar excursions of the axes of contour currents occurred along ancient slopes and rises.

Contour current deposits, or *contourites* (Hollister and Heezen, 1972), can be treated as two end members: (1) muddy contourites, and (2) sandy contourites. Muddy contourites are fine grained, mainly homogeneous and structureless, thoroughly bioturbated, and only rarely show irregular layering, lamination and lensing. They are poorly sorted silt- and clay-size sediments with up to 15 percent sand. They range from finer grained homogeneous mud to coarser grained mottled silt and mud, and their composition is most commonly mixed biogenic and terrigenous grains. According to Hollister and McCave (1984), short-term depositional rates can be extremely high, about 17 cm per year, followed by rapid biogenic reworking by burrowers. It may be difficult to distinguish between mud turbidites and muddy contourites, although some criteria have been suggested (Bouma, 1972; Stow, 1979).

Sandy contourites comprise irregular layers $< 5\text{ cm}$ thick that are either structureless and thoroughly bioturbated, or that possess some primary parallel or cross lamination which may be accentuated by heavy-mineral or foraminiferal concentrations (Bouma and Hollister, 1973). Grading may be normal or inverse, and bed contacts may be sharp or gradational. Grain size ranges from coarse silt to, rarely, medium sand, with poor to moderate sorting. The sandy facies, which may be rich in biogenic sand grains, is produced

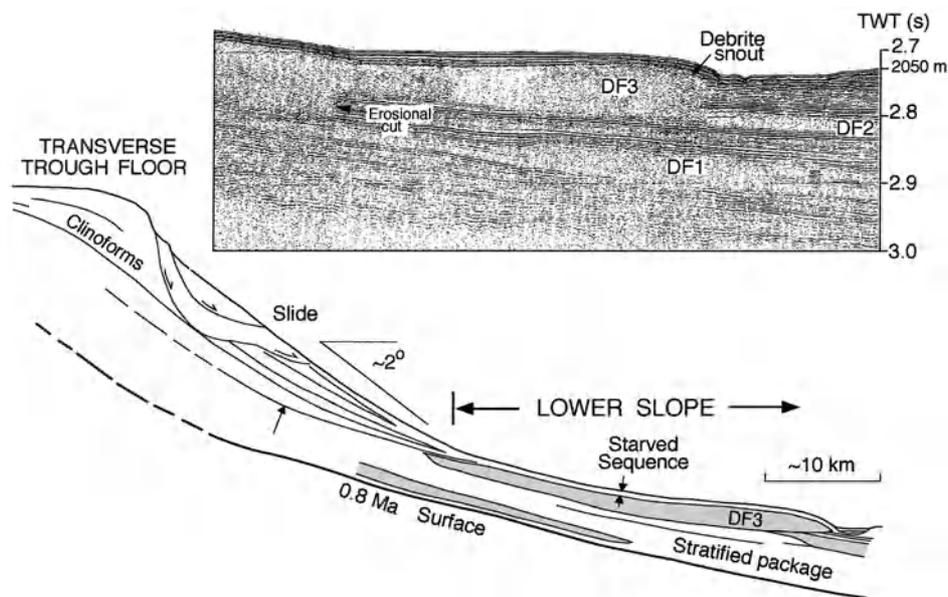

Figure S34 Single-channel seismic dip profile from the lower slope offshore Baffin Island, Canadian Arctic (modified from Hiscott and Aksu, 1994). The line drawing shows the relationship of the lower slope to the entire margin. Stratified hemipelagic deposits (including ice-rafted sediments) are punctuated by large-volume, mounded debris-flow tongues (DF1–DF3) derived from the upper slope when glaciers were depositing till and outwash at the shelf edge. The debrites have distal snouts that testify to the intrinsic strength of the viscous muddy debris.

by winnowing of fines by stronger flows (Driscoll *et al.*, 1985). Where currents are focused by seabed topography, as in the Florida Strait, coarse grained contourites may include lag gravels and cemented *hardgrounds* (Coniglio and Dix, 1992). Reworking of sandy turbidites by contour currents can result in bottom-current-modified turbidite sands, believed to be common on some continental slopes.

Muddy and sandy contourites commonly occur together in vertical upward coarsening to upward fining sequences (Faugères *et al.*, 1984; Stow and Piper, 1984). A complete sequence shows inverse grading from a fine homogeneous mud, through a mottled silt and mud, to a fine-grained sandy contourite facies, and then back to a muddy contourite. The changes in grain size, sedimentary structures and composition probably are related to long-term (1 kyr to 30 kyr) fluctuations in the mean current velocity (Stow and Piper, 1984).

Oxygenation and organic-matter deposition

In some slopes, particularly along the eastern sides of ocean basins (e.g., offshore west Africa, California, and Peru), the wind-driven surface circulation causes upwelling of nutrient-rich deep water, and enhanced biological productivity above the slope. The high biological productivity leads to organic carbon and phosphate deposition and, locally, accumulation of diatomaceous deposits. Oxygen is consumed to oxidize this material, and eventually sediment pore water and possibly even the marine bottom water become anoxic, creating an *oxygen minimum* along the slope. For example, along the eastern Pacific continental margin, an oxygen minimum layer occurs in intermediate water masses, commonly at depths of 250–1500 m (Ingle, 1981).

Two levels of oxygen depletion of bottom waters are recognized by Byers (1977): *disaerobic* conditions (0.1–1.0 ml O₂/L H₂O) under which only resistant infauna survive to bioturbate sediment; and *anaerobic* conditions (<0.1 ml O₂/L H₂O) where no benthic organisms live and the sediment remains undisturbed by burrowers, commonly being finely laminated. Where the sediment pore water is *anaerobic* but the overlying bottom water is oxygenated, some filter-feeding organisms may populate the seabed, but there will be no infauna and therefore little bioturbation.

Facies successions and architecture of slope deposits

There is consensus that slope successions do not consist of predictable, depositional cycles (Pickering *et al.*, 1989; Coniglio and Dix, 1992). Instead, the facies architecture is disordered. Stow (1986) identified differences in facies associations between muddy facies of the upper versus lower slope. The upper slope is marked by more abundant coarse grained gravity-flow deposits, slide scars, erosional gullies and channels; in contrast, the lower slope is characterized by more fine-grained turbidites, relatively rare submarine channel fills, debrites, slide and slump scars, and local interfingering with contourite drifts and/or submarine-fan deposits.

Summary

Basin slopes extend from the shelf–slope break at ~100 m depth, to the top of the continental rise on passive margins (~2500 m depth), or to the landward edge of the trench along subduction margins. This includes the entire bathyal zone.

Siliciclastic slopes typically have gradients of 3–6°, whereas the upper segments of carbonate slopes can be much steeper because of biological reef development and early cementation. The upper slope is generally an area of bypass, cut by gullies and slide scars. Any draping sediments are hemipelagic or periplatform deposits (the latter for carbonate settings). Farther downslope, turbidites and debrites punctuate the slope succession, particularly in bathymetric lows like those atop accretionary prisms at convergent margins. The distal slope may be influenced by thermohaline bottom currents producing muddy and sandy contourites. In areas where oceanic upwelling enhances biological productivity, organic-rich deposits, phosphates and diatomites may accumulate under dysaerobic to anaerobic conditions.

SLURRY

Introduction

A slurry is a mixture of solids and fluid that is highly mobile under gravitational and low magnitude stresses, and remains

coherent (no bulk phase separation) during transport. In geophysical settings, a slurry is part of a spectrum of mass-flow phenomena known as sediment gravity flows. In agricultural, industrial, and engineering settings, a slurry is a coherent two-phase mixture that commonly is pumped into place rather than driven by gravity. The criterion of high-mobility is included here to distinguish a slurry from concentrated, low-mobility industrial suspensions of solids and fluid such as gels, greases, and pastes. The fluid medium of both geophysical and industrial slurries commonly consists of water but in some circumstances may consist of a gas or oil. The solids component of a slurry can have widely varying composition, size distribution, and concentration. Common geophysical and industrial slurries can consist of cohesive fine sediment, inorganic granular debris, rock fragments, coal, animal waste, sewage sludge, snow, or ice. Some familiar examples of slurries include freshly mixed concrete, drilling mud, and debris flows. The volume concentration of solids in a slurry can vary widely. In general, the finer grained the solids, the lower the concentration needed to obtain a coherent solids-fluid mixture. For example, a slurry composed of smectite and water can become coherent at a solids concentration of as low as 3 percent by volume (Hampton, 1972), whereas a granular debris flow typically does not become coherent until the solids concentration reaches about 50 percent or more (e.g., Iverson and Vallance, 2001).

Distinguishing characteristics of a slurry

A slurry differs from a dilute suspension or solids-laden fluid in terms of momentum transfer, the pressure in the suspending fluid, and phase separation of the solid and fluid constituents. In dilute suspensions or solids-laden fluids, momentum is transferred by fluid forces, and the solids are a passive component transported by the fluid (see *Gravity-Driven Mass Flows*). In a slurry, however, significant momentum transfer occurs through solid-phase interaction, owing to the greater concentration of particles. Solids are no longer transported passively, but instead move the suspending fluid in response to a pressure gradient or gravitational body force.

Nonequilibrium fluid pressure, the total fluid pressure minus the local hydrostatic fluid pressure, further distinguishes a slurry from a solids-laden fluid. In a concentrated slurry, nonequilibrium fluid pressure arises from gravitational settling of the particles, which transfers stress to the fluid phase. If the fluid can migrate easily through pore spaces around the solid particles, the nonequilibrium fluid pressure dissipates readily, otherwise it remains elevated and helps balance the weight of the overlying mixture. As long as pore-fluid pressure remains elevated, particle settling is hindered, and separation of the solid and fluid phases is limited.

A lack of phase separation over timescales relevant to the transport process can be used to further distinguish a slurry from a solids-laden fluid. In a solids-laden fluid, the phases are not intimately bound, and gravitational settling of particles is controlled by the size, shape, and density of the particles, by the density and viscosity of the fluid, and by fluid dynamics (such as turbulence). Gravitational phase separation in slurries, however, is related to dissipation of nonequilibrium fluid pressure (e.g., Major, 2000; also see *Gravity-Driven Mass Flows*). An approximate estimate of the time necessary for phase separation to occur in most geophysical slurries is obtained by examining the ratio h^2/D , where h is the thickness

of the slurry and D is the hydraulic diffusivity, a property that depends on the compressibility and permeability of the mixture and the viscosity of the fluid. Values of D are influenced by the concentration and size distribution of solids in a slurry, and can range over several orders of magnitude. Concentrated suspensions of sand that contain at least a few percent silt and clay have diffusivities on the order of 10^{-7} m^2 per second or smaller, whereas dilute suspensions of sand have diffusivities on the order of 0.1 m^2 per second. In the context of mixture transport, the wide range in diffusivity values illustrates why the mixture dimension (h), as well as its solids and fluid properties, influences whether it remains coherent over relevant transport timescales.

Applications

Although naturally occurring slurries, such as debris flows, subaqueous slumps, and snow-rich slushflows, commonly pose significant environmental hazards, artificial slurries are used for a number of agricultural, industrial, and geotechnical purposes. For example, fluvial and estuarine bed sediments have been dredged, mixed into slurries, and pumped to facilities for bioremediation treatment to remove contaminants (e.g., Glaser, 1997); by-products of coal treatment and other industrial wastes commonly are mixed into slurries and pumped into impoundment ponds for storage or disposal; agricultural and animal wastes are converted into slurries and spread across the land surface or injected underground for disposal; and clay-slurry barrier walls have been developed and used for industrial waste containment and other geotechnical applications (e.g., Guy, 1995).

Smectite Group

SMECTITE GROUP

Smectite, also known as “swelling clay”, is a diverse group of clay minerals with a 2:1 layer silicate structure that can expand and contract upon wetting and drying. All 2:1 layer silicates (which also include illite/mica, chlorite, and vermiculite groups) have 2 tetrahedral sheets surrounding a central octahedral sheet. Smectite 2:1 layers have a negative charge which is balanced by weakly bonded, exchangeable cations, located in the interlayer region (between 2:1 layers). Smectite interlayers also contain water, which results in little to no stacking order between 2:1 layers, a property known as turbostratic stacking.

Chemical composition, morphology, and identification

The smectite group (derived from the Greek, smectos, which means soap) shows large chemical variability, resulting in many specific mineral names (Güven, 1988). The most common smectite mineral is montmorillonite, which has the following representative chemical formula: $X_{.3} \cdot n\text{H}_2\text{O} [(Al_{1.5}Fe^{3+}Mg_{.2})Si_4O_{10}(OH)_2]^{-.3}$, where X = exchangeable cations such as Na^+ and Ca^{2+} ; n = number of interlayer water molecules, which varies but commonly is $\sim 4-5$; Al, Fe, and Mg = octahedral cations; and Si = tetrahedral cation. Tetrahedral substitutions of Al^{3+} for Si^{4+} are also common and develop negative 2:1 layer charge, which can vary from ~ -0.25 to -0.6 . Smectite has a crystal structure similar to vermiculite, except that vermiculite has a larger negative charge on 2:1 layers. There are two subgroups of smectite minerals: dioctahedral smectite, which has 2 octahedral cations per $O_{10}(OH)_2$ and trioctahedral smectite, which has 3 octahedral cations per $O_{10}(OH)_2$. Fe-rich dioctahedral smectite is nontronite and Mg-rich trioctahedral smectite has several specific mineral names including saponite (with a tetrahedral charge) and stevensite (with an octahedral charge). Much rarer examples include Co-rich, Cr-rich, Cu-rich, Mn-rich, Ni-rich, V-rich, and Zn-rich smectites. Many of the above elements, and others such as Li and F, occur in small amounts in common smectite minerals.

Smectite morphology, which depends on conditions of formation, includes subhedral flakes, euhedral elongate laths and ribbons, and less commonly, euhedral rhombohedra and hexagons (Güven, 1988). Because natural smectite is nearly always very fine-grained (typically $< 2 \mu\text{m}$), identification is normally by X-ray diffraction. Upon exposure to ethylene glycol, smectite has a diagnostic 1.7 nm (17Å) basal spacing, which represents the thickness of the 2:1 layer plus interlayer.

Sedimentary petrology

Smectite is relatively common in soil, sediment, and Cenozoic to Mesozoic sedimentary rock and paleosol. It forms in a variety of surficial environments associated with waters that have relatively high cation (Na, Ca, +K)/H activity ratios and $SiO_{2(aq)}$ activities. It is thermodynamically metastable compared to other more ordered silicates; it forms readily, however, because of fast reaction kinetics (Essene and Peacor, 1995).

Smectite forms commonly in soils, particularly in areas with moderate to relatively low rainfall, poor drainage, and neutral to basic soil waters (Chamley, 1989, pp. 21–50). The relatively weak leaching capacity of such soil waters allows retention of soluble elements (Na, Ca, Mg) and silica necessary for smectite formation. Smectite forms by alteration of volcanic glass, feldspars, mafic silicates, and other aluminosilicate minerals as well as by direct precipitation from solution. Soil smectite also forms from clay mineral precursors such as illite, chlorite, and vermiculite as well as the disordered phases imogolite and allophane. Most commonly dioctahedral Al-rich smectite forms in soils; however, dioctahedral Fe-rich smectite (nontronite) forms from parent rocks rich in mafic silicates. Smectite formed in a soil environment is notoriously difficult to characterize chemically because of its heterogeneity and the presence of other minerals in the clay size-fraction, making chemical characterization difficult. Soil smectite commonly occurs with an incomplete Al- or Fe-octahedral sheet in the interlayer, making it intermediate between smectite and chlorite. Soil smectite can also have a relatively high negative charge on the 2:1 layers, making it transitional to vermiculite. Such minerals are called hydroxy-interlayered smectite, hydroxy-interlayered vermiculite, or simply hydroxy-interlayered expandable. Finally, soil smectite occurs commonly as a mixed-layer mineral (i.e., 2 different structures present within a single crystallite) with chlorite, illite, or vermiculite. The presence of smectite in a paleosol can suggest an arid paleoclimate.

Smectite has a detrital origin in many other surficial depositional environments such as glacial, fluvial, desert, freshwater lacustrine, and deltaic (Chamley, 1989, pp. 53–116). Study of minerals in such settings can give insight into provenance and paleoenvironmental conditions in the sediment source area. Evaporative (saline and alkaline) lakes can produce trioctahedral Mg-rich smectite, which forms by either alteration of a precursor dioctahedral smectite or direct precipitation. Smectite tends to stay in suspension and pass directly into the marine environment rather than settle in an estuary because it is not affected as much as other clay minerals by differential settling resulting from flocculation. Flocculation (q.v.) involves aggregation of fine-grained minerals into larger masses commonly because of their interaction with saline water. As smectite is transported from continental to marine environments there is little change other than interlayer cation exchange, which commonly involves a change from Ca-rich smectite to Na-rich smectite. Authigenic Fe-rich smectite forms as a precursor to Fe-rich illite (glaucinite) in shallow, low-latitude marine environments near rivers that supply abundant dissolved iron (Chamley, 1989, 213–234). Smectite in a deep marine environment commonly has a mixed origin; much of it is detrital and Al-rich but some of it can be authigenic and Fe-rich (Chamley, 1989, 259–289).

Al-rich smectite forms during low-temperature (<~50°C) burial diagenesis or hydrothermal alteration of silicic volcanic glass and feldspar (Chamley, 1989, 333–358). Bentonites (q.v.) are soft, plastic, light-colored clay layers comprised predominantly of smectite that typically form by alteration of volcanic ash. With increasing temperature of burial or hydrothermal alteration as well as geologic age, smectite reacts to mixed-layer illite-smectite and eventually to pure illite (Chamley, 1989, pp. 359–389). Interlayer water lost during this reaction is considered important to geopressure development and petroleum migration out of source rocks (Eslinger and Pevear, 1988,

Section 5, pp. 33–42). Low-temperature burial diagenesis or hydrothermal alteration of mafic volcanic glass and mafic silicates results in formation of *palagonite*, which consists of a variety of authigenic minerals including abundant smectite that ranges from Fe-rich to Mg-rich (Chamley, 1989, pp. 291–329). High-temperature hydrothermal alteration of basalt produces mixed-layer chlorite-smectite.

Physical properties and environmental applications

The very fine grain size of smectite and presence of a negative 2:1 layer charge as well as exchangeable cations and water in the interlayer result in environmentally important physical properties including high cation exchange capacity (ability to exchange cations between the interlayer and pore water), catalytic action (ability to increase the rate of a chemical reaction), swelling (ability to incorporate large amounts of interlayer water causing expansion of 2:1 layers from each other), and low permeability. The high cation exchange capacity of smectite can influence the chemistry of natural waters and mobility of pollutants in groundwater. Smectite can catalyze chemical reactions because of its extremely large and chemically reactive surface area, including the interlayer region. The catalytic activity of smectite along with its ability to adsorb polar organic molecules, has led some to propose that smectite was important to the origin of life and that smectite minerals can even be considered crystal genes because of their ability to grow (replicate) and introduce defects (evolve) (Cairns-Smith and Hartman, 1986, pp. 130–158). In dilute water, smectite with interlayer Na can expand to up to 10–15 times the volume of the dry clay, exerting a great upward pressure. As it dries, it shrinks back to its original volume. This shrink-swell action can damage walls, foundations, and roads. Average annual damage from swelling clays in USA is several billion dollars, making it one of the most costly natural hazards (Keller, 2000, pp. 68–69). Problematic areas in USA are in Montana, Wyoming, South and North Dakota, Colorado, Texas, and Louisiana. The swelling of Na-smectite along with its relatively low engineering (shear) strength can also greatly increase damage due to liquefaction (transformation from a solid to liquid state) during an earthquake and landsliding. Swelling of Na-smectite in an oil reservoir rock can greatly reduce production potential (Eslinger and Pevear, 1988, Section 8, pp. 6–10). The extremely low permeability of smectite-rich earth materials make them effective aquitards and very useful as liners in waste disposal systems. Conversely, smectite-rich soils (known as vertisols) are not particularly productive because of their impermeable nature and their tendency to be very soft and plastic when wet and very hard when dry, which makes plowing difficult (Grim and Güven, 1978, pp. 245–246).

Commercial deposits and uses

Commercial deposits of smectite are mainly from bentonite (defined above) and fuller's earth (any natural material that has a high absorptive capacity and can decolorize oil; smectite is commonly abundant in fuller's earth). Large deposits of bentonite and fuller's earth are located in the USA (Wyoming, Mississippi, Texas, Arizona, and California), England, Germany, Russia, Japan, and many other countries (Grim and Güven, 1978, pp. 13–126). The major commercial uses of smectite are for foundry molding sands and drilling mud.

Many other minor commercial uses of smectite are listed by Grim and Güven, (1978, pp. 217–248). Molding sands, which consist of sand and most commonly smectite clay, are used by foundries to receive molten metal during the casting process. The function of smectite is to bind the sand and maintain the mold shape after hot metal is poured into it. Smectite is a major component in mud used in drilling of oil and water wells. The function of smectite is to create a viscous fluid with water that cools and lubricates the drill bit and removes rock chips by circulating drilling mud down through the hollow drill stem and up through the area between drill stem and hole. Smectite in drilling mud gives it the desirable property of *thixotropy*, which is the ability to go from a liquid state when stirred to a semi-solid state upon standing. Smectite thixotropy, which is related to its ability to undergo swelling, allows the drilling mud to stiffen and prevent rock chips from settling back into the hole when pumping of drilling mud is stopped temporarily. There are many other uses of smectite including decolorization of oil, catalysis in petroleum refining, ceramics, animal bedding, adhesives, cement, clarification of wine and water, animal feed, grease, ink, pharmaceutical products, paint, paper, pelletizing iron ore, pesticides, rubber, and soap.

Summary

Smectite represents a chemically diverse group of clay minerals with a 2:1 layer silicate structure that swells and shrinks with wetting and drying. It occurs commonly in soil, sediment, and post-Paleozoic sedimentary rock associated with waters that have relatively high cation (Na, Ca, +K)/H activity ratios and SiO_2 (aq) activities. It forms most commonly in soils from subhumid to arid climates, however, it also forms in saline and alkaline lacustrine, deep marine, and low-temperature burial diagenetic and hydrothermal environments. Aluminosilicates and silicic volcanic glass alter to Al-smectite whereas mafic silicates and mafic volcanic glass alter to Fe- or Mg-smectite. Environmentally important physical properties include high cation exchange capacity, catalytic action, swelling, and low permeability. Commercial uses are mainly as drilling mud and foundry molding sands.

SOLUTION BRECCIAS

Solution breccias are common and widespread in the geological record. Brecciation may occur entirely within one soluble rock (usually limestone or dolostone) or where more soluble evaporites are removed in mixed evaporite–carbonate and evaporite–redbed sequences. It may be extended upward by mechanical failure (stoping) into overlying insoluble strata, e.g., dissolution of ~180 m of salt has propagated through 400 m of carbonates overlain by ~650 m of clays, mudstones, and sandstones at a site in Saskatchewan (Christiansen and Sauer, 2001).

Brecciation can occur during early diagenesis when evaporites are dissolved in supratidal carbonate sequences (Choquette and James, 1988) or where caves in case-hardened carbonate sand dunes collapse. It is common at inter- and intra-stratal sites during burial and later diagenesis, caused by expulsion of basinal fluids, or by hydrothermal or meteoric waters: it may extend to pressure solution (stylolite) depths. It is also common in superficial karst terrains, where meteoric groundwater is known to brecciate carbonate rocks at depths as great as 2 km.

Breccia fabrics and matrix

Three principal fabrics are recognized (Stanton, 1966): (1) crackle breccia, where beds sag apart and crack upon dissolutional removal of support but there is little displacement; (2) mosaic pack breccia, where there is clast support. The clasts have usually dropped and vary from partly rotated to completely disorganized in orientation. Globally, clast sizes range from small pebbles to “cyclopean breccias” with blocks of hundreds of cubic meters but are normally more limited within any given breccia; and (3) rubble float breccia, which is matrix-supported. A genetic association of these fabrics is often found, consisting of crackle breccias at the top and around the perimeter of a body, pack breccia within it where beds are thicker, and float breccias where beds are thin or at the base. In some Mississippi Valley Type (MVT) deposits, these may be underlain by a basal “trash” zone of insoluble residua (Sangster, 1988).

Clast-supported breccias may be comprised of clasts and voids only, with little or no matrix or cement. This is most common in breccias in sinkholes and caves that are actively developing today. Matrix is usually present in early diagenetic, inter- and intrastratal breccias, consisting of carbonate fines and insoluble residua that have filtered down or (more rarely) allochthonous sands and clays. Older breccias of all types will normally display partial or complete cementation. Calcite is the principal cement but aragonite, dolomite and gypsum are also common. In MVT the chief cements are dolomite, FeS_2 , PbS, and ZnS.

Figure S35 A dolomite and dedolomite solution breccia created by preferential dissolution of gypsum in a sabkha sequence, the Bear Rock Formation (Lower–Middle Devonian) at Bear Rock near Fort Norman, Northwest Territories, Canada. The section is ~15 m in height.

Form and location of the principal types of breccia bodies

As noted, solution breccias are common on the surface and underground in modern karst terrains, chiefly where sinkholes, river cliffs, or shafts and chambers in caves, have collapsed. Individual collapses may be millions of cubic meters in volume. Where surficial collapses are preserved in buried paleokarsts, Choquette and James (1988) term them “mantle breccias”.

Extensive brecciation is usually present where the proximal margins of buried salt bodies on the continents are subject to dissolution by groundwaters penetrating the cover rocks, creating a receding “salt slope” (Ford and Williams, 1989, p.460). In Manitoba and Saskatchewan, Canada, the salt slope of a Devonian deposit is ~800 km in length and now at a mean depth of 200 m below the surface. It has been subroded westward an average of 130 km since burial in the Devonian.

Breccia pipes (“geological organs”, “breakthroughs”, “prismatic bodies” of different authors) are the most widely reported breccia bodies, thousands of examples being described in the world literature (Bosak *et al.*, 1989). Diameters range from <10 m to >10 km, with a majority being 20–250 m. Most are plumb vertical, with reported heights ranging from 20 m to more than 1000 m. Higher examples have usually stoped upward through one or more cover formations, which may include siliciclastics, coal measures, extrusive volcanics, etc. The upward termination may be in undisturbed rock, in downfaulted but not brecciated strata, in a closed depression at the surface, or even upstanding as a firmly cemented and resistant “castille” above an erosional plain (e.g., Hill, 1996, in New Mexico). Most breccia pipes originate in point dissolution of salt (occasionally, of gypsum or anhydrite) above a fracture junction, anticlinal crest or buried reef that channels groundwater. They may be targets for the later precipitation of economic ore, such as the

well-known uranium pipes of the Grand Canyon, Arizona (Huntoon, 1996).

Other forms are described in most detail from MVT deposits (e.g., Sangster, 1988). Breccia domes typically 30–100 m in diameter are similar to breakdown rooms in modern caves or transitional to breccia pipes. Tabular or sinuous forms are wide but shallow breccias extending for one km or more, often along paleoreef margins. Straight linear features (“runs”) and reticulate mazes include individual breccia-filled corridors up to 30 m high, 150 m or more wide, and one or more km in length. Most of these features occur at relatively shallow depths beneath long-exposure paleokarst surfaces and are believed to be genetically associated with them. Some are attributed to brecciation and subsequent sulfide ore (cement) deposition from invading hydrothermal solutions (Dzulynski and Sass-Gutkiewicz, 1989).

SPELEOTHEMS

Introduction

“Speleothem” (Greek; “spele”—cave, “them”—make)—a general term for secondary minerals deposited in natural caves (Moore, 1952). More than 250 different minerals are recorded

(Hill and Forti, 1997). At the global scale calcite precipitates in solution caves in carbonate rocks are overwhelmingly predominant, both in frequency of individual deposits and in aggregate volume. They accumulate in air-filled (vadose) and water-filled (phreatic) caves. Aragonite is second in abundance but rare as a subaqueous deposit. "Travertine" and "sinter" are alternative general terms for these two precipitates, or "tufa" when they are precipitated partially or entirely on organic frameworks, usually vegetal and in the illuminated entrance zones of caves. Gypsum is third in abundance, in gypsum caves but also in limestone caves with gypsum interbeds or inclusions, or where H_2SO_4 can be created by oxidation and react with the rock. Hydrated carbonates and sulfates (e.g., hydromagnesite, epsomite) are also quite common, usually as pastes or powders of crystallites that are small in amount. Other secondary minerals are more localized, associated with particular source conditions in the bedrock or clastic sedimentary fillings, and quite rare at the global scale. They include native sulfur, many oxides and hydroxides, halides, nitrates, phosphates, silicates, vanadates, and a few organic minerals (Hill and Forti, 1986, 1997). Perennial ice is found in many cold caves.

Calcite and aragonite speleothems

Crystallography and diagenesis

Calcite ($CaCO_3$) is trigonal, with rhombohedral or scalenohedral habit. In most speleothems it is present in microcrystalline form with the *c* axis oriented roughly across the direction of growth ("length slow" of Folk and Assereto, 1976) or as coarser palisade, columnar or equant ("coconut meat") crystal aggregates with the *c* axes oriented to growth ("length fast"; see Railsback, 2000). Large monocrystalline speleothems occur but are rare. Density and size of fluid inclusions are very variable. Many vadose speleothems display alternations of coarser and finer crystalline growth, often with temporary cessations due to drying or dissolution, zones with dust, flood mud or organic grains: existing crystals may grow through these or new crystals form upon them. Subaqueous deposits are more homogeneous. Pure calcite is translucent, or opaque white due to fluid inclusions. Strong color banding (yellow, brown, red-brown) is common, however, due chiefly to incorporation of fulvic acid chromophores from soil waters above the cave (Van Beynen *et al.*, 2001). Metals such as iron (red), copper (blue), and nickel (bright green) also provide color but rarely in visible concentrations (see Cabrol and Mangin, 2000).

Aragonite ($CaCO_3$) is orthorhombic. In caves it almost always occurs in acicular or tabular crystal habit, as clusters of small needles radiating from the rock or calcite speleothems, or as massive botryoidal aggregates forming larger deposits such as stalagmites. Twinned tabular habit is occasionally found. The deposits are more homogeneous in crystal size and more uniformly white than calcite, lacking strong color banding from organic chromophores. There are terminations due to drying, dissolution, or flood mud deposition.

Deposition of aragonite rather than calcite is usually attributed to enrichment of Mg^{2+} ions in the feedwater. This may be due to presence of dolostone or be part of an evaporative depositional sequence beginning with a core of calcite, proceeding to a surround of aragonite when the Ca^{2+} ions are sufficiently depleted and concluding with an aureole of

hydromagnesite ($4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O$) when they are exhausted. Because evaporation is important aragonite speleothems are more common in warmer climates. Railsback *et al.* (1994) report wet-dry seasonal alternations of calcite and aragonite in a Botswana stalagmite. Thicker, nonrhythmic aragonite layers are also found in some calcite speleothems.

Diagenesis is common in aragonite speleothems. Smaller botryoids are replaced by larger ones or by equant or columnar calcite. It is unusual to find aragonite older than ~100 kyr that does not display at least some calcite replacement. In purely calcite deposits there may be partial or complete replacement of microcrystalline layers by columnar calcite. Vugs become infilled with zoned cements.

Vadose morphology and size

Shapes of speleothems in vadose caves are created by gravity, or by crystal and capillary forces. Gravity forms are overwhelmingly predominant in volume. Principal types are stalactites, stalagmites, and sheets of "flowstone" on floors and/or walls (Figure S36). A "column" is a stalactite-stalagmite pair grown together.

The fundamental form is the soda straw stalactite, a thin sheath of calcite enclosing the feedwater canal. The *c*-axis is oriented downward. New growth occurs only at the tip. Diameter is determined by droplet size and ranges 2–9 mm. Calcite straws can extend for several meters before they fall under their own weight. Aragonite straws are rare, taking a clumped form with narrower necks that may represent temporary halts in deposition. Leakage or obstruction of the canal overplates the sheath, creating tapered (carrot-like) calcite stalactites up to one meter in diameter and several in length. There may be accelerated deposition on protruberances, creating a myriad of subsidiary forms such as crenulations, corbels, drapes and lesser stalactites. "Draperies" develop where feedwater trickles down an inclined roof and grow downward with *c*-axes perpendicular to growth edges. If initiated on rough surfaces they may be quite sinuous, like a drawn household drape.

Shapes of calcite stalagmites are similarly varied. The most simple is the "candlestick", which adds all new growth at the top under a nearly constant drip feed. Minimum diameters are ~3 cm. Varying drip or greater fall height causes terraced or corbelled thickening; at the extreme the form is like a pile of soup plates. More common are conical or tapered forms, broadening into domes with flowstone sheets around them. Some corbelled stalagmites are >30 m high. Domes may be 50 m or more in basal diameter. Aragonite stalagmites are much smaller, with narrow taper.

Calcite flowstones are deposited from film flow and accrete roughly parallel to the host surface, even where this is vertical. They may extend tens to hundreds of meters downstream of a single source and accumulate to thicknesses of several meters. Aragonites are again smaller and thinner. Flowstone layers interbedded with sands and clays are common in river caves. "Gours" or "rimstones" are calcite dams building upward from irregularities in small channels or on flowstone and stalagmite surfaces. The greatest impound water to depths of several meters. Rims are often strikingly crenulated.

Calcite "helictites" or "excentrics" grow where crystal or capillary forces predominate, skewing *c*-axis orientation to create narrow, curvilinear tubes extending out, up and down from rock or parent stalactites, etc. Most are short, <10–20 cm

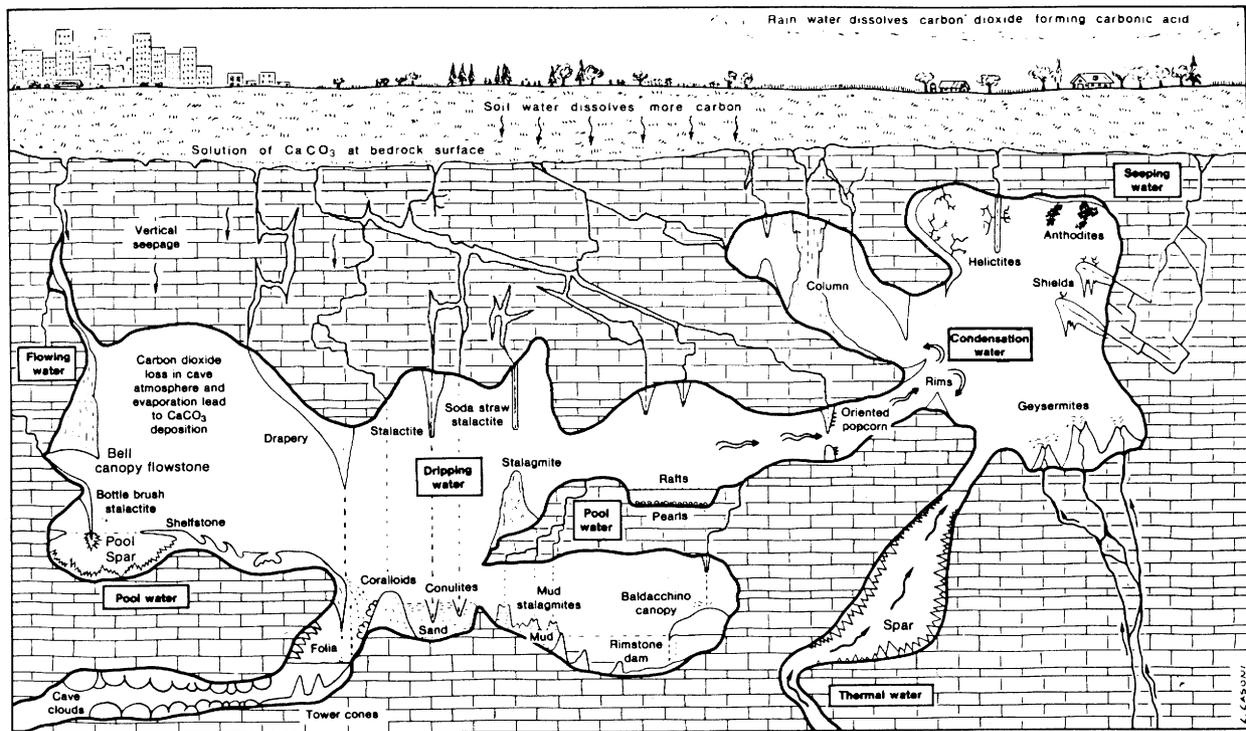

Figure S36 Model to show vadose and subaqueous speleothem precipitates; from Hill and Forti (1986) with permission.

in length. Dense clustering may form tangled masses like the Medusa's hair. "Anemolites" grow upwind into prevailing drafts. Clusters of needles fanning outward ("frostwork") are the most common type of aragonite deposit encountered in caves.

Globular forms are also common. "Cave pearls" are spheroidal accretions about a nucleus such as grit agitated by water dripping into a pool. "Popcorn" or "cave coral" are semi spherical accretions on host flowstone or other surfaces, often in dense, multi-layered clusters.

Subaqueous speleothems

Calcite may precipitate from thermal and meteoric waters. The principal thermal form is a spar lining on all surfaces, e.g., most of the 150+ km of passages in Jewel Cave, South Dakota. Deposition extends from the watertable to a limiting depth determined by pressure and Ca^{2+} saturation state. Aggregate thicknesses of one meter more are known. Spar linings are also common in meteoric caves. A wealth of more complex, branching crystal structures and rounded microcrystalline "clouds" can form in static pools. Water surfaces are marked by growth of shelfstone around the edges and floating rafts of microcrystalline calcite accreting around dust particles.

Distribution and abundance

Stalactites, stalagmites and flowstones may occur as isolated individuals in a cave, in clusters or aligned along feedwater fractures, or broadcast. Density may increase until all surfaces are covered.

Vadose speleothems grow most readily at shallow depths beneath soils rich in CO_2 in humid tropical and temperate conditions. These conditions permit year-round deposition, which may be accelerated by evaporative effects during dry periods. The largest individuals and greatest densities are found in these settings. Accumulations generally diminish in drier and cooler climates. Large stalagmites found in some desert or arctic caves tend to be relicts from earlier, more favorable conditions.

Many caves have several levels. Speleothems are often fewer and smaller in the lower levels, which are usually younger. In any setting speleothem deposition is largely prohibited where there are impermeable beds, e.g., shales, above a cave.

Growth rates, age and environmental studies

Under optimal conditions (large thermodynamic excess of Ca^{2+} ions, drip rate and evaporation) soda straws may extend several cm in a year. Normal accretion rates (increase of thickness of a growth layer) in other speleothems probably range between $\sim 1.0 \text{ mm}/10^3 \text{ years}$ in cold climate flowstones to $>1.0 \text{ m}/10^3 \text{ year}$ in warm cave entrances. The lowest rate reliably measured (by U series dating) is $\sim 0.001 \text{ mm}/10^3 \text{ year}$ in a thermal water spar close to the pressure limit for deposition. Some speleothems appear to have accreted at constant rates but others vary by factors of ten or more. Many contain hiatuses caused by drought, cold or change of groundwater routing.

Many speleothems can be dated accurately (± 1 percent error) by the $^{230}\text{Th}/^{234}\text{U}$ method if they are less than $\sim 500 \text{ kyr}$ in age. Variations of $^{18}\text{O}/^{16}\text{O}$ isotope ratios along the dated growth trend may indicate paleotemperature changes at the site and $^{13}\text{C}/^{12}\text{C}$ ratios suggest correlative changes of vegetation

amount or type. Where present, annual or event banding revealed by UV fluorescence and other techniques now permits very high resolution reconstructions of past conditions above a cave (see Hill and Forti, 1997, pp. 271–284).

Gypsum speleothems

Crystallography and morphology

Gypsum occurs as acicular, curved, equant, prismatic or tabular crystals as contact or penetration twins and as long fibers. Individual prismatics >1.0 m in length are known. Gypsum is deposited in three principal modes in caves: (1) as evaporitic inclusions of coarse, fibrous crystals growing as lenses up to several cm in thickness in bedrocks or cave sediments, which they rupture—“evapoturbation”. (2) as scattered tiny patches, thicker encrustations or excentric extrusions, on rock, sediment or calcite speleothems. Most frequent are “flowers”, extruded, twisting bundles of fibrous crystals up to 50 cm in length. Epsomite and mirabolite, the most common Mg, and Na sulfates, also display this form. Clusters of gypsum needles grow from sulfate-rich sediments and fibers of “hair” from roofs. Much larger, bifurcating stalactites are reported from a few caves, e.g., “The Chandeliers”, Lechuguilla Cave, New Mexico. (3) as regularly bedded floor deposits or wall encrustations in evaporating lakes or pools: thicknesses of several meters occur in Carlsbad Caverns, New Mexico, where much is reprecipitated from alteration crusts formed by H₂SO₄ reacting with the limestone walls.

SPICULITES AND SPONGOLITES

Introduction

Spongolites and spiculites are common in the rock record, and represent environments that were dominated by sponges, a phylum of organisms that inhabit practically all modern aquatic environments (Reitner and Keupp, 1991). Sponges use silica and/or carbonate and/or organic tissue to build skeletons composed of discrete spicules or amalgamated spicules that form a rigid skeleton. A sediment predominantly composed of discrete spicules is termed a spiculite, whilst one predominantly composed of rigid bodied sponges is termed a spongolite.

Taxonomy

Phylum Porifera contains an estimated 15,000 living sponges making it one of the most diverse and successful groups of aquatic organisms. Fossil and extant sponges are divided into two subphyla: Cellularia (classes Demospongia, Calcarea, Archaeocyatha); and Symplasia (class Hexactinellida; Hooper, 2000). Most demosponges and hexactinellids form their skeletal material from siliceous spicules and/or spongin (organic tissue), with some calcareous “corraline” demosponges. Calcarea and Archeocyatha have calcareous skeletal components. Most sponges contain discrete spicules within a mass of cells (“soft sponges”), with relatively few taxa containing rigid skeletons formed by articulation, secondary silicification/calcification, or fusion of spicules. Spicule morphologies are extremely diverse, with taxonomic identification determined from the complete spicule complement, and arrangement. Relatively few spicules are diagnostic, making identification from isolated sponge spicules generally only possible to a high taxonomic level. This has resulted in paleontological concentration on rigid skeleton sponges. Accurate identification from isolated spicules is one of the most pressing problems in sponge paleontology. Rigid skeleton sponges traditionally include: lithistids (siliceous), stromatoporoids (calcareous), sphinctozoans (calcareous), chaetitids (calcareous), and sclerosponges (calcareous basal skeleton, siliceous spicules). However, it is now generally accepted that these “fossil groups” are primarily optimal sponge body plans rather than monophyletic lineages, and that these body plans have evolved convergently from various demosponge and calcarea lineages during the Phanerozoic (e.g., Debrenne, 1999; Pisera, 1999). The current paleontological revision will hopefully clarify the many problems with fossil sponge identification. Hexactinellid (siliceous) and archaeocyathid (calcareous) are apparently the sole monophyletic groups amongst rigid bodied sponge fossils (see figure 6 of Debrenne, 1999, Hooper and van Soest, in preparation).

Paleoecology

Sponges are sessile benthic invertebrates that gather food by filtering particulate, colloidal and dissolved nutrients from water actively pumped through internal canals and chambers (Hooper, 2000; Rigby and Stearn, 1983). In general they are slow growing, contain bacterial symbionts, and have a cell-colony metabolic organization. Sponges reproduce both sexually and asexually, with sponge larvae motile for only a

short period before encrusting a firm substrate. They generally have low growth rates and long lifespans (Reitner and Keupp, 1991), and are some of the most evolutionally conservative animals known (e.g., Pisera, 1999). Freshwater sponges are restricted to a few lineages, and fossil spiculites and spongolites are generally interpreted as indicators of marine environments (Hooper, 2000). Sponges are most common on temperate carbonate shelves, within reef and rocky substrate environments, and within muddy, low-energy environments (van Soest *et al.*, 1994). Their general preference is for oligotrophic, low energy, fine-grained, low sedimentation-rate environments. However, sponges exploit many different habitats and such a diverse and evolutionally conservative group of animals will have developed species-dependent environmental controls (e.g., Maldonado *et al.*, 1999). Paleocological issues deserve considerable further investigation.

Sponge-dominated deposits have previously been interpreted as indicating deep and/or cold-water environments (Beauchamp and Desrochers, 1997) due to modern hexactinellid spiculite and spongolite accumulations in arctic and antarctic regions (Conway *et al.*, 1991). However, fossil spiculites and spongolites, including hexactinellid communities, have been interpreted as shallow and warm (Gammon *et al.*, 2000), and the presence of hexactinellid and demosponge faunas throughout modern oceans, including tropical assemblages, suggests modern sponge habitats may not be representative of the past because of the inability of modern sponges to compete with more highly evolved organisms such as photosymbiotic corals (e.g., Lévi, 1991; Tabachnick, 1991). The presence of shallow-marine deposits composed primarily of deep-marine sponges also suggests that water-depth is not a major control factor for sponges (Gammon *et al.*, 2000).

The modern ocean is undersaturated with respect to silica, leading to rapid sea-floor dissolution of sponge skeletal remains. Additionally, carbonates and silica buffer solutions to substantially differing pH's. Opaline biogenic silica is therefore generally unstable within predominantly calcareous sediments, and vice versa (Johnson, 1976). Siliceous sponge assemblages are probably significantly impoverished by diagenesis and assemblage reconstruction is particularly challenging.

Spiculite and spongolite

Modern Arctic and Antarctic spiculite and spongolite deposits contain matted, interlocked spicule-mat textures developed on glacial moraine substrates in deep shelf localities (Conway *et al.*, 1991). The very high length:width ratio of interlocked spicules produces a cohesive sediment structure that resists erosive currents and provides greater substrate aeration which promotes microbial populations. The resulting muddy, microbially-influenced matrix may be a good analogue for ancient spicular mudmounds. Ancient spiculites are occasionally cross-bedded, but more commonly massive, possibly due to such spicule networks. Detailed textural work on spiculites is a promising avenue for further sponge community research.

Modern lithistid localities are muddy, deep shelf localities, which is consistent with muddy spongolite deposits in the rock record (e.g., Wiedenmayer, 1994). Such fossil sponge faunas represent *in situ* assemblages, but are often poorly preserved due to diagenesis. There are no modern analogues for ancient calcareous or siliceous sponge reef/bioherm spongolites (e.g., Reitner and Keupp, 1991). These have coarse-grained whole

and fragmented sponges with or without copious syndimentary cements. Interpretations exist for both deep and shallow waters reefs (Vacelet, 1988), consistent with the generally large depth ranges and nonphotosymbiotic metabolisms of modern sponges.

Spiculites and spongolites have been formed repeatedly throughout the Phanerozoic. The earliest known sponge fossils are Late Neoproterozoic, but sponge-dominated environments started with early Cambrian archaeocyathids, the world's first metazoan reef builders (Debrenne, 1999). Sphinctozoans and stromatoporoids were common reef builders during the Paleozoic (mainly Ordovician–Devonian), whilst siliceous sponges tended to form spongolite bioherms and spiculitic mudmounds.

Siliceous sponges particularly enjoyed Mesozoic tropical Tethyan environments, where they arose to dominance repeatedly through the Jurassic and Cretaceous (mainly lithistids with some hexactinellids in relatively deep shelf environments; Pisera, 1999). Calcareous stromatoporoids and sphinctozoans made brief appearances as reef-builders, but were not as prolific as Paleozoic forms (Debrenne, 1999).

The general lack of Tertiary spiculites and spongolites has been correlated to the diatom radiation that is inferred to have decreased oceanic dissolved silica, a key nutrient for siliceous sponges (Maldonado *et al.*, 1999). However, sponge-dominated sediments occur through the Eocene (Europe and Australia; Gammon and James, 2001; Pisera, 1999). These deposits are primarily shallow-marine deposits in unusual basinal settings, emphasizing the Phanerozoic trend of sponge displacement to more marginal habitats by more evolved taxa.

STAINS FOR CARBONATE MINERALS

Introduction

Stains have been devised for the rapid identification of many common minerals; Reid (1969) provides an excellent compendium. The identification of minerals, however, can now be achieved with much greater certainty using modern analytical techniques (SEM, microprobe and so on). Stains have been devised that display intracrystalline variations in chemical composition although techniques such as cathodoluminescence, fluorescence and backscatter electron imaging can display this type of information more comprehensively and reliably than staining. Some stains, however, are very versatile, they can be used in the field, on rock slabs or thin sections; they are inexpensive, easy to use and rapid to apply.

Staining carbonate minerals

The staining of carbonate minerals has a long history (Lemberg, 1887) and involves a plethora of different methods (Freidman, 1959, 1971; Reid, 1969).

General carbonate stain

The most widely used stain for carbonates employs a mixture of Alizarin red S and potassium ferricyanide dissolved in a dilute hydrochloric acid solution. Set procedures are published for this dual stain (Dickson, 1965, 1966; Evamy, 1963, 1969) but the stain can, within certain limits, be modified to suit the needs of the observer and the type of material being stained. The organic dye Alizarin red S (ARS) will produce a pink to red stain on any carbonate that will react with dilute acid. The reaction between carbonates and acid is usually controlled (1–2 minutes at 25°C for thin sections) so that the more reactive minerals, such as calcite and aragonite, stain red but the less reactive ones, such as dolomite and siderite, remain unstained. Calcite is however an anisotropic mineral that is more soluble in a direction parallel to its *c*-axis than normal to the *c*-axis. The ARS stain (at HCl concentrations between 0.2 percent and 1.0 percent, vol./vol.) can differentiate calcite sections that are normal to the *c*-axis (stained pink) from those that are parallel to the *c*-axis (stained red). This appears counterintuitive—the *c*-axis normal section reacts more vigorously with the acid yet stains less intensely, and

vice versa. This is due to greater evolution of CO₂ bubbles from the *c*-axis normal surface preventing the stain from settling. The *c*-axis parallel sections produce fewer bubbles and stain precipitation is unimpeded. This differentiation is only effective at acid concentrations between 0.2 percent and 1.0 percent (vol./vol.) given stain times of between 1 minute and 2 minutes.

The intensity of the ARS stain is affected by HCl concentration. At 1.5 percent the stain is faint, vigorous evolution of CO₂ bubbles occurs, and the section is etched thinner (from 30 μm to ~15 μm) after being treated for 1 minute. At 0.1 percent HCl concentration and 1 minute staining time the calcite *c*-axis orientation is weakly differentiated, and the intensity of the stain masks the underlying fabric. Staining for more than 2 minutes at 0.1 percent HCl causes the layer of stain to crack and peel off the stained surface. Reaction between calcite and acid in the 1–2 minutes recommended for staining is very sensitive to acid concentration, which can be adjusted to develop the desired stain intensity. Dolomite does not stain using these acid concentrations but as iron is substituted into the dolomite lattice it becomes more reactive. Ferroan dolomite and ankerite react with dilute HCl, effervescing and staining with ARS. The ARS stain color of ankerite (mauve) can be distinguished from calcite (red) but in the dual stain the mauve color is suppressed due to intense staining by potassium ferricyanide.

Potassium ferricyanide (PF) produces a precipitate of Turnbull's blue when ferrous iron is released to the staining solution. It might be expected that siderite (ferrous carbonate) would react with this stain but siderite does not react with dilute cold HCl, iron is not released to the staining solution and consequently no stain is precipitated. The rate of reaction of the PF stain, as with ARS, is controlled by reaction rate between carbonate and HCl. Calcites and dolomites containing ferrous iron do react with the stain but dolomite reacts less vigorously than calcite so the intensity of PF stain is not proportional to the iron concentration of the two minerals. The PF stain is very sensitive to ferrous iron concentrations in calcite and will distinguish differences in concentration in the order of a few 100 ppm. Lindholm and Finkelman (1972) correlated iron concentration of calcite with stain color, but to match their color range their staining procedure must be reproduced exactly. The relationship between iron concentration and stain color is non-linear as the reactivity of carbonate minerals increases with rising iron concentration (Reeder, 1983). Ferroan calcite stains blue and ferroan dolomite stains green to turquoise. As iron concentration increases in these two minerals the colors converge. The difficulty in distinguishing such iron-rich carbonates can be overcome by staining with ARS alone.

When iron concentrations are low the dual staining procedure can be modified to increase iron differentiation. Extending the staining time in the dual stain beyond 90 seconds is inadvisable as the stain cracks and thick deposits of ARS obscure the section. Material with low iron concentrations can be stained first in a PF/HCl solution for 60 seconds before staining with the dual (ARS + PF) stain. The distribution of ferrous iron (resolvable to 1 μm) in thin section or rock slab can be differentiated in a few minutes using this stain (Figure S37*).

* Figure S37 appears on Plate II, facing page 115.

Distinguishing aragonite from calcite

Feigl's stain (Feigl, 1937), a solution of silver and manganese sulfates to which sodium hydroxide is added (for preparation see Friedman, 1959), stains aragonite black. Other orthorhombic carbonates also react positively with Feigl's stain. The black color is due to a precipitate of manganese oxide and metallic silver. Calcite remains unstained during limited exposure to Feigl's solution. The stain differentiates aragonite from calcite due to their different solubilities and also causes differential etching between the two minerals. Schneidermann and Sandberg (1971) have used this selective etching (imaged by SEM) as an additional feature of the stain to help distinguish between the two minerals. The latter authors also recommend using $\text{MnSO}_4 \cdot \text{H}_2\text{O}$, rather than $\text{MnSO}_4 \cdot 7\text{H}_2\text{O}$, to prepare the stain, diluting the original recipe with water, and warming the solution. Variations in crystal size and orientation have led to differing results using Feigl's stain so that many regard the stain as unreliable.

Distinguishing Mg calcite from calcite

The Titan-yellow (Clayton yellow) stain for assessing the Mg content of calcite was described by Friedman (1959) modified by Winland (1971) and again improved by Choquette and Trusell (1978). Choquette and Trusell give the staining and fixing procedure for this stain which barely stains calcite with up to 3 percent MgCO_3 stains Mg calcite with 5–8 percent MgCO_3 pink to pale red, and Mg calcite with >8 percent MgCO_3 a deep red color. This indication of Mg content is qualitative because crystal orientation and size affect the stain in addition to Mg content. The stain is cheap and simple to use but has not gained wide acceptance.

Conclusions

Stains have been used to determine mineralogy and intracrystalline chemical variations although both these properties can now be more reliably and quantitatively determined using analytical techniques. Stains can however be applied to outcrop, rock slabs or thin sections in a few minutes at negligible expense. Their application requires little training other than some basic safety training in the use of chemical substances and an understanding of how the stain operates.

STATISTICAL ANALYSIS OF SEDIMENTS AND SEDIMENTARY ROCKS

Statistical analysis is a standard tool used by sedimentologists, who are concerned with sampling and describing properties of populations of particles. They use summary statistics such as the range, mean, mode, median, standard deviation, variance, skewness, and kurtosis to transmit information about sediments. Univariate, bivariate, and multivariate statistical tests are among their basic statistical tools. Descriptive statistics in geology date back to the 19th Century when Charles Lyell used the ratio of living to extinct invertebrate fossils to subdivide the Tertiary into epochs as reported in his *Principles of Geology* (1833) (see Merriam, 1981).

Because much of the historical data in the earth sciences are qualitative, nonparametric statistics are used for their analysis. Nonparametric tests do not require assumptions about the populations from which the samples were taken as do parametric tests. There also is an inherent amount of uncertainty in geological properties because of irregularly spaced or missing data. Methods for determining the spatial relations and display of sediment properties, therefore, are especially important. Dieter Marsal's (1987) book is an excellent introduction to statistics for the geoscientist; John Davis' (1986) book on statistics and data analysis is an introductory to immediate level text with many examples and a computer program, STAT, on disk; and Nick Rock's (1988) numerical geology is an intermediate text for university courses on the subject with an extensive reference list and glossary of terms.

With introduction of quantitative methods, the subject of sedimentation gradually transformed into sedimentology. One of the first papers in this transition was the classic *On the*

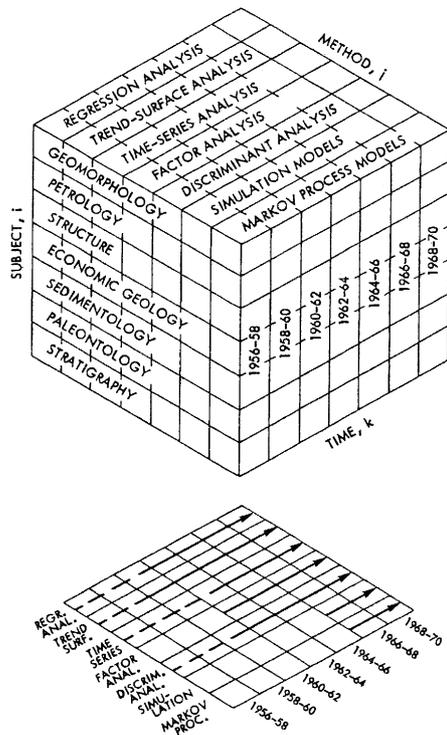

Figure S38 Subset of geological subjects, methods of data analysis, and time in two-year periods (upper); horizontal slice to show time of entry of computer applications in sedimentology (Krumbein, 1969, p. 254). see section on: William Christian Krumbein.

Application of Quantitative Methods to the Study of the Structure and History of Rocks by Henry C. Sorby in 1908, which presented results based on a mass of data accumulated from stream experiments; W. Mackie described rounding of particles in a 1897 paper, *On the Laws that Govern the Rounding of Particles of Sand*; and Johann A. Udden published his paper, *Mechanical Composition of Clastic Sediments*, in 1914 (see Merriam, 1981, for references). This early work on clastic sediments was followed by the contributions of C.K. Wentworth, William C. Krumbein (arguably the most influential of the numerical sedimentologists; see article in this volume), A.B. Vistelius, and J.C. Griffiths, who applied regression analysis, time-series analysis, factor analysis, discriminant analysis, and Markov chain analysis to sedimentological problems (Figure S38).

Bill Krumbein and Francis Pettijohn's 1938 textbook, *Manual of Sedimentary Petrography*, was a primer on the analysis of sediments and included two chapters on statistical methods, a forerunner of Krumbein's later work. Robert Folk's manual, *Petrology of Sedimentary Rocks* (1961) contains basic statistical techniques for the analysis of clastic rocks; Robert Miller and James Kahn published a book on a general survey of statistical methods in 1962; the Krumbein and Franklin Graybill book on statistical models in 1965 was an introduction to the subject with emphasis on sediments; but John Cedric Griffiths' *Scientific Method in Analysis of Sediments* published in 1967 was at the time the ultimate publication on statistics applied to sediments and sedimentary rocks. Griffiths' book was followed

by Frits Agterberg's tome on geomathematics (1974) and Walther Schwarzacher's book on sedimentation models (1975), both for the advanced student and professional.

Carbonate sediments have been treated differently than clastic sediments because they are not amenable to disaggregation and particle analysis. John Imbrie and Edward Purdy were among the first to apply factor analysis to carbonates in their 1962 paper, *Classification of Modern Bahamian Carbonate Sediments*, followed by Imbrie's *Factor and Vector Analysis Programs for Analyzing Geological Data* in 1963 and Purdy's *Recent Calcium Carbonate Facies of the Great Bahamas Bank* in the same year (see Merriam, 1981, for references).

Statisticians, too, have applied their tools to problems in the earth sciences since the turn of the 20th Century. Karl Pearson studied the variation in homogeneous material; A.N. Kolmogorov used the lognormal law of distribution of particle sizes to analyze crushed rock; Churchill Eisenhart was interested in significance tests on lithological variation; C.J.C. Ewing discussed operator variation in heavy-mineral separation; S.S. Wilks explored statistical inference; K.V. Mardia worked with directional data; G.S. Watson contributed to statistics of orientation data; D.M. Hawkins wrote on robust statistics; J.C. Gower was concerned with sediment classification; M.F. Dacey applied Markov chain analysis; and J. Tukey suggested that methods of confirmatory data analysis, such as the jackknife approach, were logical and useful for geological problems.

In the early 1960s a French engineer, Georges Matheron, introduced to the earth sciences a new branch of statistics known as *geostatistiques* (geostatistics), in his papers *Traité de géostatistique appliquée*, parts 1 (1962) and 2 (1963). For an introduction in English, see Matheron (1963). The new school is based on the idea of regionalized variables or partially dependent observations located in two- or three-dimensional space. Kriging is the name applied for methods of interpolating spatial geological data that makes use of geostatistical concepts.

STORM DEPOSITS

Large storms have wide-ranging effects in a spectrum of environments from outer shelves to coastal plains. The most common deposits of storms in the rock record are sandstone beds deposited under powerful near-bottom water motions produced by waves and currents. Early studies of the effects of storms on modern shelves (e.g., Hayes, 1967) sparked interest in finding analogues in the rock record. This resulted in the development of storm facies models, with particular emphasis on hummocky cross-stratification (HCS) (Walker, 1984). The origin and dynamics of the depositing flows were considered controversial (see Swift *et al.*, 1983; Walker, 1984) and initial models relied on cross-shelf transport by turbidity currents (Hamblin and Walker, 1979). Actualistic models of storm dynamics subsequently constructed by oceanographers and marine geologists largely focused on nearly shore-parallel geostrophic currents. Duke (1990) suggested that ancient shallow-marine storm deposits (tempestites) were deposited by geostrophic combined flows and subsequent work indicates that combined flows are in fact recorded in ancient sandy tempestites (e.g., Midtgaard, 1996). However, many ancient storm-deposited sandstone beds show greater thickness and cross-shelf distribution than their modern counterparts (Leckie and Krystinik, 1989; Myrow and Southard, 1996). In addition, the time between successive beds in many deposits in the rock record may be many orders of magnitude too large to explain as a simple series of storm events.

The stratification preserved in tempestites, particularly HCS, has been studied experimentally (Arnott and Southard, 1990) and through the analysis of grain fabric (Cheel, 1991). Such studies, and those of modern shelves (e.g., Amos *et al.*, 1996), confirm that HCS forms as a result of complex oscillatory flow or combined flow (waves and currents). A wide range of vertical stratification sequences is possible within individual storm-deposited beds (Myrow and Southard, 1991). Three processes operate during storms to produce the wide range of tempestites encountered in the sedimentary record: geostrophic currents, wave oscillations, and excess-weight forces (density-induced flow) (Myrow and Southard,

1996). The relative importance of these three processes may change during individual events and between events both within and between basins. Thus considerable variability is possible in the character of individual beds, although most beds display graded bedding and evidence for flow deceleration.

Geostrophic flows are near-shore-parallel flows that result from Coriolis deflection of water masses that are driven offshore in response to pressure gradients associated with coastal setup. Combined flows result from the superposition of storm-generated waves with these flows. Because these geostrophic flows are oriented slightly obliquely offshore, instantaneous bed shear stresses in the combined-flow boundary layer show asymmetry in the offshore direction (Duke, 1990). Sediment transport results from the nonlinear addition of the two components of flow in the boundary layer, with the net result that wave oscillations are stronger in the offshore direction and thus preferentially move sediment in that direction. Whether this asymmetry in transport can account for significant cross-shelf transport is unclear. Regardless of transport mechanisms, most tempestite successions show patterns of decreased bed thickness and evidence for less powerful currents from onshore to offshore. An exception to this rule occurs in areas of nearshore sediment bypass (Myrow, 1992).

In many cases, ancient deposits contain evidence for powerful offshore-directed flow, which is at odds with deposition under combined flows. Such flow is possibly driven, at least in part, by excess-weight forces. These forces result from high suspended sediment concentrations (SSCs) near the bed. High SSCs can result from resuspension of shoreline sand by storm processes. A number of studies indicate that very high SSCs (up to 4 g/L) are produced on shorefaces and inner shelves and that this leads to powerful seaward-directed sediment-laden flows (e.g., Wright *et al.*, 1994). Plumes associated with fluvial discharge events may also produce hyperpycnal (bottom-hugging) flows, and such flows are termed oceanic floods (Wheatcroft, 2000). These could be pre-ignited with regard to autosuspension, but this is unnecessary for significant cross-shelf transport because storm waves can provide the extra turbulence needed to maintain flow. Results of both oceanographic (e.g., Cacchione *et al.*, 1999) and modeling experiments of the northern California coast indicate that gravity driven underflows associated with ocean floods are an important factor for cross-shelf transport of fine-grained sediment. Such flows have high SSCs (up to 2.5 g/L) even at mid-shelf depths (50 m to 70 m).

The sequence-stratigraphic context of tempestites may have a strong control on their abundance, nature, and stratigraphic distribution. Transgressive to early highstand conditions may have higher accommodation space and thus greater potential for Coriolis effect to produce geostrophic flow, whereas late highstand conditions promote greater bottom friction and more offshore-directed flow (McKie, 1994). Late highstand to early lowstand systems tracts of third- or higher order sequences tend to have abundant tempestites due to mobilization of coastal sand during relative sea level fall (Einsele, 1996). Sediment supply by rivers, or *in situ* carbonate production, has a first-order control on tempestite thickness and abundance. More work is needed to better constrain the recurrence intervals of ancient deposits. Comparison of these data to those from the Modern will help

to establish the degree to which actualistic models apply to the ancient.

STROMATACTIS

Stromatactis is a spar body common in Paleozoic carbonate mud-mounds but much less common in Mesozoic ones. Although it has been regarded originally as a fossil (Dupont, 1881), and later as a permineralized unfossilizable organism or as recrystallized patches of the host carbonate, most carbonate workers now agree that it is the result of centripetal cementation in a cavity system, regardless of the origin of the cavity (e.g., Bathurst, 1982; Lees and Miller, 1985; Bourque and Boulvain, 1993; several papers in Monty *et al.*, 1995). Because it is a diagenetic structure, and not a fossil, stromatactis should not be capitalized, nor italicized. There is no consensus on the definition of stromatactis and the origin of the cavities into which it developed.

Some workers define stromatactis in an all-inclusive manner and consider that stromatactis is all spar bodies having a flat base and digitate top resulting from the cement filling of cavities, no matter if the spar bodies, and hence the cavities, are connected or isolated in the host rock (e.g., Monty, *in*

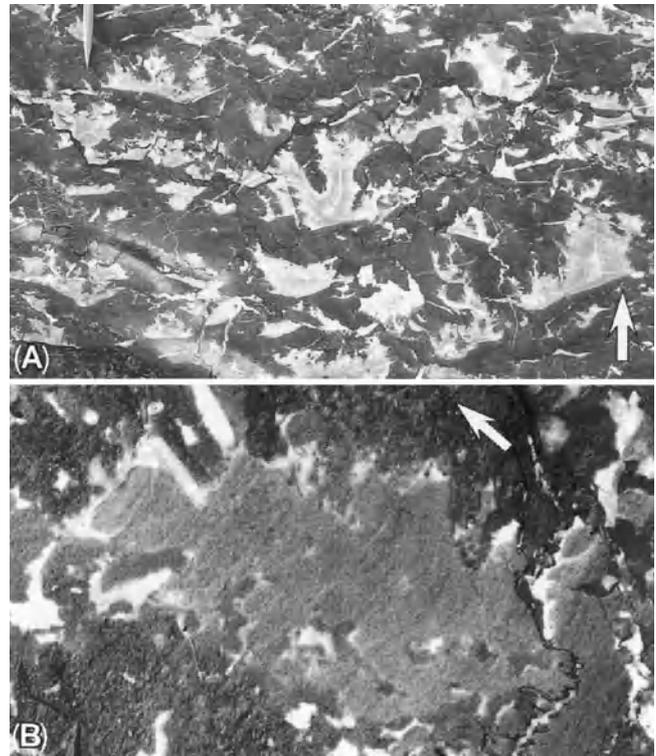

Figure S39 Stromatactis and related structure from Devonian (Frasnian) mud-mounds in the Belgian Ardennes. (A) Typical stromatactis limestone showing cross-section in a stromatactis network. Although the spar bodies look as individuals, they are interconnected in the third dimension. Les Maquettes Quarry. Width of picture is 35 cm. (B) Cross-section of filling of layered sediment in the original cavity network that has inhibited stromatactis development; Croisette Quarry. This kind of structure has been misidentified occasionally as stromatolite. Width of picture is 9 cm. Arrows indicate sedimentary polarity.

Monty *et al.*, 1995). Others consider that too wide-open a definition of stromatactis has led to a misuse of the term, and that stromatactis is a specific fabric that should be more restrictively defined (e.g., Bathurst, 1982, 1998). Based on original material described by Dupont (1881) in the Belgian Ardennes, and following Bathurst (1982) who drew attention to the occurrence of stromatactis in reticulate swarms, Bourque and Boulvain (1993, p.608) proposed to restrict the term stromatactis to “a spar network, whose elements have flat to undulose smooth lower surfaces and digitate upper surfaces, made up principally of isopachous crusts of centripetal cement and embedded in finely crystalline limestone”.

Stressing the network nature of stromatactis brings into relief that stromatactis is one of a two end-members continuum of a specific cavity network filling controlled by two antagonistic processes, internal sedimentation versus centripetal marine cementation. When the rate of internal sedimentation is lower than the rate of marine cementation, centripetal cementation of the cavity network forms stromatactis (Figure S39(A)); when the rate of internal sedimentation is higher than the rate of marine cementation, layered sediment inhibits stromatactis development and fills entirely the cavity network (Figure S39(B)) (see Neuweiler *et al.*, 2001, for discussion on the processes involved and their causes).

Several scenarios were proposed to account for the formation of the cavity system, among which: (1) winnowing of noncohesive mud sandwiched between layers of early cemented sediment crusts (Bathurst, 1982) or lithified microbial mats (Pratt, 1982) on the sea-floor; (2) collapse of muddy sediment bridged by cohesive microbial mats on the sea-floor (Lees and Miller, *in* Monty *et al.*, 1995); (3) fluid escape after the collapse of decayed microbially bound sediment in the shallow burial environment (Monty, *in* Monty *et al.*, 1995); and (4) collapse of uncemented material in an early cementing sponge/mud mixture in the shallow subsurface environment (Bourque and Boulvain, 1993).

STROMATOLITES

Stromatolites are critical geological features as they are the only biogenic sedimentary structures that have an age range extending fully from the early Archean to the Recent, thereby demonstrating a fundamentally uniformitarian phenomenon. First described from the Cambrian of New York State by J. H. Steel in 1825, and already widely recognized by the time the term “stromatolite” was coined by E. Kalkowsky in 1908 for Triassic examples, it was C. D. Walcott in 1914 who noted their predominance in Precambrian strata and first deduced a microbial origin (Riding, 1999). M. Black was the first to document, in 1933, the stromatolite-forming activities of living microbial mats, on tropical tidal flats of Andros Island, Bahamas. The discoveries of modern analogs of columnar forms in Shark Bay, Western Australia in 1961 (Figure S40(A), (B)) and at Lee Stocking Island, Bahamas in 1986 are milestones in the earth sciences (see Golubic, 1991). 3.5 Ga stromatolites from Western Australia represent the oldest physical evidence of biological activities, most certainly photosynthetic, on Earth. In turn, stromatolites signpost the search for evidence of life on other planets.

Definition

Even though the evidence for prior microbial activity is usually circumstantial, the definition of stromatolite has evolved as the composition and metabolism of benthic microbial mats and biofilms in various settings and the wide variety of resulting structures and their evolutionary context have become better understood. Mucilaginous mats and biofilms are complex communities dominated by bacteria and, in the photic zone, by cyanobacteria, although other microorganisms may contribute. While shallow-marine and lacustrine calcareous stromatolites are the most commonly recognized (Riding, 2000), other deposits that can be embraced by the term include many tufas or travertines, phosphate crusts, silica sinters, and manganese nodules, for which a microbial control or influence can be determined or inferred. Thus, Riding (1999; see also Krumbein, 1983) advocated a broad approach: a stromatolite is simply a *laminated benthic microbial deposit*. Although there is no constraint of scale, stromatolites are typically centimeter- to meter-sized, and laminae micrometers to millimeters in thickness. Spheroidal counterparts that rolled around during formation are oncoids (or oncolites). Non-laminated structures similar to stromatolites are thrombolites (Pratt, 1995).

Morphology and microstructure

Stromatolites include beds and domes with planar, wavy, or convex lamination, and reefal masses composed of conical or

convexly laminated columnar and branching forms (see examples in Walter, 1976) (Figure S41(A)–(E)). In addition, Phanerozoic marine stromatolites are commonly intergrown with sessile invertebrate skeletons (Figure S41(F)). Beginning

in the 19th century, many fossil stromatolites were given linnéan binomial names. This practice has declined, although a number of recurring “form-genera” are still commonly used as descriptors.

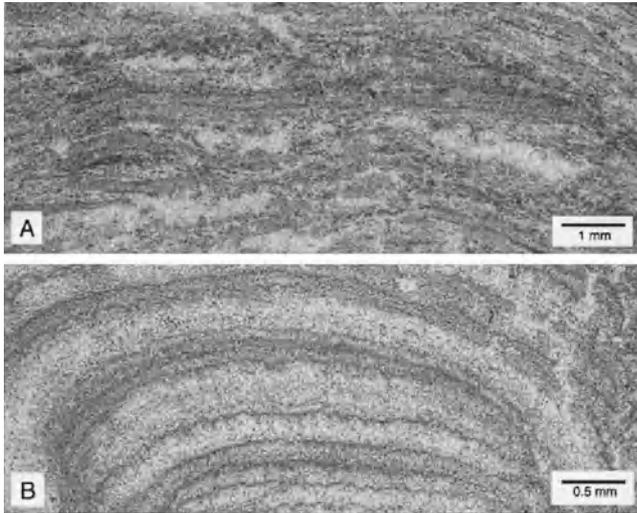

Figure S42 Stromatolite microstructure, photomicrographs of thin sections. (A) Laminae of micrite and clotted micrite, separated by finely crystalline calcite cement. I-5 member, Atar Group (Neoproterozoic), Mauritania. (B) Laminae of micrite and recrystallized micrite. Peg Formation (Paleoproterozoic), Northwest Territories.

Lamination consists of rhythmic combinations of microbially triggered and sometimes inorganic precipitates, mineralized microbes, physically trapped sedimentary particles, and primary pore space that is subsequently cemented (see examples in Riding and Awramik, 2000) (Figure S42(A), (B)). Calcareous stromatolites are especially vulnerable to diagenetic modification, such as recrystallization, dolomitization, and silicification. The last process may fortuitously preserve microbial remains before substantial degradation (e.g., Knoll *et al.*, 1991). In general, some degree of syngeneic lithification is a prerequisite to preservation.

Evolution

Stromatolites are conspicuous in younger Archean and Proterozoic shallow-marine carbonate successions (e.g., Walter *et al.*, 1992; Hofmann, 2000). A Precambrian biostratigraphy based on morphology and microstructure has been attempted but has not proved convincing. Still common in the Cambro-Ordovician, they also occur sporadically in younger strata. The apparent decline in abundance of marine stromatolites has been attributed to competition for substrate space by encrusting invertebrates and calcareous algae, the effects of grazing and burrowing animals, chemical changes in seawater, and evolving sedimentological conditions (Pratt, 1982; Grotzinger and Knoll, 1999). Evolutionary aspects of stromatolites from other settings are uncertain at present.

Frontiers

Microbial biofilms and mats are complex systems, constantly in a state of flux between growth and decay, and much remains to be learned about microbially induced diagenesis and the process and temporal significance of lamina formation and overall growth rates in both ancient and modern examples of

all types. A thorough assessment of stromatolitic structures of non-carbonate mineralogy and from non-marine settings, such as hot springs, is still in progress. Lastly, if present, the remains of past microbial activities on other planets—astrobiology—may come from stromatolitic rocks, the cue for continued research on Earth's own record.

STYLOLITES

Introduction

Stylolites are macroscopic serrate subplanar surfaces at which mineral material has been removed by pressure dissolution, resulting in a decrease in total volume of rock. Stylolites are

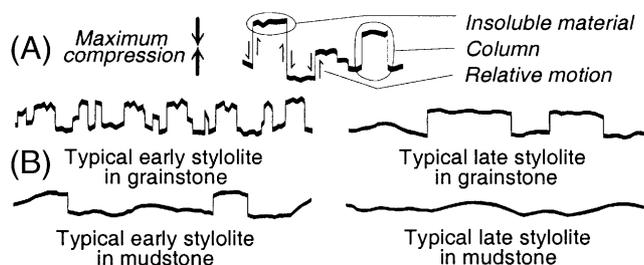

Figure S43 (A) Components of a stylolite. (B) Typical profiles of stylolites in different carbonate lithologies (after Andrews and Railsback, 1997, figure 15).

made readily visible by the accumulation of residues of relatively insoluble minerals, such as pyrite, oxides, clays, and other silicates. If no such residue has accumulated, a stylolite may be recognizable only by its truncation of elements of the host rock's preexisting fabric.

Stylolites commonly consist of interfitting striated columns capped by subplanar laminae of insoluble material (Figure S43(A)). The columns form parallel to maximum compressive stress, as parcels of rock on each side of the stylolite are pushed past each other. The columns are commonly perpendicular to the general plane of the stylolite, but they can be inclined relative to it. The columns are typically parallel to the direction of maximum compression during their formation.

Stylolites take their name from these columns, in that "stylolite" is derived from the Greek word "stylos" (for column or pillar). In older works and some recent Eurasian literature, individual columns are sometimes called "stylolites", but more recent publications generally use that term for the entire surface defined by the columns as a group. Thus a horizontal stylolite in modern American usage consists of many vertical stylolites as defined in some older or Eurasian usage.

Stylolites are common in many limestones and dolostones, can be common in evaporites and deeply buried sandstones, and have been reported in igneous rocks (Golding and Conolly, 1962). Stylolites parallel to bedding of sedimentary rocks are commonly thought to result from compression by overburden, whereas stylolites perpendicular to bedding (transverse stylolites) are usually attributed to tectonic compression. Transverse stylolites can predate or postdate bedding-parallel stylolites in the same rock (Andrews and Railsback, 1997).

Development

Development of a stylolite requires a solution into which minerals can dissolve and a pore network through which dissolved solids can diffuse or advect from the developing stylolite. Porosity also enhances stylolite development by localizing stress on nonpore areas and thus increasing stress there. Some models of stylolite development have therefore suggested that bedding-parallel stylolites form in zones of prior high porosity (Merino *et al.*, 1983), and that most if not all transverse stylolites form along preexisting fractures.

Because its formation involves movement of two rock volumes toward each other, development of a stylolite requires a previously lithified host rock. Compression of unlithified

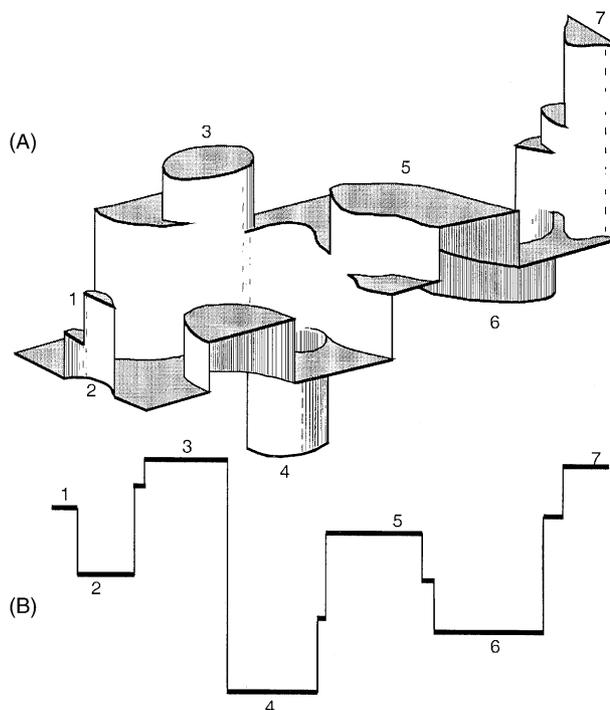

Figure S44 (A) Three-dimensional image of a stylolite (after Smith, 2000, figure 7e). (B) One two-dimensional profile of stylolite shown in A. Numbers identify like positions in the two images.

grainy sediments commonly results in intergranular, rather than whole-rock, compaction, and serrate intergranular contacts can form. Such contacts are microscopic stylolites, the lateral extent of which is limited to the area of contact between two grains. Either intergranular compaction and suturing or (more commonly) cementation can lithify a sediment sufficiently for a true macroscopic stylolite to form.

Stylolites vary from serrate to undulatory, but even most undulatory surfaces ("dissolution seams") are serrate at microscopic scales. Development of a serrate surface requires dissolution that is alternately localized on opposite sides of the stylolite. In limestones, stylolites in grain-rich rocks (grainstones and packstones) are generally more serrate than those in wackestones and micstones, presumably because juxtaposition of various grain types and of intergranular pores localizes destruction of rock volume (Railsback, 1993) (Figure S43(B)). Stylolites that formed early in a rock's history are commonly more serrate than those formed later, presumably because more extensive lithification reduces variability of rock fabrics and of solubility on opposite sides of a stylolite (Andrews and Railsback, 1997) (Figure S43(B)).

Problems and progress

Many studies of stylolites have examined their host rocks as a means to determine lithologies or rock characteristics favoring formation of stylolites. Such studies are potentially flawed, however, because the lithology in which the stylolite formed has inevitably been destroyed during that stylolite's growth. The lithology (or lithologies) in which a stylolite is presently observed may in fact have characteristics that halted, rather

than promoted, stylolite development. Otherwise, the present host lithology would have been destroyed by further development of the stylolite.

Traditional studies of stylolites have examined planar sections cut parallel to the columns. Such studies have used the resulting two-dimensional images to classify stylolites according to their general appearance (Park and Schot, 1968; Buxton and Sibley, 1981), quantify their morphology using as many as five parameters (Railsback, 1993; Andrews and Railsback, 1997), or measure their fractal dimension (Drummond and Sexton, 1998). More recently, sequential sectioning has been used to generate three-dimensional images of stylolites (Smith, 2000), which demonstrate that the sides of columns form an anastomosing interconnected surface that can serve as a pathway for fluids (Figure S44).

Significance

Stylolites are significant in several fields. Stylolites are important petrologically because they modify rock fabrics and because they generate dissolved solids that precipitate elsewhere as cement. Stylolites are significant to stratigraphy because weathering of stylolites generates apparent bedding in many stratigraphic sections and because loss of material along stylolites can cause significant stratigraphic shortening unrelated to erosion. Hydrologically, stylolites have been cited as barriers to fluid flow and, in other settings, as conduits for fluid flow. Stylolites are also commonly used as records of compressive stress in tectonic studies, and development of transverse stylolites can contribute to crustal shortening parallel to the direction of their columns.

SUBMARINE FANS AND CHANNELS

Like alluvial fans (*q.v.*), submarine fans are cone-like accumulations of sediment, developed at a change of slope, generally below a single major feeder channel (though a few fans may have more than one channel, generally they are not all active at the same time). Submarine fans and channels, however, are much larger and more common than subaerial fans, and have been constructed mainly by turbidity currents and other sediment gravity flows (see *Gravity-Driven Mass Flows*). The coarser sediment is largely confined to the distributary channels, and much of the fan may be composed of silt or mud deposited by overflows on levees (Figure S45). The need for a single major feeder channel to produce a fan means that, although carbonate turbidites are common (see *Turbidites*), carbonate fans are rare. The large size of many submarine fans often produces a geometry that is constrained by preexisting topography (which may, in turn be related to active tectonics) so that a typical fan shape is not well developed. In addition, examples of thick siliciclastic turbidites constructed at the base of submarine slopes but lacking fan geometry have also been described (as submarine ramp deposits: Heller and Dickinson, 1985; Reading and Richards, 1994).

Modern submarine fans-channel systems were first described from offshore California in the late 1950s and recognition of small ancient submarine fans in the stratigraphic record followed shortly after (see historical review in Pickering *et al.*, 1989, pp. 1–4). The facies model of Mutti and Ricci Lucchi (1972: see figure S47) established a pattern for interpretation that persisted, with variations, for the next 20 years. Subsequent mapping of the ocean basins revealed that submarine fans include some of the largest geomorphic features on the earth's surface, reaching lengths of 1,500 kms and widths of almost 1,000 kms (Indus fan: Kolla and Coumes, 1987; McHargue and Webb, 1986; and see McHargue in Weimer and Link, 1991). Such fans are much too large to be recognizable in exposed ancient rocks, and the deposits would be difficult to recognize even in subsurface basin studies. Large submarine channels have been described from the deep sea, with channel depths of more than a km, and widths of more than 10 kms, flanked by levees that rise tens of meters above the surrounding surface and extend many kms away from the channel. Such channels are also difficult to recognize in ancient rock outcrops, though a few of comparable size have been identified in subsurface studies (Walker, 1992).

Large fans are generally composed of finer sediment than the "classical" small fans described by Mutti and Ricci Lucchi, and attempts have recently been made to describe alternative fan models characteristic of finer grained turbidite systems (Reading and Richards, 1994; Bouma and Stone, 2000: see Figure S51). It is claimed that large volumes of sediment and the presence of mud increases the "efficiency" of sand transport, thereby allowing more sand to be carried through the midfan channels to the distal fan and basin plain. Bouma (in Bouma and Stone, 2000) suggests that fine grained fans are typical of passive margin tectonic settings, with long fluvial transport leading to deltas, and from them to the head of the main distributary channel. The sand in them is concentrated at the base of the slope, and/or is transported efficiently through

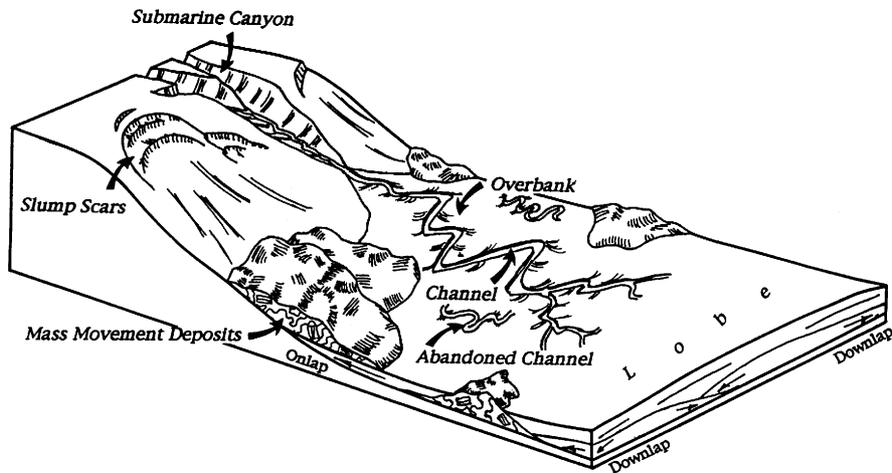

Figure S45 Surface morphology of a submarine fan. From Normark *et al.* (1993, their Figure 6 on p.100).

channels to distal sandy lobes. Coarse grained fans, in contrast, are typical of more tectonically active regions, with only short fluvial feeder systems, and with no prominent delta: much sand may be supplied into the feeder channel by longshore drift. Much of the coarse sediment is deposited in the midfan region. Though large fans may be dominated overall by finer sediment, many do contain substantial amounts of sand, for example the Amazon fan (Piper and Normark, 2001: see figure S48).

Not all submarine channels are directly related to submarine fans: the best known exception being the Northwest Atlantic Mid-ocean channel, described by Hesse and Rakofsky (1992). For an ancient large-scale canyon/channel complex, not obviously related to a fan, see Bruhn and Walker (1997).

Ancient submarine fans include many large petroleum reservoirs: they have become increasingly important as exploration has moved into deeper water, offshore. For a review of the special problems posed by exploration of such fans see Weimer *et al.* (2000).

Canyons, channels, and depositional lobes

Canyons

The upper parts of submarine channels, particularly those that incise the edge of the continental shelf are generally called canyons. They have been known since the end of the nineteenth century. In most cases, they are clearly erosional features, with some even eroded through hard igneous or metamorphic rocks. The eroding agent remained controversial until the 1950s. Though the main agent of erosion is now thought to be turbidity currents, there is still debate about the role played by other agents, including rivers (during lower stages of sea level), mass-wasting processes (including slides, slumps, and debris flows), sand flows, earthquakes, and structural or tectonic features. At lower sea levels (especially during the last ice age) rivers flowed across the continental plains (the shelves at higher sea-level stands), and entered what are, at higher stands, the heads of submarine canyons. Then, because of the lower water temperatures and higher suspended

B. Erosional/depositional (mixed)

C. Depositional

Figure S46 Erosional and depositional channels, as indicated by seismic profiles. From Clark and Pickering (1996, their Figure 1 on p.195, based on the earlier work of Normark).

sediment loads in the rivers, the river flows plunged below the surface of the sea to form “hyperpycnal flows:” that is, turbidity currents formed directly from river flows, without the deposition and resuspension that is generally necessary today (Mulder and Syvitski, 1995).

During the greater part of the existence of a canyon, there is only temporary storage of sediment, but filling of the canyon, and therefore its preservation in the geological record, can certainly take place. Many, but not all, modern submarine canyons are related, if not indeed directly connected with major rivers. A good compilation of the early literature is given in Whitaker (1976) and the more recent literature is reviewed by Pickering *et al.* (1989).

Channels

The term channel is reserved for features underlain by nearly contemporaneous sediment, on fan surfaces, or in deep-sea basins. Channels are of all sizes, and may be either erosional or depositional in character (Figure S46), as clearly indicated by

seismic profiling, for both modern and ancient channels (Clark and Pickering, 1996). Most active channels are directly connected with the main feeder canyon or channel, but some in the mid to lower fan have local “headwaters” on submarine slopes or on the flanks of large levees. In the midfan region, the position of the active channel changes frequently due to avulsion. The scale of submarine channels is generally larger than that of subaerial river channels, because they are adjusted to transmit intermittent turbidity current flows, many of which are large events, and most of which travel more slowly, on a given submarine slope, than a river of comparable size would on a comparable subaerial slope.

Generally, many of the flows exceed the capacity of the channel, so most submarine channels have very large constructional levees, compared with rivers. In large fans, the thickness of levee deposits may reach hundreds of meters (Figure S49). Coriolis effects are proportionately larger for turbidity currents than for rivers, causing more frequent overbank flow on one side of submarine channels, so that one levee is generally higher than the other. In other respects, submarine channels show many features in common with subaerial channels, including internal terracing, braiding, and meandering.

Though many flows overflow channels, particularly in the middle and lower parts of fans, most of the coarser sediment (sand, and especially gravel) is carried in the lower part of the flow, so is confined to the channels, and only spread out a sheet-like deposits where the flows emerge from the distal end of the channel (Figure S50).

On submarine fans, well-developed channels are characteristic of the middle region of the fan. While the channels are active, there are generally sites of sediment by-passing, or accumulation only of the coarsest lag deposits. Aggradation and catastrophic events cause channels to change position frequently on the fan surfaces, and abandoned channels are

filled by smaller flows carrying finer sediment, so in the geological record they can frequently be recognized by their basal erosion surface and lag, by amalgamation surfaces, and by fining and thinning upward sequences in the sandstone filling, even when the channel geometry cannot be clearly seen in the outcrop. For further details see Clark and Pickering (1996).

Depositional lobes

Depositional lobes, with only minor channels, and with a generally convex-up profile can be mapped below (distal to) distributary channels on some modern fans. Their presence is inferred in ancient fans, by the existence of “packets” of relatively coarse turbidite beds (some meters or tens of meters thick), separated from other packets by finer sediments. Though some authors have claimed that these “packets” show thickening and coarsening upward sequences (supposedly produced by progradation of the lobes) statistical studies have failed to support this as a general trend. Attempts to relate the statistical trends actually exhibited by turbidite sequences to fan environments have been reviewed by Carlson and Grotzinger (2001).

Facies models for small, coarse fans

Many authors have proposed models (almost all of them variations of the original model of Mutti and Ricci Lucchi, 1972) to aid in the identification of ancient fans and in the description and interpretation of the observed facies. For succinct accounts, see Walker (1992) and Normark *et al.* (1993; and in Weimer and Link, 1991), and for a more extended account see Pickering *et al.* (1989). Besides the use of trends in bed thickness and grain size, these schemes use the frequency

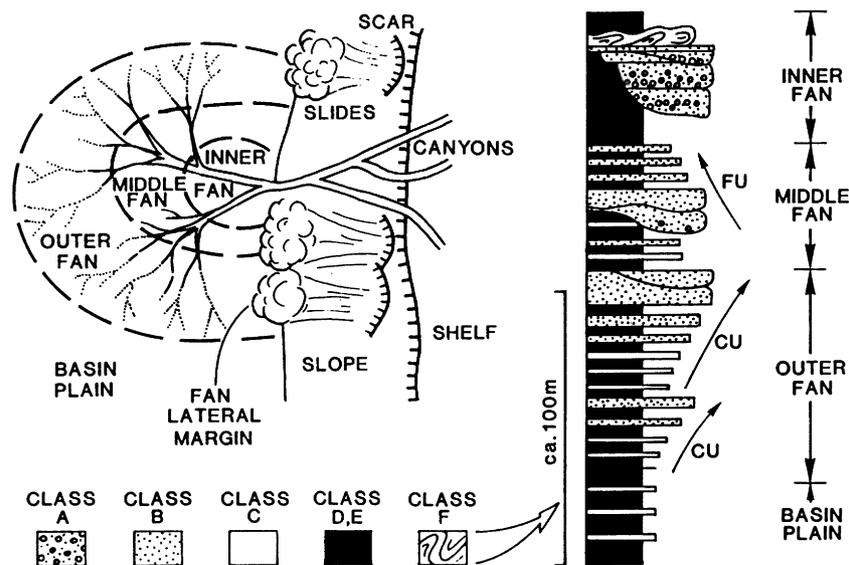

Figure S47 The fan model of Mutti and Ricci Lucchi (1972) as redrawn by Pickering *et al.* (1989, their Figure 7.2 on p.162). “Class A”, etc. refer to facies: A are conglomerates, B are coarse sandstones, both generally massive and amalgamated. C are “classical turbidites” of the proximal type, that can be described by the “Bouma sequence” of internal structures (found mainly on the outer fans and basin floor). D and E are thin alternations of mud and sand. F are chaotic facies. FU refers to fining and thinning upward, CU to coarsening and thickening upward.

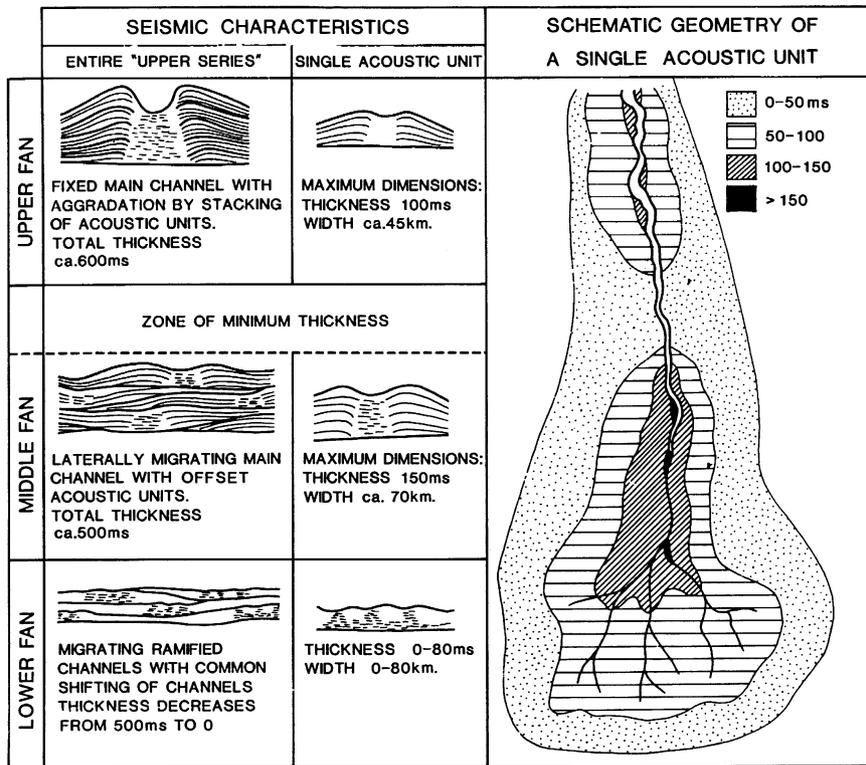

Figure S49 Schematic diagram showing channel-levee systems on the Rhone Fan. Thicknesses are in two-way seismic travel times, where 1 ms is about 0.75 m. From Pickering *et al.* (1989, their Figure 7.19 on p.177).

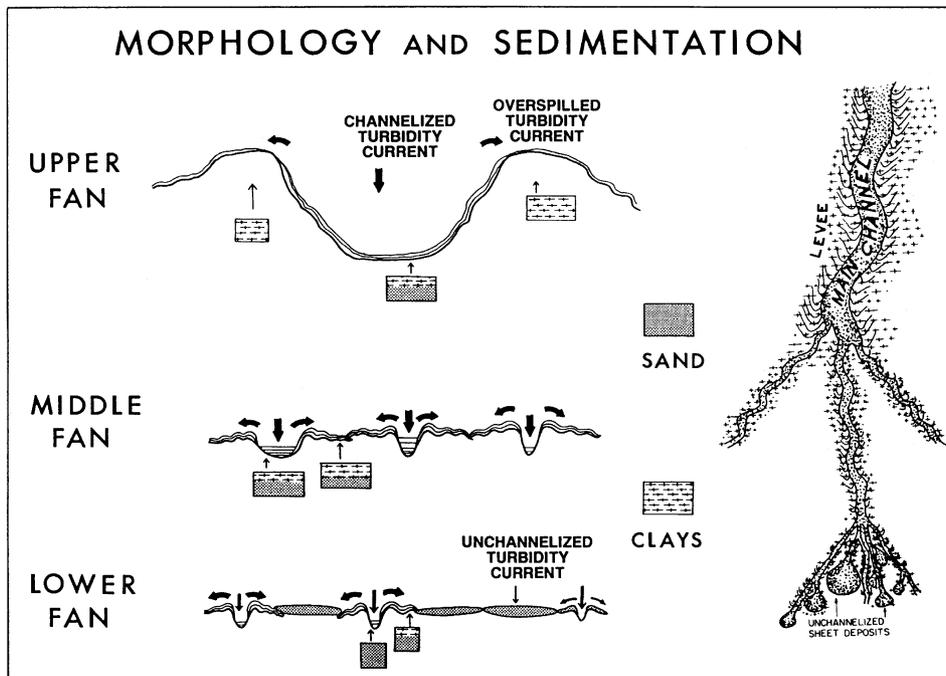

Figure S50 Model of sedimentation for the Indus fan channels, proposed by Kolla and Coumes (1986, their Figure 18 on p.674). The decreasing influence of channelized turbidity current down channel is shown in the sections on the left, along with the increasing importance of overbank flows, and apparent branching of channels shown on the plan on the right.

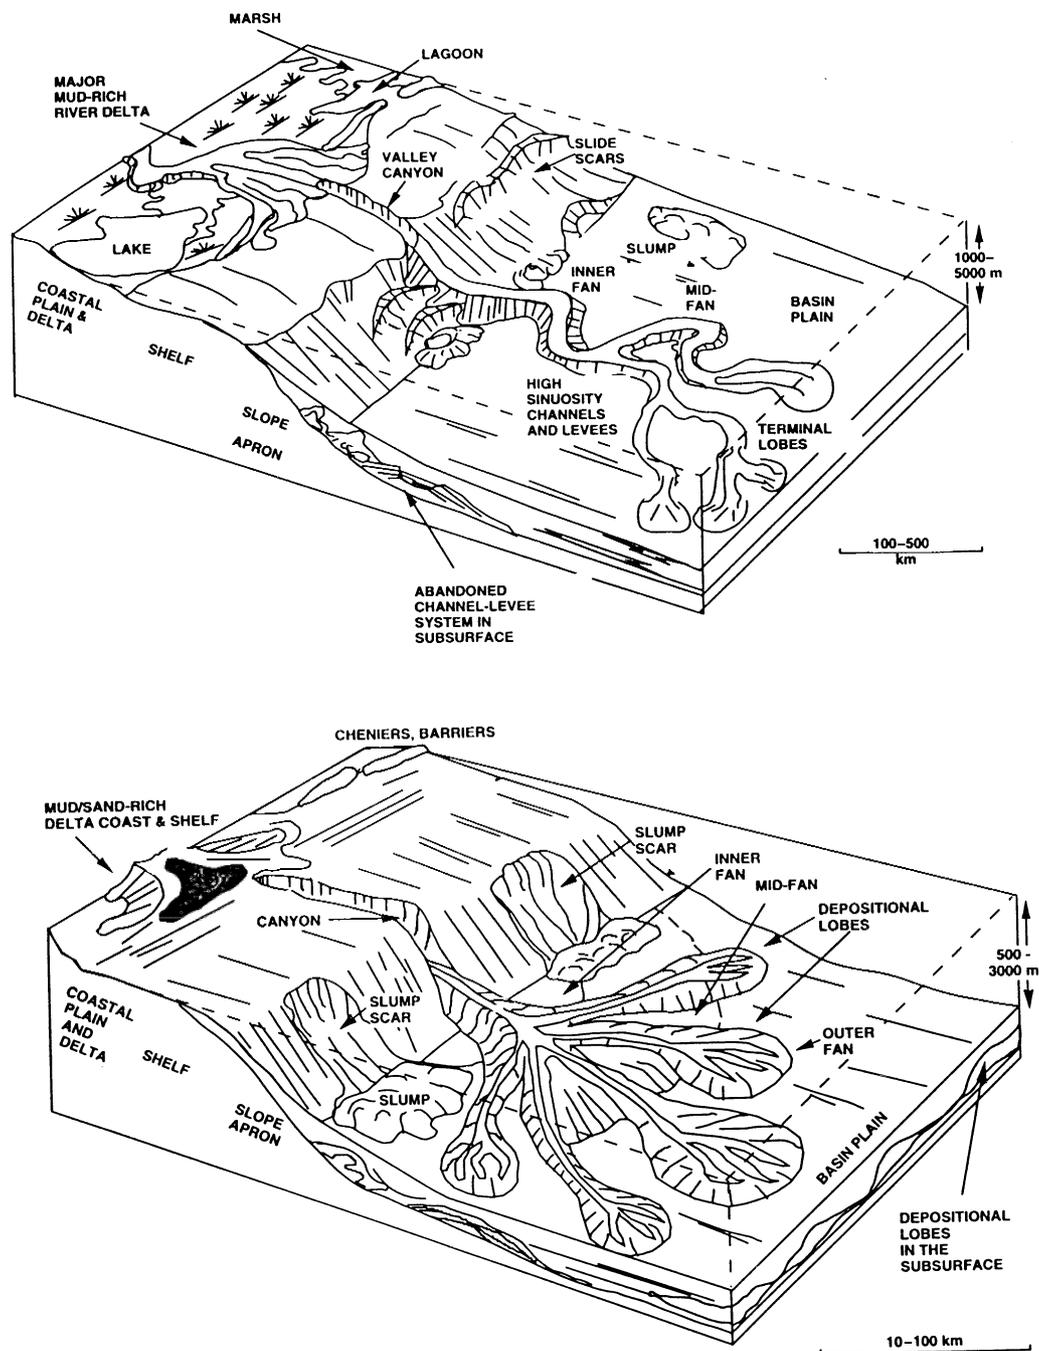

Figure S51 Two “end member” models for large fans (from Reading and Richards, 1994: top, their Figure 3, on p.801; bottom, their Figure 5 on p.803). The upper figure shows a model for a “point source mud-rich submarine fan” and the lower shows a model for a “point-source mud/sand-rich submarine fan.” Note the difference in scale, and in the abundance of levees, channels, and lobes.

of amalgamation of beds, and the types of internal structures displayed by the sand beds, to identify not only channels and lobes, but also ancient levee deposits, and to distinguish fan deposits from the sediment gravity flow deposits of other environments, such as basin plains. Though the models are still useful, sequence stratigraphic concepts, developed since the

1980s, show that they need to be modified to include the effects on submarine systems of tectonics and changes in relative sea level, both of which can affect the nature and frequency of the events supplying sediment into the feeder channel, and therefore the facies and stratigraphic sequences that are produced by the fan.

Models for large fans

Thus far, few attempts have been made to develop general models for very large fans, such as the Mississippi and Amazon fans. Individual modern fans, however, are discussed and analyzed in Kolla and Coumes (1987), Weimer and Link (1991), Droz *et al.* (1996), Bouma and Stone (2000), and Piper and Normark (2000). Figure S48 shows a map of the Amazon fan, Figure S49 shows a “model” based on the Rhone fan, and Figure S50 shows a “model” for the deposits of an active channel on the Indus fan. Reading and Richards (1994) have presented a spectrum of models, two of which are shown in Figure S51. Larger physical scale implies that large scale controls (climate, tectonic, and sea-level change over long periods of time) become more important. So sequence stratigraphic concepts are just as crucial as sedimentological processes, and are more useful when outcrop is not available and only large features can be observed, using seismic methods in the subsurface.

Some authors prefer to abandon the idea of “facies models,” and instead prefer to use the concept of “architectural analysis.” In this approach, each fan, or larger “turbidite system” is unique, but is constructed from recognizable “architectural elements” of several different scale (e.g., in order of increasing scale: beds, facies associations, stages, systems: see Mutti and Normark, in Weimer and Link, 1991). Thus there are not just a few “models” but an almost limitless number of possible “complexes” that may be constructed using the various “elements.” In assessing the recent literature, the reader should keep in mind the difficulty in observing the smaller-scale “elements” in deep water, and the present limited understanding of the physical processes involved (turbidity currents, debris flows, etc.) at very large scales.

SUBSTRATE-CONTROLLED ICHNOFACIES

Three substrate-controlled ichnofacies have been established (Ekdale *et al.*, 1984): *Glossifungites* (firmground), *Trypanites* (hardground), and *Teredolites* (woodground).

The *Glossifungites* ichnofacies

The *Glossifungites* ichnofacies is environmentally wide ranging, but only develops in firm, unlithified substrates such as dewatered muds. In clastic settings dewatering results from burial and the substrates are made available to tracemakers if

Substrate Controlled Ichnofacies

Glossifungites: Semi Cohesive

Trypanites: Hardgrounds

Teredolites: Woodgrounds

Figure S52 Substrate controlled ichnofacies; (A) The *Glossifungites* ichnofacies is indicative of semi cohesive substrates like dewatered muds or compacted sands; (B) The *Teredolites* ichnofacies is indicative of a woodground like a peat deposit; and (C) The *Trypanites* ichnofacies is indicative of fully cemented substrates like hardgrounds, disconformities, and beachrock.

exhumed by later erosion (Pemberton and Frey, 1985). Exhumation can occur in terrestrial environments, as a result of channel meandering or valley incision, in shallow-water environments as a result of meandering tidal channels, coastal erosion, erosive shoreface retreat, or as a result of submarine channels cutting through previously deposited sediments. Such horizons commonly form at bounding discontinuities and may be critical in the evolving concept of sequence stratigraphy (Pemberton *et al.*, 1992; Pemberton and MacEachern, 1995).

The *Glossifungites* ichnofacies (Figure S52(A)) is characterized by: (1) vertical, cylindrical U or tear shaped pseudo borings, sparsely to densely branching dwelling burrows, and/or mixtures of burrows and pseudo borings; (2) protrusive spreiten in some burrows that develop mostly through animal growth (funnel shaped *Rhizocorallium* and *Diplocraterion* [formerly *Glossifungites*]); (3) animals that leave the burrow to feed (e.g., crabs) as well as suspension feeders; and (4) low diversity, but commonly abundant individual structures.

The *Teredolites* ichnofacies

The *Teredolites* ichnofacies (Figure S52(B)) consists of a characteristic assemblage of borings or burrows in woody or highly carbonaceous substrates. Woodgrounds differ from this substrates in three main ways: (1) they may be flexible instead of rigid; (2) they are composed of carbonaceous material instead of mineral matter; and (3) they are readily biodegradable (Bromley *et al.*, 1984). Such differences dictate that the means by which, as well as the reasons for which these two types of substrates are penetrated are different. Because currents can raft woody substrates, it is important to determine whether the borings are autochthonous or allochthonous. Only the autochthonous forms are true members of the *Teredolites* ichnofacies. These assemblages may also be important in defining sequence and parasequence boundaries (Savrda, 1991). The use of bored logs to define bounding surfaces as in the concept of log-grounds (i.e., Savrda *et al.*,

1993) should be avoided, as it is very difficult to ascertain when the logs were bored. Such logs are clasts and should not be treated in the same manner as the *Teredolites* ichnofacies.

The *Teredolites* ichnofacies is characterized by: (1) sparse to profuse club shaped borings; (2) boring walls that are generally ornamented with the texture of the host substrate (i.e., tree ring impressions); (3) stumpy to elongate subcylindrical excavations in marine or marginal marine settings; and (4) shallower, sparse to profuse nonclavate etchings (isopod borings) in freshwater settings.

The *Trypanites* ichnofacies

The *Trypanites* ichnofacies (Figure S52(C)) develops in fully lithified substrates such as hardgrounds, reefs, rocky coasts, beachrock and other omission surfaces. As such, development of this ichnofacies also corresponds to discontinuities that have major sequence stratigraphic significance. Bromley and Asgaard (1993) subdivided the *Trypanites* ichnofacies into two ichnofacies; the *Entobia* ichnofacies for rocky shorelines (also see De Gilbert *et al.*, 1998) and the *Gnathichnus* ichnofacies for bored shells and boulders found further offshore. Bored shells and boulders, however, are not substrates that can be correlated because it is difficult to ascertain when the boring activity was initiated.

The traces in the *Trypanites* ichnofacies are characterized by: (1) cylindrical to vase, tear or U shaped to irregular domiciles of suspension feeders or passive carnivores; (2) raspings and gnawings of algal grazers and similar organisms (mainly chitons, limpets, and echinoids); (3) moderately low diversity, although the borings and scrapings of individual ichnogenera may be abundant; and (4) borings oriented perpendicular to the substrate which may include large numbers of overhangs. In contrast to the *Glossifungites* ichnofacies, the walls of the borings cut through hard parts of the substrate rather than skirting around them.

Significance of substrate controlled ichnofacies

In clastic settings, most of these trace assemblages are associated with erosionally exhumed (dewatered and compacted or cemented) substrates, and hence, correspond to erosional discontinuities. Woodgrounds consist of xylic clasts or interwoven mats of vegetation, forming resilient substrates that are not necessarily erosionally exhumed. In carbonate settings, firmground or hardground surfaces may occur at the sediment water interface, due either to erosional exhumation or non-depositional breaks with associated submarine cementation (Bromley, 1975). Depositional breaks, in particular condensed sections, may also be semilithified or lithified presumably at the upper contact (or downlap surface) and may be colonized without associated erosion. In general, however, the recognition of substrate-controlled ichnofacies may be regarded as equivalent to the recognition of discontinuities in the stratigraphic record.

Although certain insect and animal burrows in the terrestrial realm may be properly regarded as firmground (e.g., Fürsich and Mayr, 1981) or more rarely, hardground suites, they have a low preservational potential and constitute a relatively minor component in the geologic record of such associations. The overwhelming majority of these assemblages originate in marine or margin marine settings. A discontinuity

may be generated in either subaerial or submarine settings; but colonization of the surface may be regarded to be marine influence, particularly in pre Tertiary intervals. This circumstance has important implications, so far as interpretation of the origin of the discontinuity is concerned.

The substrate controlled ichnocoenose typically cross cuts a preexisting softground suite and, hence, reflects conditions post dating both initial deposition of the unit and erosion of that unit. The suite also corresponds to a hiatus between the erosion event (which exhumes the substrate) and deposition of the overlying unit. During this time gap, organisms colonize the substrate. By observing (1) the softground ichnofacies (contemporaneous with deposition of the unit); (2) the ichnofacies of the exhumed substrate; and (3) the ichnofacies of the overlying unit, it is possible to make some interpretation regarding the origin of the surface and the allocyclic or autocyclic mechanisms responsible.

Taphonomy: Sedimentological Implications of Fossil Preservation

SULFIDE MINERALS IN SEDIMENTS

The formation processes of metal sulfides in sediments, especially iron sulfides, have been the subjects of intense scientific research because of linkages to the global biogeochemical cycles of iron, sulfur, carbon, and oxygen. Metal sulfide precipitation can occur during several stages of diagenesis and burial of continental-margin, pelagic, and non-marine sediments. During early stages of diagenesis, anaerobic sulfate-reducing bacteria consume organic carbon and sulfate and produce hydrogen sulfide and bicarbonate. Pyrite (FeS_2) is formed by the reaction of this biogenic sulfide with reactive, detrital iron-bearing minerals near the sediment-water interface (Kaplan *et al.*, 1963; Berner, 1970, 1984). The initial reaction products are iron monosulfide minerals that may subsequently transform to pyrite by reaction with polysulfides or other reactive oxidants (e.g., Morse *et al.*, 1987). Pyrite formation in sediments is thought to be limited either by the microbial production of sulfide (organic carbon or sulfate limitation) or by the availability of reactive iron minerals (iron limitation). During later stages of diagenesis and deep sediment burial, thermochemical sulfate reduction may become important and more refractory iron oxides, typically unreactive during early diagenesis, are sources of iron in sulfidation reactions. Studies of metal sulfides in sediments and sedimentary rocks employ analytical techniques such as microscopy, sulfur isotope ratio measurements, and trace element measurements. Relationships between the concentrations and partitioning of sedimentary Fe, S, and C provide important tools for reconstructing paleoenvironments over a range of temporal and spatial scales (e.g., Goldhaber and Kaplan, 1974).

Transition metal sulfides (e.g., NiS, CuS, ZnS, CdS, HgS) have exceedingly low solubility products and might be expected to form during early diagenesis. However, with the exception of iron, d-transition metals are typically present in trace amounts in sediments, which does not allow for any significant accumulation of sulfide minerals other than those of iron. Consequently, iron sulfides are the only metal sulfides commonly recognized in marine and non-marine sediments. In contaminated sediments or systems with high metal loadings, sulfides of Zn, Cd, and Cu have been reported (e.g., Luther *et al.*, 1980). Trace metals are frequently found associated with pyrite and include Co, Ni, Cu, Zn, As, Mo, Cd, Sb, Hg, and sometimes Mn. In particular, As, Hg, and Mo have a high affinity for pyrite and are generally enriched in pyrite relative to bulk sediments (Raiswell and Plant, 1980; Huerta-Diaz and Morse, 1992). Questions remain as to whether the trace metals found associated with the sulfide fraction are as discrete phases or as coprecipitates with the abundant iron sulfides.

Several iron sulfide phases have been synthesized in the laboratory, either as transient intermediates or as stable end products, and are therefore likely to form in sedimentary environments. These phases are: disordered mackinawite, Fe_{1+x}S ; mackinawite, Fe_{1+x}S ; cubic iron sulfide, FeS ; hexagonal pyrrhotite, Fe_{1-x}S ; greigite, Fe_3S_4 ; smythite, Fe_9S_{11} ; marcasite, orthorhombic FeS_2 ; and pyrite, cubic FeS_2 . Pyrrhotite and pyrite represent the thermodynamically stable phases at the temperatures and pressures of early diagenesis (Berner, 1967). Disordered mackinawite, mackinawite, and

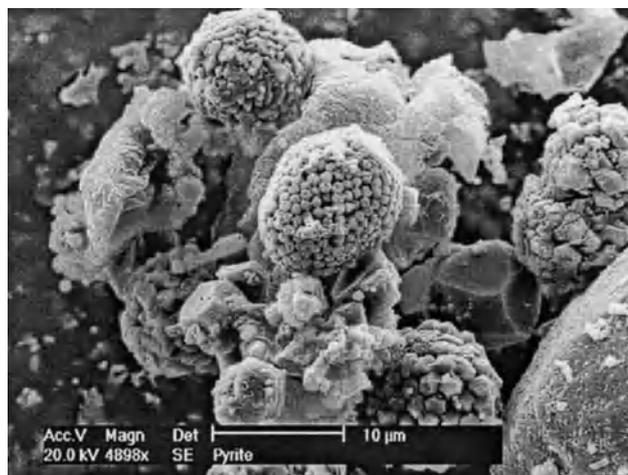

Figure S53 Group of pyrite framboids (modern slope sediments, Black Sea).

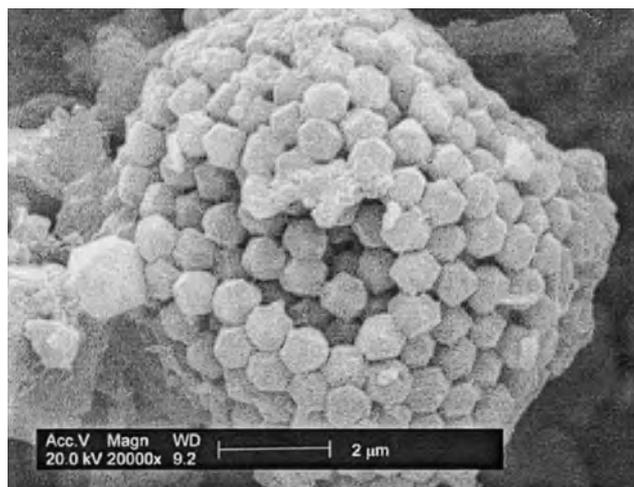

Figure S54 Framboid with pyritohedral microcrystals (Cretaceous sediments).

greigite are metastable with respect to pyrite and/or stoichiometric pyrrhotite but are considered to be the principal precursor phases to pyrite (e.g., Schoonen and Barnes, 1991). Smythite and cubic FeS are exceedingly rare (Krupp, 1994). Marcasite has not been identified in modern sedimentary environments but is present in some ancient sedimentary rocks. Marcasite formation is thought to require a low pH and high concentration of polysulfide species. Greigite was originally reported from Tertiary lacustrine deposits but has been more recently documented in sediments as old as Upper Cretaceous siliciclastics (Reynolds *et al.*, 1994). Despite its predicted stability, hexagonal pyrrhotite is apparently very rare as an authigenic phase in sediments and sedimentary rocks. In marine and non-marine sediments, pyrite is the normal end product of sulfate reduction and iron mineral sulfidation. The kinetics of transformation from precursor iron sulfides to pyrite may be slow (years) or fast (days) depending on factors such as pH, redox state, and temperature.

Pyrite is the most common authigenic mineral in recent marine and lacustrine sediments, as well as in sedimentary rocks, especially gray- to black-colored shales (Arthur and Sageman, 1994). It occurs typically as single grains 1 μm to 10 μm in size, as framboids mainly <20 μm in diameter, as groups of framboids termed polyframboids, and as replacements of organic matter (Figures S51–S53). Microcrystals and framboids are the basic textures that form during sediment deposition and diagenesis (Raiswell, 1982). Microcrystals are usually subhedral to euhedral; octahedrons and pyritohedrons are common. The term *framboid* refers to a unique raspberry-like microtexture, which has been the subject of numerous studies. The ordered, cell-like arrangement of pyrite microcrystals in framboids has resulted in a long-lived debate on whether they are organic or inorganic in origin (see Wilkin and Barnes, 1997 and references therein). These textures can survive to low-greenschist facies metamorphism. Pressure solution and overgrowth may occur during low-grade metamorphism and deformation. With progressive deformation, pressure solution produces flattened grains perpendicular to the maximum compressive stress that results in the development of foliations and lineations (McClay and Ellis, 1983). Mass transfer during pressure solution has important implications with respect to the distribution of trace elements and the sulfur isotopic systematics of sulfide ores.

There are other examples of localized, macroscopic to microscopic varieties of pyrite found in modern and ancient sediments. Some examples are pyritized organic matter, pyritized burrow tubes, shell infillings of pyrite, carbonate shell replacement by pyrite, pyrite concretions and nodules, and perhaps most spectacularly, the pyritization of soft-bodied materials (e.g., Briggs *et al.*, 1991; Canfield and Raiswell, 1991).

A second setting where metal sulfides accumulate in sedimentary systems is in areas such as mid-ocean ridges where hydrothermal fluids discharge into seawater. Rapid cooling of the hydrothermal fluids as they interact with cold ocean water causes the precipitation of dissolved solutes, often as very-fine grained sulfide minerals (“black smokers”). Metal sulfides may also precipitate on the walls of the vents or in vertical tubular structures (“chimneys”). Pyrite again

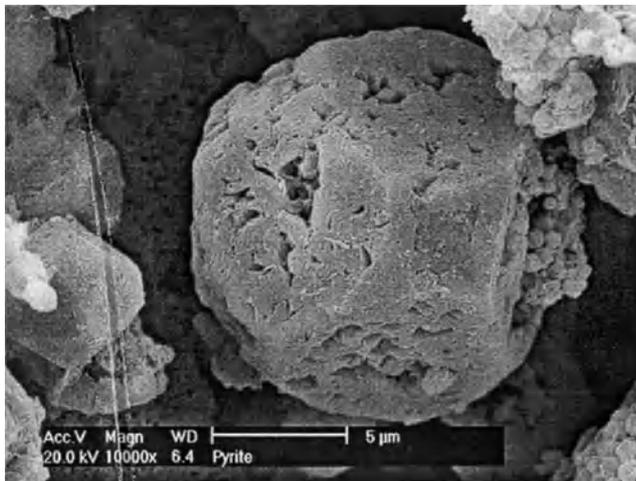

Figure S55 Pyritohedral grain of pyrite (Cretaceous sediments).

dominates the sulfide mineralogy of these submarine volcanogenic deposits although sulfide precipitates can also include those of Cu and Zn. Precious metals such as Ag and Au may also be enriched in the products of these hydrothermal processes. Volcanogenic massive sulfide deposits have been important sources of base metals; notable are the deposits in Japan (Kuroko-type) and the Iberian Peninsula (Pyrite Belt). Such volcano-sedimentary deposits grade into bedded metal sulfide ores that often show no clear associations with volcanism or hydrothermal activity. The origin of these sediment-hosted sulfide ores historically has been controversial; however, this important class of mineral deposits includes some of the most famous ore districts (e.g., Broken Hill, Australia; Sullivan, North America; Kupferschiefer, Europe; Zambian Copper Belt, Africa). In these deposits, metal sulfides are thought to have formed syngenetically, precipitated from hydrogen sulfide of hydrothermal or microbiological origin.

Geologic evidence suggests the persistence for over 3 Ga of deep-ocean hydrothermal systems. The discovery of life and diverse ecosystems that have adapted to the warm, anoxic environments of seafloor hydrothermal systems, along with the discovery of ancient sulfur-metabolizing bacteria has spawned hypotheses that such environments could be the sites for the origin of life on earth. Metal sulfides in sediments may have played a role in catalyzing reactions and/or providing energy sources through redox reactions that ultimately led to the buildup of complex organic molecules, thereby guiding the transition from a prebiotic earth to a biotic earth (e.g., Wächterhäuser, 1988).

SURFACE FORMS

The nature of surface forms

Surface forms are geometrical features that develop on a surface of cohesive or noncohesive sediment by the action of a flow of fluid over that surface. Surface forms are commonly produced by flows of water in streams and rivers, by tidal currents in shallow coastal areas, by continental-shelf bottom flows, and by various kinds of flows in the deep ocean. The generating flows on continental shelves may be purely unidirectional, or purely oscillatory as a result of the passage of surface waves, or combinations of unidirectional and oscillatory flows. They are also common in environments on land where winds are strong enough to move sand along the surface. Some surface forms are generated solely by localized erosion of the sediment bed; others are generated by transportation of sediment along and over the bed in a pattern of local erosion and deposition without overall net erosion of the surface, and perhaps with overall net deposition.

The range in both the scale and the geometry of surface forms is extremely wide. The scale of common surface forms ranges from centimeters to kilometers horizontally and from centimeters to at least tens of meters vertically. Most surface forms show more or less elongation in their geometry, either transverse to the flow or parallel to the flow, although some are oblique to the flow direction and others are approximately equidimensional rather than elongate. In part this wide range of diversity is owing to a wide range in conditions over which a generating process acts, but in part also because the processes that generate surface forms are diverse. It is clear that surface forms are a polygenetic phenomenon: a number of disparate effects of fluid flow give rise to them.

Surface forms may or may not exist in a state of equilibrium with the generating flow. Equilibrium of surface forms is

common when the flow persists in a nearly unchanging state for a time long enough that the surface forms can adjust their characteristics fully in response to the flow. In other cases, the development of the surface forms lags behind changes in the flow. Such disequilibrium makes for even greater variety in surface forms, and it is a complicating factor when attempts are made to use the characteristics of preserved surface forms for making interpretations of the former flow that generated the forms.

The size of sediment in the bed of sediment on which surface forms can exist ranges widely, from cohesive or semicohesive clays and muds to gravels. Distinctive erosional forms, like flutes and flow-parallel furrows, are characteristic of fine, cohesive sediment surfaces. Rugged flow-transverse forms, like ripples and dunes, are characteristic of coarse silts, sands, and (with lesser frequency) gravels.

The significance of surface forms

Surface forms are of interest to a wide range of specialists in the natural sciences, including geologists, geomorphologists, geographers, and oceanographers, because they are so varied in their scale, geometry, and origin and are so characteristic of natural flow environments, both subaqueous (under water) and subaerial (under air). Moreover, even apart from their intrinsic interest, surface forms are of interest for practical reasons as well. Large subaqueous surface forms many meters high can be obstacles to navigation, and their movement can be a threat to submarine structures. The rugged topography of surface forms in rivers and tidal channels causes flow separation at the crests and therefore large values of form drag. Surface forms are thus the most important determinant of resistance to channel flow, and hydraulic engineers have expended much effort on the development of depth–discharge predictors based on the hydraulic relationships of the surface forms (Vanoni, 1975, p. 114–152). The nature of the surface forms is also closely bound up with the sediment transport rate in unidirectional flows, in that the downcurrent movement of rugged flow-transverse surface forms largely involves recycling of bed load within the forms. Sedimentologists have given much attention to certain kinds of surface forms because of their role in generating stratification, which is one of the most useful tools available for interpreting ancient sedimentary environments (see *Bedding and Internal Structures*).

Terminology and classification of surface forms

Terminology for surface forms is diverse and can be confusing. Nonspecialists are confronted with a wide variety of terms, among the most common being ripples, dunes, antidunes, sand waves, sediment waves, furrows, and flutes. The general term surface form is nearly synonymous with the common terms bed form or bedform. Some workers use the term bed form for an individual, distinctive geometrical element that is formed on a sediment bed by a flow of overlying fluid. In that context, the individual bed forms constitute a bed configuration, which is the aggregate of all of the bed forms that are present in a given area of the sediment bed at a given time. Others use the term bed form (more commonly, bedform) for both the individual element and the entire configuration, with the intended sense derived from the context of the description or discussion.

Even under an unchanging flow, and with unchanging sediment characteristics, the particular geometry of the bed configuration that is actively coupled with the flow at a given time differs in detail from that of the configuration at any other time. It is sometimes useful to think of the average characteristics of such a collection of equivalent configurations as the bed state. Bed states with closely related geometry and kinematics, formed under a particular range of flow and sediment characteristics and readily distinguishable from those formed under different ranges of conditions, are sometimes called bed phases, in loose analogy with thermodynamic phases. Some examples of such bed phases are current ripples, subaqueous dunes, subaerial dunes, flutes, or erosional furrows (see classification below).

Surface forms can be classified in a variety of ways. An ideal classification would distinguish among genetically different kinds of forms, and within those kinds, characteristic subclasses based on differences in geometry and kinematics as a function of differences in flow and sediment characteristics. There is no universally accepted classification scheme for surface forms. Widely recognized categories of surface forms are shown in Table 1. Owing to the complexity and diversity of processes that generate surface forms, such a classification is bound to be inadequate to express the full range of the phenomenon, but it can serve as a guide to the principal kinds of surface forms discussed in later sections of this article.

Flows that generate surface forms

Flows of water that generate surface forms range from unidirectional to oscillatory. In unidirectional flows, water velocity is always in the same direction, although speeds may vary on timescales ranging from seconds to tidal periods and longer. In purely oscillatory flows, water movements range from back-and-forth movement in a single orientation to more complex oscillations in which water motions change direction seemingly at random owing to the superposition of more than one oscillatory component, as for example at the bed of an ocean or a lake where the water surface is characterized by a complex multidirectional wave spectrum. In most subaerial environments, the wind is notoriously changeable in both speed and direction, although in some areas of the world, sand-moving winds blow very consistently from a narrow range of directions.

Subaqueous surface forms generated by unidirectional flows

Flow-transverse surface forms

Flows of water over noncohesive beds of silt, sand, or gravel generate a variety of rugged surface forms. These forms are most common in sands. It has been customary to think in terms of a progression of regimes of surface forms with increasing flow strength: current ripples, dunes, plane-bed transport, and antidunes. The picture is actually more complicated, however, because the succession of different kinds of surface forms varies not only with flow strength but also with sediment size.

Flow-transverse surface forms have been studied in water channels and flumes, by both hydraulic engineers and earth scientists, since the beginning of the twentieth century.

Particularly notable studies are those by Gilbert (1914) and Simons and coworkers (Simons and Richardson, 1963; Guy *et al.*, 1966). For a summary of laboratory data, see Southard (1991). Theoretical studies of the existence of rugged flow-transverse surface forms have had a long and varied history. A long-standing approach has been through stability analyses, in which the equation of motion, supplemented with a relationship between flow strength and sediment transport, is appropriately linearized and then a small perturbation is introduced. If the perturbation is damped, then a planar transport surface is stable; if the perturbation grows, then the bed develops into rugged surface forms. The most successful of such approaches has been that of Richards (1980).

Graphical representation

There have been many attempts to represent the range of conditions that produce each kind of surface form in graphs. Such graphs are loosely analogous to the thermodynamic phase diagrams. Such graphs are useful ways of portraying the relationships among the various kinds of surface forms, to the extent that the existence fields in the graphs do not overlap. Because of the effect of water temperature on water viscosity, these variables must be in nondimensionalized form in order to represent the existence of the various kinds of surface forms in a rational way. In the graphs presented below, these nondimensionalized variables have been converted to their 10°C equivalents, to make comparison with actual flow conditions more readily apparent.

There have been two main approaches to the construction of graphs of the existence fields of flow-transverse subaqueous surface forms. In one approach, the shear stress the flow exerts on the sediment bed is used to represent the strength of the flow, from the standpoint that it is this shear stress that actually moves the sediment. The problem with this approach is that when the bed is roughened with rugged surface forms, most of the bed shear stress is from drag rather than skin friction, which is the part of the bed shear stress that actually moves the sediment. Such graphs are successful only to the extent that the skin friction can somehow be separated out from the total bed shear stress. The most recent example of such a graph is by Van den Berg and Van Gelder (1993), shown here as Figure S56. The graph in Figure S56 uses a nondimensionalized form of the skin friction, computed according to a rational method, and nondimensional median sediment size.

The other approach to graphs of the existence fields is to use the mean velocity of the flow as a surrogate for the flow strength. The problem introduced by using the mean flow velocity is that the flow depth must be introduced as a leading variable as well, because various combinations of flow depth and flow velocity correspond to the same bed shear stress. The advantage of such a representation, however, is that it sidesteps the problem of partitioning the bed shear stress and leads to unambiguous characterization of the existence fields. The most recent example of such a graph is by Southard and Boguchwal (1990), shown here as Figure S57. The graph in Figure S57, which shows surface forms in terms of nondimensional mean flow velocity and nondimensional median sediment size, is drawn for just one value of nondimensional mean flow depth. For greater (lesser) flow depths, the existence fields shift their position up (down), and the shapes of the fields change somewhat as well.

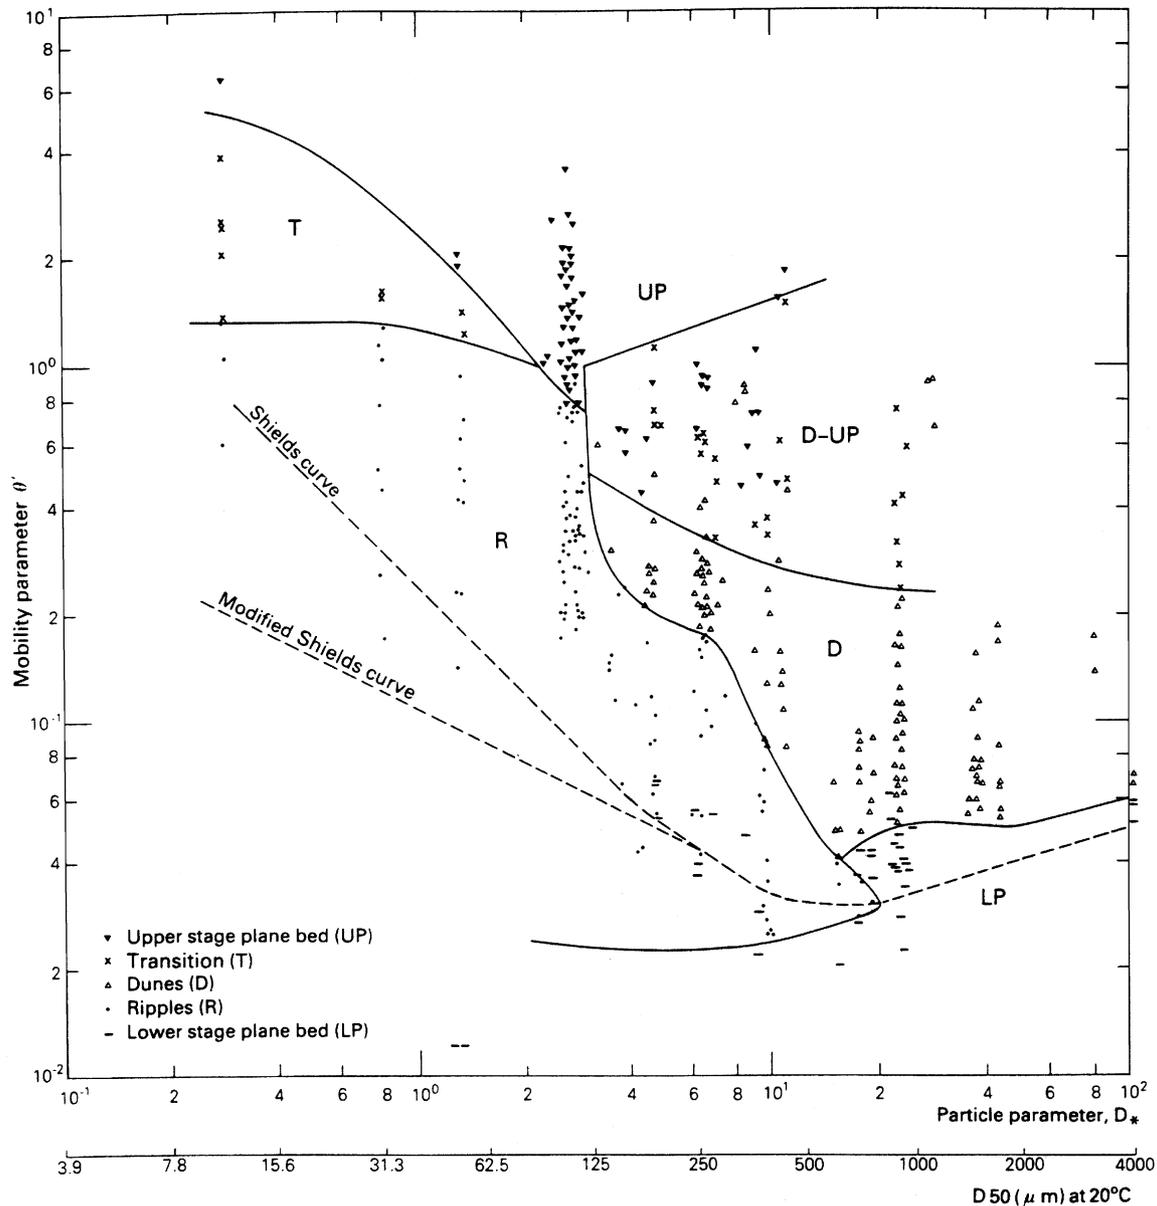

Figure S56 Graph showing existence fields of surface forms generated by unidirectional water flows in shallow channels. Data are from various sources. The mobility number θ' is a nondimensional measure that expresses the shear stress exerted on the particles by the flowing water, and D^* is a nondimensional measure of the median particle diameter. The lower vertical axis gives the equivalent value of actual median particle diameter at a reference water temperature of 20°C. (From Van den Berg and Van Gelder, 1993.)

Current ripples

Over a wide range of sediment sizes, from the finest noncohesive silts up to about 0.7 mm, and for flow strengths ranging upward from the threshold for sediment movement, the equilibrium surface form is current ripples. For sediment sizes less than about 0.2 mm, ripples give way to a planar transport surface with increasing flow strength; for coarser sizes, ripples pass abruptly into dunes with increasing flow strength.

Current ripples are rugged small-scale bed forms with crests and troughs oriented dominantly transverse to flow. Their downcurrent surfaces have slopes usually at or near the angle of repose of the sediment (of the order of 30°), although tending to be less at high flow strengths, and their upcurrent slopes are usually much gentler. Spacings are usually 0.1–0.2 m, and heights are usually no more than a few centimeters. Height and spacing are nearly independent of flow strength, flow depth, and sediment size.

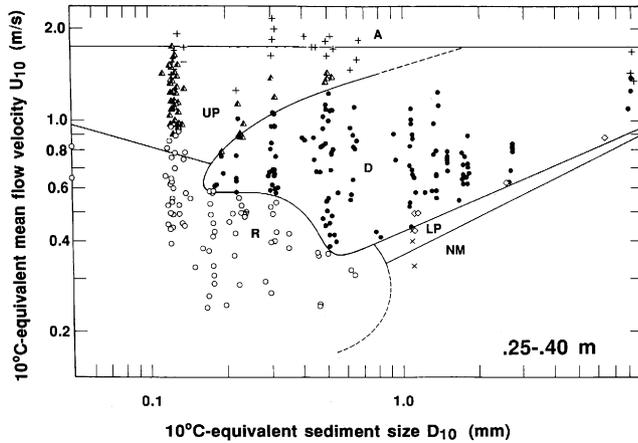

Figure S57 Graph showing the existence fields of surface forms generated by unidirectional water flows in shallow channels, with flow depths ranging from 0.25 m to 0.40 m. Data are from various sources. On the vertical axis, U_{10} is a nondimensional measure of the mean flow velocity, expressed as the equivalent value of the actual mean flow velocity at a reference temperature of 20°C. On the horizontal axis, D_{10} is the corresponding measure of the median particle diameter. A, antidunes; UP, upper-stage plane bed; D, dunes; R, ripples; LP, lower-stage plane bed; NM, no movement. (From Southard and Boguchwal, 1990.)

When current ripples first make their appearance on a planar sediment surface, they are strongly regular and straight-crested, but as they grow toward equilibrium they develop substantial irregularity in geometry: crests and troughs tend to be sinuous and variable in height, and when traced laterally individual ripple crests end by merging with another ripple crest or disappearing into a trough.

Ripples move in the downcurrent direction at speeds orders of magnitude less than the flow velocity by means of erosion of sediment from the upstream surface and deposition on the downstream surface. Individual ripples exist for time periods corresponding to downcurrent movement typically equal to less than ten ripple spacings before merging with another ripple. Meanwhile, new ripples are formed by division of a preexisting single ripple.

Subaqueous dunes

Over a range of sediment sizes from about 0.2 mm upward into gravels, and over a wide range of moderate to high flow strengths (Figures S56, S57) subaqueous dunes are the stable surface form under unidirectional water flows. In sediments finer than about 0.7 mm, dunes succeed ripples with increasing flow strength; in coarser sediments, dunes make their appearance at flow strengths not much greater than the threshold for sediment movement. With increasing flow strength, dunes are washed out to a planar transport surface.

In the past, surface forms here called dunes have variously been termed megaripples and sand waves as well as dunes. In recent years (see Ashley, 1990) it has become widely accepted to describe all such large-scale rugged flow-transverse forms as dunes. Some investigators, however, consider large-scale sand waves in tidal environments to be fundamentally different from dunes in unidirectional flows (Allen, 1980).

Dunes are much like ripples in geometry and movement. At relatively low flow strengths, dunes tend to be regular and straight crested (often called “two-dimensional dunes”), whereas at relatively high flow strengths they tend to be sinuous and discontinuous (often called “three-dimensional dunes”), with strong variability of crest and trough heights. For three-dimensional dunes, the existence of deep scour pits along troughs is especially characteristic.

The spacing of dunes ranges upward from somewhat less than half a meter to thousands of meters, and the height of dunes ranges upward from a several centimeters to many tens of meters. The controls on dune size are complex, but it seems clear that there is no fundamental limit to dune size, if the combination of flow strength and sediment size are appropriate and flow depth is sufficiently great. There is a well-defined break in size between current ripples and dunes.

Antidunes

Over a wide range of noncohesive sediment sizes, and for high flow strengths and relatively shallow depths, the equilibrium surface form is antidunes. Antidunes are trains of undulatory surface forms that develop on a planar transport surface. For a given flow depth, antidunes always develop if the flow strength is increased sufficiently, although the common limitations to possible flow strengths in nature mean that antidunes are characteristic only of rather shallow flows, except perhaps under conditions of catastrophic flood flows. Antidunes tend to move slowly upstream, growing in height and therefore in steepness as they move. Eventually the entire train of antidunes becomes unstable; the antidunes then break, causing much suspension of sediment, and the bed surface reverts to being nearly planar, whereupon the antidunes slowly reform.

Mud waves

In many regions in the abyssal ocean, at the foot of the continental slope, the surfaces of large bodies of fine sediment known as sediment drifts are covered with large-scale, low-amplitude wavelike features; for a well-documented recent example, see Flood and Shor (1988). These features have variously been called sediment waves, mud waves, or abyssal antidunes (the last because they seem to have shifted upcurrent; see below). Similar but smaller waves have been observed on the flanks of channels on submarine fans (e.g., Normark *et al.*, 1980; McHugh and Ryan, 2000).

The sediment of which the waves consist seems invariably to be fine mud. The spacing of these waves ranges from one kilometer to as much as twenty kilometers, and heights are in the range of five meters to one hundred meters. Slopes of the flanks of these waves are seldom greater than one degree. Despite their gentle slopes, the waves are strikingly revealed by subbottom echo-sounding techniques. In some cases these waves are symmetrical, but typically they have shifted slowly in the direction that is known or assumed to be upcurrent. The subbottom record shows clearly that in most cases there has been deposition on both flanks of the wave, but at a lower rate on the flank toward which the wave has shifted. The internal stratification of waves shows clearly that they existed, and were the site of active continuous or semicontinuous deposition, for geologically long times. In some cases they are seen to be draped with different sediment and therefore inactive; in other cases they seem likely to be active still.

The dynamics of the mud waves are not fully understood. The waves seem to have been formed by slow deposition of fine sediment from bottom currents with moderate velocities and presumably low sediment concentrations. In the case of the waves on sediment drifts, the depositing currents seem to be bottom-hugging contour currents carrying low concentrations of suspended sediment, which however are substantially greater than the much cleaner water higher in the water column. In the case of the waves on submarine fans, the evidence points to mild turbidity flows that result from overbank spillage of channelized episodic turbidity currents from channels onto broad levees. The similarity in features between these two different environments suggests a common origin. The most widely accepted theory (Normark *et al.*, 1980; Flood, 1988) is that these waves are a manifestation of a pattern of nearly stationary internal waves generated in the near-bottom interval of vertical density gradient that is occasioned by the upward decrease in suspended-sediment concentration.

Flow-parallel surface forms

Furrows are a kind of flow-parallel surface form that is produced by localized erosion of cohesive sediments subjected to moderately strong unidirectional or bidirectional currents in a generally depositional regime. They have been reported from the abyssal ocean (e.g., Hollister *et al.*, 1974), estuaries (e.g., Flood, 1981), and lakes (e.g., Viekmán *et al.*, 1992).

Furrows range in depth from a meter to more than ten meters, and in width from a meter to as much as one hundred meters. In cross section they often appear to be roughly trapezoidal, with steep and often rippled side slopes and a nearly flat floor. Spacing of the furrows ranges from more than ten times width to even less than width. The sediment surface between furrows is generally flat. Individual furrows can extend for distances greater than one kilometer, and perhaps much farther, given the difficulties of continuous observation over broad areas in inaccessible environments. Furrows commonly bifurcate in tuning-fork-like junctions, which open toward the oncoming current. Measured current strengths in furrowed areas range from five centimeters per second in abyssal examples to more than half a meter per second in shallow continental shelves and large lakes. In at least some cases there is good evidence of continuing deposition in the areas between the furrows, and this has to be reconciled with the obviously erosional nature of the furrows themselves.

It is generally believed that the furrows are a manifestation of the existence of patterns of helicoidal streamwise secondary circulation superimposed upon the mean flow. The furrows become localized along streamwise zones of flow convergence, where low-density aggregates collect in windrows and abrade the underlying cohesive sediment as they are moved down-current. The sediment put in suspension then tends to be carried upward in the ascending branch of the circulation cell. In this view, the furrows can be maintained by occasional strong erosive flows on a background of overall fine-sediment deposition during long periods of weaker flow. See Flood (1983) for an exposition of this theory.

Erosional forms: flutes

When an erosive current passes over a bed of cohesive sediment, the sediment surface tends to take on a characteristic fluted geometry. The individual flutes vary in their shape, but

their distinctive characteristic is an approximately bilateral symmetry about a vertical plane parallel to the flow but a strong asymmetry when viewed normal to that plane, whereby the depth of the scour and the steepness of the surface are much greater at the upstream end than at the downstream end. The adjective "heel-shaped" (Allen, 1984) is an apt descriptor. The typical flute, when viewed from above, has an upcurrent end with approximately parabolic shape, although in many cases the upstream end of the flute is more pointed or has an asymmetrical corkscrew shape. The geometrical pattern of the flutes shows considerable variety, as does the density of flutes on the sediment surface. Most flutes are on streamwise scales of the order of ten centimeters, but they range upward in size to at least a few meters, and there have been reports of giant flute-shaped scours that seem to be the result of especially powerful turbidity currents (e.g., Shor *et al.*, 1990). Much of our understanding of the nature and origin of flutes has come about through the experimental work of J.R.L. Allen (for a summary, see Allen, 1984).

Flutes tend to be formed by powerful currents, like turbidity currents or river floods, which form the flutes during an initial erosive phase and then bury them during a later depositional phase. Much of what is known about flutes is derived from observations of the bases of sandstone beds less resistant overlying shales in the ancient sedimentary record; the sandstones record the casts (i.e., the negative imprints) of the flutes. There has been much success in producing realistic flutes experimentally; see Allen (1984) for a summary of such work (and see *Scour, Scour Marks*). It is clear that flutes are the result of net erosive removal of material from the sediment surface without further interaction with the eroded material with the sediment bed downstream; the eroded material goes directly into suspension rather than being transported as bed load. The close similarity between flutes formed on cohesive mud beds and those formed by dissolution on soluble surfaces of rock or ice by flowing water supports that notion.

Subaqueous surface forms generated by oscillatory and combined flow

Oscillation ripples

Noncohesive sediments over a wide range of sediment sizes assume surface forms in a wide range of sizes and geometries in bidirectional purely oscillatory flow. Such forms have been the subject of systematic study in both natural environments and laboratory tanks since early in the twentieth century. Among the earliest of modern laboratory studies is that of Bagnold (1946); the classic field study was by Inman (1957).

Field studies of oscillatory-flow surface forms suffer from the difficulties of observation under conditions of heavy seas, and laboratory studies have concentrated mainly on the fairly short oscillation periods to which small apparatus are limited. More recent laboratory studies at much longer oscillation periods in a large oscillatory-flow tunnel are reported by Southard *et al.* (1990).

A useful way to describe the conditions of existence of oscillatory-flow surface forms is to consider them as a function of three leading variables: median sediment size, maximum oscillatory velocity, and oscillation period. As with unidirectional-flow surface forms in the preceding section, the ranges of existence of the various oscillatory-flow surface forms can

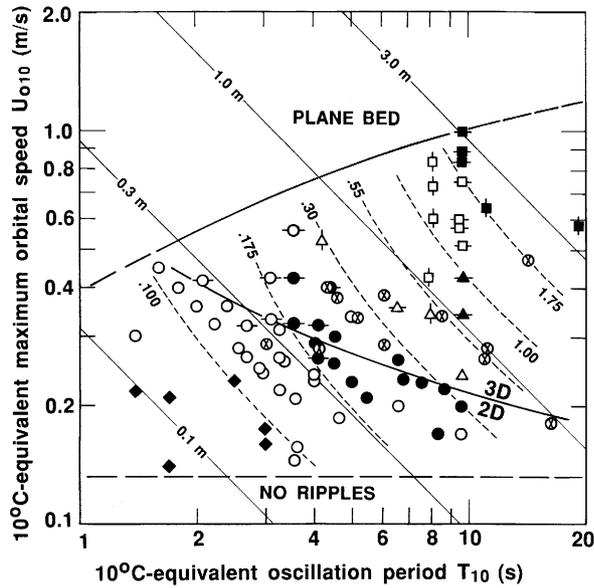

Figure S58 Relationships of oscillatory-flow surface forms in a graph of nondimensional maximum oscillatory flow speed U_{o10} versus nondimensional oscillation period T_{10} , expressed as equivalent values at a reference temperature of 10°C , for particle sizes of about 0.1 mm . Symbols for spacing of surface forms: solid diamonds, $<0.100\text{ mm}$; open circles, $0.10\text{--}0.175\text{ m}$; solid circles, $0.175\text{--}0.30\text{ m}$; open triangles, $0.30\text{--}0.55\text{ m}$; solid triangles, $0.55\text{--}1.0\text{ m}$; open squares, $1.0\text{--}1.75\text{ m}$; solid squares, $>1.75\text{ m}$. The dashed curves are approximate contours of surface-form spacing. Horizontal and vertical tick marks represent three-dimensional configurations; symbols without tick marks represent two-dimensional configurations. (From Southard, 1991.)

be viewed in a three-dimensional graph with nondimensionalized versions of these three variables along the axes.

Figure S58 is a velocity–period for a sediment size of about 0.1 mm , with axes expressed as 10°C -equivalent maximum oscillatory velocity and oscillation period. For a wide range of oscillatory velocities above the threshold for sediment movement, ripples are the equilibrium surface form. At even higher oscillatory velocities, the ripples are washed out to a planar transport surface. Over most of the ripple field, ripple spacing increases upward to the right, with increasing velocity and period. The spacing of the ripples scales closely with the orbital diameter (the distance traversed by water particles in the course of a single oscillation). For relatively small velocities and periods the ripples are geometrically regular and straight-crested, but with increasing velocity and period there is a well-defined change to less regular geometry. The graph for coarser sand sizes is similar, but the transition to plane-bed transport is at a higher velocity, and the ripples are regular and straight-crested over the entire existence field.

The nature of oscillation ripples formed by more complex multidirectional oscillatory flows is poorly understood. In the case of what are called ladderback ripples, for which two different sets of oscillation ripples are superimposed, it is generally assumed that a second set of ripples become superimposed on an preexisting set without, however, completely obliterating the earlier set. Geometrically complex small-scale ripples showing mixtures of hexagonal and even

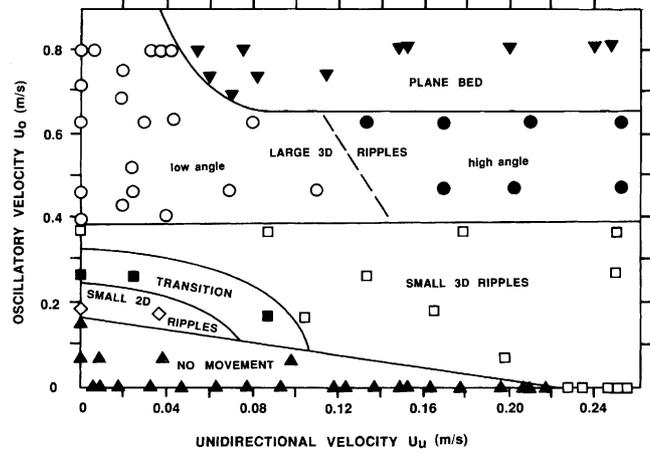

Figure S59 Relationships among combined-flow surface forms in a plot of nondimensional maximum oscillatory flow speed U_{o10} versus nondimensional maximum unidirectional flow speed U_{u10} , expressed as equivalent values at a reference temperature of 10°C , for particle sizes of around 0.1 mm and oscillation periods of around 9.5 second . Solid circles, combined-flow ripples; open circles, plane-bed sediment movement (for large U_{o10}), no sediment movement (for small U_{o10}). Data are from various sources. (From Arnott and Southard, 1990.)

pentagonal shapes might be generated by multidirectional oscillatory flow, inasmuch as normal-to-crest profiles are close to being symmetrical, but observational data are not available to confirm such a view. Hummocky forms with rounded crests interspersed with swales, in a seemingly random pattern on lateral scales of up to a meter, are known from bedding planes in ancient shallow-marine deposits. It is not clear whether such forms are generated by strong bidirectional or strong multidirectional oscillatory flows, because of the difficulties of observation in modern field and laboratory flow environments under such conditions.

Combined-flow forms

Combined flows are common in natural flow environments, especially shallow marine and lacustrine settings, where strong winds associated with storms cause both unidirectional and oscillatory water motions. The range of such combined flows is enormous, and it should be expected that the surface forms generated by those flows should accordingly show a wide range of scales and geometries.

Much less is known about the nature of combined-flow surface forms than about those generated by unidirectional and oscillatory flows. There have been few recent field studies; that by Amos *et al.* (1988) is representative of the problems and possibilities of making such observations in shallow marine settings. Moreover, there have been few laboratory studies, and even an ambitious laboratory program can hope to cover only a narrow subset of combined-flow surface forms there have been few laboratory studies. Among the few recent studies, Arnott and Southard (1990) made a systematic survey of combined-flow surface features in a large combined-flow duct but for only a single oscillation period, a single sediment size, and a wide range of oscillatory flow velocities but only a narrow range of unidirectional flow velocities (Figure S59).

It is clear from studies of combined-flow surface forms up to now that only a small unidirectional flow component is needed to make the forms strongly asymmetrical. The consequence is that combined-flow forms, at least in fine sands, look superficially like current ripples. A broad range of larger-scale combined-flow forms generated by stronger oscillatory flows with a subordinate unidirectional component look superficially like small unidirectional-flow dunes, although the sediment size is much finer than can support unidirectional-flow dunes. This may be the main reason why reports of combined-flow surface forms preserved in the sedimentary record have been so much scarcer than their importance would seem to imply. Much more observation is needed before even a first-order picture of the range of combined-flow forms is available.

Subaerial surface forms

When the wind blows over a surface of loose sediment at a speed sufficient to move the particles, the surface is molded into a variety of configurations with characteristic scale and geometry. The smallest-scale features are called ripples, and larger-scale features are called dunes, although with much variation in terminology. Modern studies of subaerial surface forms date from the classic field and laboratory work by Bagnold (1941). For recent summaries of the nature, classification, and dynamics of subaerial surface forms, see Greeley and Iversen (1985), Pye and Tsoar (1990), Nickling (1994), and Lancaster (1994).

It is generally agreed that there is a fundamental dynamical distinction between subaerial ripples and dunes. This is reflected in a well-defined break or gap in the range of sizes of the two kinds of features. It is less clear whether there are natural breaks in the range of dune sizes. Wilson (1972) reported a clear break between two classes of large-scale subaerial surface forms, which he called dunes and draa, but later workers (e.g., Ellwood *et al.*, 1975) have been more inclined to believe that there is a smooth variation in large-scale eolian forms, without any natural breaks.

A complicating factor in classifying subaerial surface forms and understanding their dynamics is that in most settings wind speed and direction are at least to some degree variable. This is less of a problem for ripples than for dunes, however, because typical small-scale ripples respond to sand-moving winds on timescales of minutes to hours, whereas dunes, with their far greater bulk relative to rates of sand transport, require much longer times to become equilibrated to a steady wind.

Another reason behind controversy over the dynamics and classification of subaerial surface forms is that nature tends to give us biased realizations of the phenomena. Fractionation of particle size along transport paths causes particle-size distributions to evolve in particular ways, and this has a tendency to obscure the picture of dynamics and classification by making it difficult to obtain an even view of the process and features involved.

Comprehensive data on equilibrium subaerial forms generated by steady winds, of the kind that have been obtained for subaqueous forms in laboratory water channels and tanks, would constitute a natural basis for evaluating the fundamental nature of subaerial forms. Only for small-scale subaerial ripples, however, have studies been carried out in large wind tunnels in which not only wind strength but also particle size and sorting are varied over a wide and unbiased

range. Such studies are virtually impossible for large-scale subaerial features.

The dynamics of subaerial surface forms and subaqueous surface forms should be expected to be at least in part fundamentally different, because of the great difference in the ratio of sediment density to fluid density in the two cases. In transport of mineral-density particles by water, the density ratio is less than about three, except for local and uncommon concentrations of higher-density mineral particles, whereas the density ratio in most eolian settings is of the order of 10^3 . In consequence, particle transport by wind is much less affected by fluid turbulence; the sediment particles, once set into motion, tend to follow trajectories, usually described as ballistic, that are governed much more by particle inertia than by fluid turbulence. It should also be expected, however, that this difference is much more significant for subaerial ripples than for subaerial dunes. The scale of ripples is of the same order as the typical excursion lengths of the transported particles, whereas dunes are far larger. The dynamics of wind ripples are in some way governed by instabilities associated with the nature and scale of particle excursions, whereas the dynamics of dunes is in some way related to instabilities associated with larger-scale streamwise variations in sediment transport rate, in ways that are likely to be broadly similar to subaqueous dunes.

Mineral-density particles in water and in air, the two cases of density ratio that are important on Earth, represent only two points along the spectrum of density ratios. It seems likely to many if not most astronomers that there are planets in other solar systems with surface conditions represented by a far larger range of sediment-to-fluid density ratios. Very little is known about such cases; in particular, the question arises: do the surface forms we know as current ripples and wind ripples grade continuously from one to the other, or is there a break in existence in some intermediate range? For some comments on ripples on other planets, see Greeley and Iversen (1985).

Subaerial ripples

Subaerial ripples are small-scale features that are oriented transverse to the wind. They range in spacing from less than a centimeter to as much as a few tens of meters, and in height from a few millimeters to as much as a meter. The most common ripples range in spacing from a few centimeters to between ten and fifteen centimeters. These are variously called impact ripples or ballistic ripples, which are genetic terms that reflect commonly held views on their dynamics (see below). Some investigators refer to these simply as "normal" ripples. They are strikingly regular in their geometry, with long, straight crests and troughs that commonly extend for some meters before either ending or bifurcating. Crest height and trough depth vary little in the transverse direction. In vertical profile the ripples are noticeably asymmetric, with upwind (stoss) slopes of $8\text{--}10^\circ$ and downwind (lee) slopes of $20\text{--}30^\circ$. For an especially illuminating field study of wind ripples, see Sharp (1963).

From a number of field and laboratory studies, summarized by Pye and Tsoar (1990) and Lancaster (1994), it is known that ripple size increases with both wind velocity and particle size. There is some evidence as well that ripple size increases as the sorting of the sediment decreases (i.e., the spread of sizes around the mean increases).

Many theories have been proposed for the dynamics of wind ripples, and there is as yet no general agreement. The classical viewpoint, dating from the pioneering work of Bagnold (1941), is that the ripple spacing is governed by the saltation distance of the moving particles. This view has been challenged by Sharp (1963) and more recently by Anderson (1987).

Larger subaerial ripples in coarser sediment, well into the pebble size range (>2 mm), although less common than the smaller ripples in sands, are well-known. These have variously been called granule ripples or megaripples. Sediment size distributions are usually bimodal, and the ripples tend to be less regular in the crest pattern. There is disagreement about whether these are dynamically distinct from the more common smaller ripples. Also reported in the literature are small-scale but much less regular ripples, variously called fluid drag ripples or aerodynamic ripples, which are formed by strong winds in very fine sand or coarse silt.

When saltating sand particles move across a damp sand surface, as on a beach at low tide during a strong offshore wind that transports sand from coastal dunes onto the beach, some of the particles adhere to the surface and remain there, held by surface tension. They are wetted by capillarity, and in turn capture more saltating particles. In some cases the surface remains approximately planar as it aggrades; in other cases, a pattern of irregularly transverse ridges, called adhesion ripples, develops. Adhesion ripples commonly have spacings of the order of a centimeter and heights of a fraction of a millimeter to a few millimeters. Less regular patterns without any appreciable transverse orientation have been called adhesion warts.

Subaerial dunes

Subaerial dunes are mounds or ridges of sand that are shaped by the wind. In a narrower definition, dunes are independent of surrounding topography; in that respect, dunes are features that develop in broad areas that are underlain by loose sand and are subjected to sand-moving winds. In addition, however, certain features that are commonly termed dunes are accumulations of sand that form to the windward or leeward sides of cliffs, hills, or other topographic features, large and small. One of the most extensive studies of dunes in the broad regions of dunes in subtropical deserts, known as sand seas, is by McKee (1979).

An often bewildering variety of terms have been used to describe or classify dunes. Many of these terms are partly or wholly synonymous, and many have been used only in local areas. This diversity in terminology is in great part a reflection of the great variability in conditions under which dunes form, as noted below. Breed and Grow (1979) provide an extensive correlation among the various classifications schemes.

Dunes vary extremely widely in scale and geometry. This should not come as a surprise, inasmuch as several factors exert important controls: the size, sorting, and thickness of loose sediment available to be formed into dunes; wind speed and its variability; wind direction, and its variability; vegetation; and downwind change in time-mean sediment transport rate, which determines whether the dunes are experiencing net aggradation, net degradation, or a neutral condition. Leaving aside the stabilizing effect of vegetation, it is generally considered that the most important of these are the nature of the wind regime and the thickness of available sediment.

Many classifications of dunes have been proposed. These classifications are of two kinds: morphologic or morphodynamic. A morphologic classification is based solely on observable dune geometry, whereas a morphodynamic classification takes account of assumed characteristics of wind and transport regimes. One of the most common morphodynamic classifications divides dunes into longitudinal, transverse, and oblique with respect to the direction of net sand transport. This classification is not without problems, however, because it is commonly difficult or even impossible to establish the direction of net sand transport, owing to the variability of the wind and the long timescales over which the wind and transport must be averaged.

In some regions with dunes, the sand-moving winds are very consistently from a narrow range of directions, so that there is a simple relationship between the dominant wind and the net sediment transport direction. In other cases, however, the sediment-transporting wind is complexly multidirectional, and the relationship between the wind and the net transport direction is less obvious. In the case of star dunes, the dunes are formed in areas with little or no net transport.

Much of the variability in dune characteristics is a consequence of the effective average thickness of transportable sand in a given area in relation to the potential size of the dunes. For a given dune size, some minimum thickness of sand is necessary to assure full coverage of movable sand even in dune troughs; conversely, for a given thickness of movable sand, there is an upper limit to dune size without "starvation" (i.e., exposure of rigid substrate) in dune troughs.

The effect is especially relevant to variations in geometry of transverse dunes. When only a minimum of movable sand is available, barchans are the typical dune form. Barchans are isolated, crescent-shaped dunes with sharp horns pointing downwind. They have a gentle upwind slope and generally an angle-of-repose downwind slope. With increasing availability of movable sand, the barchans begin to join at the horns, and they eventually form continuous but sinuous and irregular transverse ridges. Eventually even troughs are occupied by movable sand.

Linear dunes, often strikingly regular in their geometry and commonly oriented nearly parallel to what is thought to be the direction of net sand transport, are common in regions of abundant sand supply. Such dunes are especially characteristic of the world's great subtropical deserts. In most such regions, the troughs between the linear dunes are nonetheless starved of sand. In such areas individual linear dunes can be continuous for distances of as great as two hundred kilometers. The origin of these linear dunes continues to be controversial. In one view, they are formed under the influence of helical secondary circulations superimposed on the mean wind in the atmospheric boundary layer. Such circulations are known to exist, but no convincing direct evidence has yet to be adduced that they are instrumental in the generation and maintenance of linear dunes.

Smaller-scale dunes are commonly seen to be superimposed on larger-scale dunes. Dunes with superimposed smaller dunes are termed compound dunes. There is often uncertainty about whether the superimposition represents an equilibrium condition or a manifestation of adjustment of the dunes to changing conditions. In at least some cases it seems clear that the former is the case.

The fundamental question as to why dunes form is an enduring one. Two approaches, which are not fundamentally

different, are possible. In one approach, which is relevant to conditions of minimum sand supply, one can think in terms of the conditions needed to localize a patch of sand moving over a rigid substrate and then cause the patch to grow into one or a series of dunes. This approach was first developed systematically by Bagnold (1941). In the other approach, one can assume a thick continuous bed of sand and think in terms of how the sand-moving wind generates one or another dune type. In the latter approach, which is the one usually taken in the case of subaqueous surface forms, the problem of the dynamics and classification of dunes might be considered from the perspective of a "thought experiment" in which a full bed of sand is subjected to a wide range of wind conditions but also a gradually shrinking thickness of the sand layer, to reveal changes as sand starvation makes its appearance and increases in importance. For subaerial dunes, of course, the feasibility of an actual experiment of that kind is extremely limited, owing to the large scales involved.

SURFACE TEXTURES

Introduction

The advent of the scanning electron microscope (SEM) brought a new tool to the sedimentologists armory. In particular, it allows images to be obtained at a variety of magnifications (10–10 k times) together with a depth of field unobtainable with a light microscope, especially at high magnifications. Despite the high cost and considerable complexity of the instruments introduced in the late 1960s a number of workers exploited the relative ease of geological sample preparation for the SEM. It was, for example, no longer necessary to produce surface replicas, necessary with transmission electron microscope techniques, as the surface itself was imaged. Subsequent advances in ease of use of the SEM has, in effect, meant that bench top instruments can now be used as “super microscopes” for a wide range of sedimentological purposes and that even casual users can obtain a high degree of proficiency at a basic level.

One early geological use of the SEM, by Krinsley and co-workers, was to view surface textures of individual sand-size grains as an extension of optical microscopic examination of detrital grains. An outline description of the SEM itself and a recent review of surface textures together with a general overview of the use of the SEM in glacial geology is given in Whalley (1996) and a wide-ranging review of the technique and associated methods can be found in various papers in Marshall (1987) and the more general books on the use of SEM in sediments by Smart and Tovey (1981, 1982).

Principles of the technique

Large energy inputs into transportive sedimentary systems usually produce attrition of particles as well as sorting. It is the small scale, inter-particle, attrition, which produces changes in shape and rounding, as well as impacts of surfaces, that are revealed by SEM examination. Thus, the fundamental concept behind the examination of surface textures is that detrital grains, undergoing transport, will abrade and that the core (or original) grain will reflect the process of sediment movement by the development of a distinctive surface texture. This texture is in addition to, but associated with, any changes produced in the grain rounding or shape modification that may occur. Chemical action on grain surfaces may be found under suitable environments and surface textures are also produced in as a result of such modifications. For many years it was recognized that “frosting” was a typical texture seen on detrital grains from both present-day deserts as well as grains from the geological record. Krinsley’s exploitation of the SEM was to show that a range of distinctive microscale features could be identified from various sedimentological environments (e.g., Krinsley and Marshall (1987) for an overview). The technique thus associates specific surface textures (often a range of features) on the surfaces of grains with corresponding

sedimentological events, thereby giving clues as to the sediment’s history. Quartz, most usually sand-sized, grains are generally used for identification of surface textures because of their ubiquity, although garnets or heavy minerals (e.g., Stieglitz, 1969) have also been used. There are however dangers in using surface textures as a unique method of sediment fingerprinting.

Sampling and preparation of material

Cost, both “beam time” and subsequent viewing time, is a problem with SEM examination. As SEM surface texture examination is an individual rather than a bulk technique, the representativeness of a sample is, or may be, problematical. Even a minimum of 30 grains can be expensive if multiple samples are to be examined. As the technique is largely dependent upon visual characterization (see below) a bias may be introduced so blind sampling and sediment preparation is recommended. Indeed, to be as objective as possible, the person viewing grains and identifying the textures should not be the person who needs the data or interprets the findings. Such precautions may not be necessary if the technique is used as check or as an adjunct to other methods of characterization.

Grains for mounting should be cleaned by gentle washing, adhering material being removed with hydrochloric acid and stannous chloride. Ultrasonic treatment has been discouraged by some workers although it may be useful unless grains are very delicate. Sieving should be avoided at any stage of the sampling/selection process as this may introduce new surface textures. It is usual to examine grains in the 250–1000 μm range. At the simplest level, preparation involves sticking grains to an SEM specimen stub and grains of this size can be picked up by micro-forceps under a binocular microscope and arranged on the specimen stub. This allows easy identification of quartz (or other mineral type) but may introduce a sampling bias. Under the SEM it may not be possible to identify the mineralogy without the use of an elemental detector (usually an energy-dispersive spectrometer, EDS/EDX) which, although useful, is still an expensive ancillary item for desk-top SEMs. The specimen stub surface is best coated with double-stick tape as grains placed carefully on this usually adhere well. Coating by gold (sputtering) or carbon (evaporation) provides good electrical continuity over the surface, poor contact gives charging under the electron beam which degrades the image. Grains may be placed on stubs in rows or in a spiral to allow subsequent “revisiting”. Typically, rather more than 30 grains should be placed to allow for poor photography, etc at the observation stage. Sprinkling is an alternative way of providing many grains for examination but experience shows this frequently gives poor electrical connection for larger grains and less easy identification due to overlapping. However, sprinkling may be the only way to mount small grains (<250 μm). An electronic spatula is one way to distribute grains carefully and a gentle jet of clean dry air both removes surplus grains and improves adhesion.

Observations under the SEM

The normal (secondary/emitted) mode of SEM observation is generally employed for visual characterization. There may be advantages in cathodo-luminescence (Smart and Tovey, 1981) and back-scattered images for certain specialized needs but are rarely necessary. The traditional way of observing has

been to identify a row of grains and move progressively along, identifying grains and recording on a lab sheet, and to take a low power photograph of each with one or more higher power (200–1000 \times) photographs of each grain and its surface textures. Because of the expense and/or pressure on beam time, photographs are best examined for subsequent feature recognition rather than when observing by SEM. A certain amount of experience is necessary to identify useful features and this tends to slow the direct examination process. Conventional photography may take a minute or more to obtain an image. With the advent of quality video photography it has become much easier to take many images, and at a variety of scales, so it is most convenient to carry out all the detailed examination “off-line”. This reduces the cost of both beam time and the time needed to perform conventional photography. Identification of grains on lab sheets is important as it may be necessary to revisit grains to obtain quality photography for publication purposes.

Identification of textures

That it should be feasible to differentiate between the basic environments of eolian, beach, fluvial attrition, etc. is perhaps remarkable. However, the early experiments did show that grains from an undisputed, single component provenance examined by SEM did provide unique and different textures. A “surface texture” is often identified by a suite of microfeatures and early papers listed a few of these components and showed representative micrographs. To identify provenance therefore, grain textures are identified from photographs of sample grains which are then compared with catalogued images. The “SEM atlas” of Krinsley and Doornkamp (1973) is still widely used for this purpose. A few example illustrations are given in this article. There has been discussion about the degree to which interpretation can be made. Care must be taken to avoid over-interpretation, especially where grains have undergone multiple transport cycles. Further discussion on this can be found in Whalley (1996).

An apparently more quantitative method than texture comparison was subsequently evolved whereby the individual features or texture components were recorded and then

compared with lists of features categorized from known environments. These lists were built up from both original and previously published papers. The number of texture components may vary from paper to paper but percentages/histograms or presence/absence have been used to provide assessment of a suite of textures (Bull and Culver, 1979). The paper by Higgs (1979) is useful as it provides both a semi-quantitative assessment and a selection of micrographs. It should be noted that the range of environments which can be identified uniquely is somewhat limited, although various authors have tried to extend the possibilities. Some of these possibilities are mentioned below (see also Whalley, 1996).

Sedimentological information about environments is imprinted upon the *tabula rasa* of an original grain. This is easily appreciated when grains are freshly weathered but it is less easy to identify environments unambiguously if grains are part of a multi-stage cycle. Further, it should be noted that many of the features or texture components are not independent. For example, a grain released from a rock mass by weathering or by impact, such as a block falling on talus, both produce sharp edges and corners, stepped and rippled surfaces (“Wallner lines”) as a direct product of brittle fracture (see Gallagher, 1987, for a detailed discussion). These texture suites are typical of mechanically-weathered sediments but also of some glacial sediments. Thus, although there has been considerable energy involved in the creation of new surfaces, the surface texture is no different. This has produced some problems in the recognition of a truly “glacial” surface texture. Although modified grain edges, gouges and chattermarks may be found and which may be the result of true subglacial action, their significance has been debated. Orr and Folk (1983) suggested that chattermarks are not necessarily environmentally controlled, rather that the visibility of chattermarks trails is related to mineralogy and weathering. It is probable that there be several ways to produce such features.

Modifications to an original grain surfaces are of two basic kinds; mechanical and chemical. As well as the complete fracture through a grain, the former also relates to modification of surfaces or edges by impacting, usually spinning, grains in a fluid medium. Edges and corners are abraded first because spinning grains catch each other (Figure S60). This action also

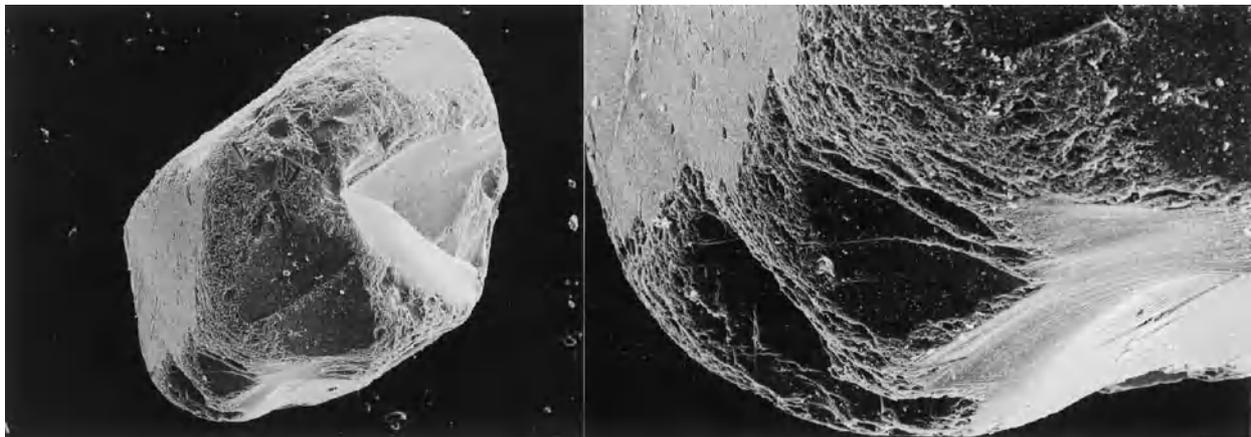

Figure S60 (A) A grain of crushed Brazilian quartz from a sample which has been abraded in a closed air jet system for 4 hours. Picture width = 500 μm . (B) Detail of (A) showing the abrasion of the edge and corners although the main faces are almost devoid of any impact textures. Picture width = 230 μm .

produces a gradual modification in grain angularity to produce more rounded grains. Thus, the basic shape may also be modified. Surfaces, being less exposed to spinning grain protuberances, are less prone to modification than edges. In experiments of rounding of sand grains in eolian environments it has been shown (Whalley *et al.*, 1982) that textures are of mechanical formation even though they appear to be similar to some textures resulting from chemical action.

Chemical action on grains is usually found in the form of surface etching, or as silica re-precipitation; some crystallographic orientations are particularly susceptible to etching. The typical forms are varieties of etching and diagenetic features (Krinsley and Doornkamp, 1973). Crystallographic orientation with respect to etched surfaces may also play a part in determining the size and prominence of etching and silica re-deposition. Weathering on mineral grains has been used as a means of dating deposits. For example, Black and Dudas (1987) used a method of estimating surface weathering of soils of glacial origin in Alberta, although others have found no clear association between post-depositional diagenesis and time. It would appear that there needs to be further research in elucidating the actual formative mechanisms for chemical as well as mechanical surface texture formation.

It should be noted that identification of these surface textures, both as individual components and suites, is ultimately the result of a pattern matching processes in the brain. This is a surprisingly effective and discriminating process but is very difficult to make quantitative. Only the feature counting method allows for some quantification but it too is applied after the pattern recognition process has been accomplished and is still subject to vagaries of feature identification. Categories may overlap or result from differences in crystallographic orientation or of applied stress field. Only one published experiment (Culver *et al.*, 1983), using the feature counting method, shows a measure of the operator variance of the surface texture method. It may be significant however that (from unpublished data) five experienced users of SEM texture analysis, when given a set of micrographs "blind", correctly and uniformly identified the provenance/transport history of six samples in less than five minutes. The conclusion suggests that using the brain as a classifier may work at least as well as lengthy and tedious feature counting methods.

Particle form: surface texture, shape, angularity, and roundness

Traditionally, "size" is measured and interpreted as a bulk attribute whereas components of a particle's "form" are analyzed individually and then aggregated. The components of form F (effectively in 2 dimensions, the observation plane, if the sphericity is ignored) can, following Whalley (1972), be related by:

$$F = f(\text{sh}, \text{sp}, \text{a}, \text{r}, \text{t})$$

Where sh = shape, sp = sphericity, a = angularity, r = roundness, and t = surface texture. These inter-related concepts are associated with the attrition of grains undergoing transport processes. Shape/sphericity, angularity and roundness are numerically ascribed but the chart comparisons for angularity-roundness are of only ordinal measure. True quantitative measures, such as Fourier and fractal methods,

have been employed by perimeter quantification (see Orford and Whalley, 1991, for review and papers in Marshall, 1987). However, there are still very few published studies which incorporate quantitative assessment of form components together with surface texture analysis. Automatic image analysis methods exist for some simple shapes but these have not, to date, been used with the rather complex surface textures found on the three dimensions of quartz grains. However, it is possible that in the future neural networks and high powered computing may produce some degree of feature extraction which can aid quantification and improve objectivity as well as speed analysis.

Uses and limitations of the technique

After the first flush of papers using SEM to examine surface textures there were some sceptics about the viability of the method. This was less a failure of the technique but rather that it was sometimes used to "over-interpret" samples. Subsequently, despite recognition of the technique's utility, it has not developed into a *necessary* form of sediment analysis. However, it is a useful adjunct, in association with techniques such as size analysis, to assist identification of sedimentary environments. It can be especially useful where there are only a few grains available such as from an ice core or wind-blown collector or in forensic sedimentology.

The following sections summarize the main "texture-environments" which have been used with SEM surface texture analysis and add to comments made above. Photomicrographs are provided to show some of the ideal textures. However, published books and papers must be used to show the range of textures for any analyzes. The main works which show good examples of textures and the use of the technique include: Krinsley and Doornkamp (1973), Marshall (1987), Whalley (1978, 1996), a bibliography of older references is given in Bull *et al.* (1986).

Weathered and glacial textures

As noted above, "weathered" (i.e., untransported) grains have a similar, if not identical, surface texture to certain grains of glacial provenance. In particular, grains transported on a glacier surface as well as perhaps some englacially-transported grains have not been subjected to any form of modification. Thus, it is not possible to use surface textures to differentiate these environments without considerable care. It is not possible to say that a texture is definitively glacial without other, supporting, evidence. However, it has been possible to show that certain modifications to the angular characteristics can be given by subglacial grinding or fluvio-glacial action. Mahaney (1995) has suggested that glacial grains can be used as indicators of age and ice sheet characteristics. The transport mode by glaciers must be clearly differentiated: supraglacial transport is unlikely to produce any textures which are different from weathered grains or grus, subglacial action may produce distinctive abrasion of some edges and faces.

Glacio-marine deposits

It has been suggested that glacio-marine environments can be identified by SEM texture evaluation. However, this has usually necessitated the identification of "glacial" textures.

Examination of micrographs in these papers does not equivocally support a glacial transportive environment.

Periglacial environments and possible relative dating of deposits

SEM surface textures have been used to help unravel the complexities of periglacial environments but the difficulty of distinguishing between “weathered” and “glacial” environments applies here too. If left long enough, usually in an alkaline environment, even quartz grains weather. This can be related to the formation of diagenetic features on grain surfaces. It is possible that grains in a near-surface environment (e.g., moraine ridges) can produce differences of weathering textures which allow relative ages to be ascribed to the sampled features.

Eolian processes

It is generally believed that eolian grains are distinctive and have characteristic surface textures (Figure S61). Various stages in the rounding process have been identified and it is probable that silt-sized particles can be produced as rounding took place. This latter characteristic has also been used to assist in the interpretation and characterization of loess deposits. Silt, especially as loess (Figure S62), could be useful in the identification of terrigenous sediments in, for example, marine deposits. Early investigators suggested that features known as “upturned plates” were not only characteristic but indicative of the velocity of the transporting wind. This has not however, been followed up as the rotational velocity of spinning grains appears to be the significant factor involved (Whalley *et al.*, 1982).

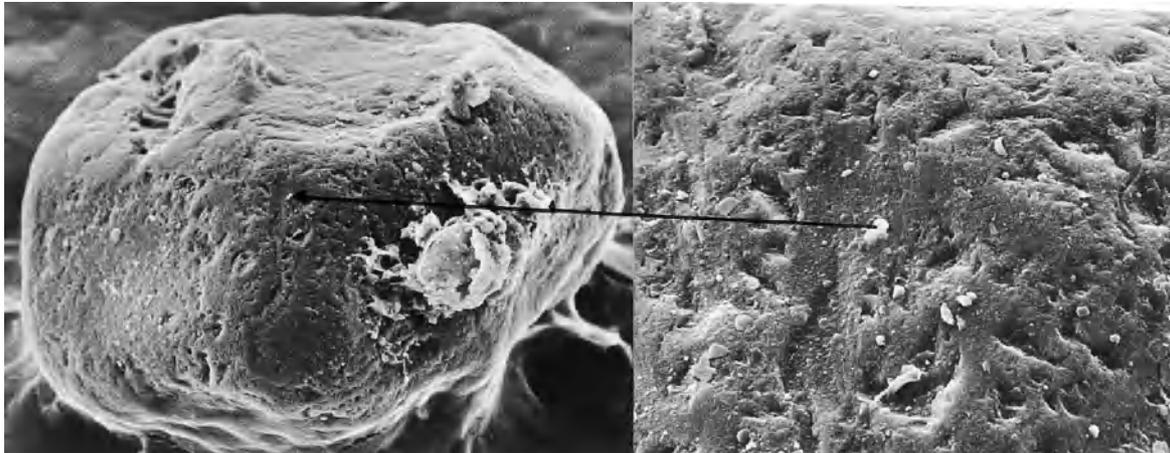

Figure S61 (A) Present day eolian grain from Bahrain dune showing the distinctive rounded outline and smoothed edges and corners while (cf. Figure S60) the faces also show impact features. Picture width = 250 μm . (B) Detail showing a typical eolian texture with micro-scale impact features. Picture width = 45 μm .

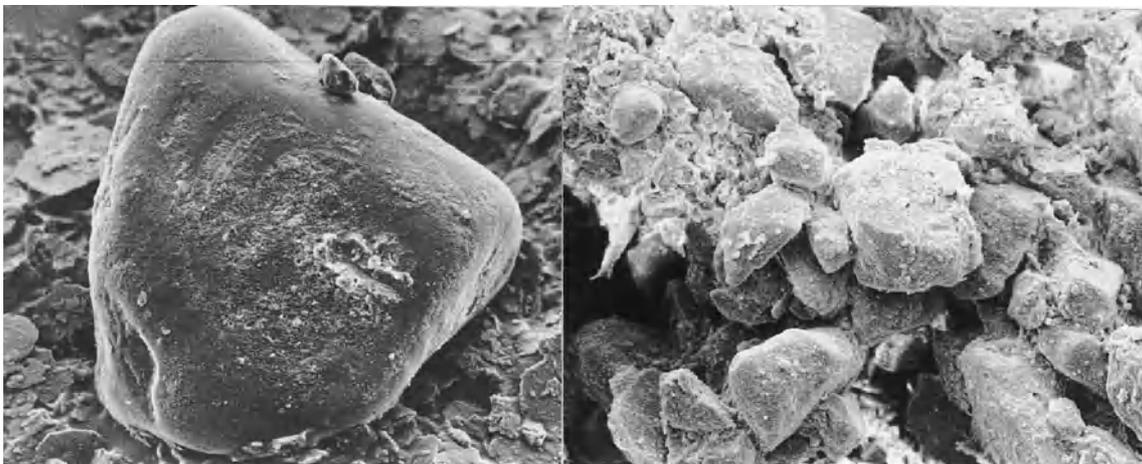

Figure S62 (A) A sand-sized grain from a loessic deposit (East Kent, England) with rounded outline but some surface precipitation which smooths out some of the surface detail. Picture width = 320 μm . (B) A more general view of some of the same loess deposit showing a variety of angular grain outlines in the fine sand fraction as well as silt-sized particles. This is a fracture surface of a small piece of the loess. Picture width = 200 μm .

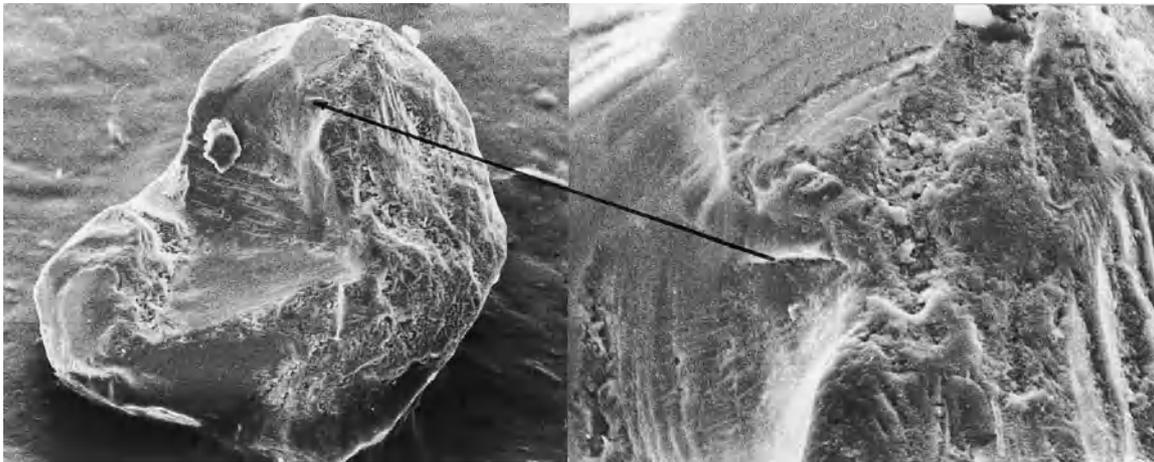

Figure S63 (A) Present day quartz material (Ben Ledi, Scotland, derived from gneiss) showing both fracture characteristics as well as some modification of the edges and corners which might be due to eolian activity. This is a good illustration of how difficult it can be to discern the mode of origin of a grain/deposit unless something is known about the environmental history before interpretation. Picture width = 220 μm . (B) A detail of Figure S63(A) showing the conchoidal fracture and parallel arcuate lines which are typical of brittle fracture. The edges and corner however do show that there has been some modification of the textures and that they are akin to eolian textures (Figure S60). Picture width = 50 μm .

Beach processes

There are distinctive surface textures found on beach sediments with small impact versus resulting from the highly turbulent and energetic processes of breaking waves on beaches. Fractured grains, with the fractures cutting across the rounded grain profile and texture, are common and distinctive.

Volcano-clastic material

Tephra particles identified by SEM are distinctive (Marshall, 1987) and have been found frequently in glacial deposits and peats and have been used, together with chemical composition, to mark horizons.

Summary

With relatively inexpensive SEMs and simplicity of use, taking micrographs of quartz (and heavy minerals, etc.) for surface texture analysis is a useful adjunct to conventional sedimentological techniques. How and how intensively it is used, depends upon the ultimate objective. Only rarely will the technique provide unequivocal evidence of a transport environment but it is certainly useful in identifying problem cases and assisting with interpretations. It seems clear that there is still room for experimentation to define mechanisms more closely and perhaps to elucidate the energetics of sedimentological transport processes and temporal factors affecting diagenesis.

SWASH AND BACKWASH, SWASH MARKS

The terms swash and backwash collectively refer to the oscillatory motion of the shoreline due to the continuous arrival of waves. They also describe the associated thin lens of water behind the moving shoreline that periodically covers and uncovers the beach face. Some researchers use the term swash to describe the complete cycle of shoreline oscillation (i.e., both landward and seaward motion), whereas others use the term swash to describe the landward motion of the shoreline and use the term backwash to describe its seaward motion. Other terms synonymous with swash and backwash are wave-runup and -rundown, respectively.

Most of the early work relating to swash was carried out by applied mathematicians with an interest in nearshore oceanography. Benchmark papers from this discipline are those by Carrier and Greenspan (1958) for the case of non-breaking waves, and Shen and Meyer (1963) for the case of breaking waves. Coastal engineers principally interested in wave overtopping of structures have also contributed extensively to our knowledge, with the paper by Battjes (1971) providing the foundation for much of the engineering literature. Prior to the mid 1970s comprehensive field measurements of swash and backwash are absent from the literature. Since that time the number of publications has increased rapidly. Currently swash-backwash hydrodynamics and swash-zone morphodynamics are major research topics in the fields of coastal-oceanography and coastal-geomorphology/sedimentology (see Komar, 1998 and Hughes and Turner, 1999 for recent reviews).

Process description

The nature of swash and backwash varies between two end-member beach types: steeply-sloped *reflective beaches* and gently-sloped *dissipative beaches*. The nomenclature relates to the predominance of reflection or dissipation of energy in the wind- and swell-wave bands of the nearshore wave spectrum.

On *steeply-sloped beaches* the swash-energy spectrum (calculated from measured time series of shoreline position or elevation) typically displays a narrow peak somewhere between 0.05 Hz and 0.2 Hz. This frequency of shoreline motion is related to the continuous arrival of wind- and swell-waves at the beach face, either as surging or plunging breakers. There is often an additional peak in the swash spectrum at a frequency that is half that of the incident wind- or swell-wave frequency, and arises due to the reflective nature of steeply-sloped beaches. The interference between incident and reflected waves produces a standing wave field in the nearshore zone, which can influence the swash-backwash process. Possible standing wave types are leaky modes whose crests are parallel to the shoreline and edge wave modes whose crests are normal to the shoreline. The latter results in a rhythmic variation of the maximum swash limit along the beach.

On *gently-sloped beaches* a significant amount of the incident wave energy is dissipated via bed friction and turbulent wave-breaking across a broad surf zone. Consequently the shoreline motion associated with the arrival of each wind- or swell-wave is often negligible, and the swash is said to be saturated in this frequency band. In contrast with steep beaches, the swash-energy spectrum typically displays a broad-banded peak somewhere between 0.05 Hz and 0.005 Hz (termed the infragravity frequency band) and a logarithmic decrease in energy toward the wind- and swell-wave frequency band. The infragravity shoreline motion dominant on dissipative beaches is associated with long waves that are initially bound to incident wave groups, but subsequently released at the seaward margin of the surf zone. These long waves have such a low steepness that they are reflected by even the gentlest of beach slopes. So despite the strong dissipation of high frequency waves on gently-sloped beaches, standing waves still develop in the nearshore due to the interaction of incident and reflected long waves. Again the standing wave types can be either leaky modes or edge wave modes.

Several aspects of swash-backwash behavior have been quantified using the *Iribaren number*, ξ_o ,

$$\xi_o = \frac{\beta}{(H_o/L_o)^{0.5}}$$

where β is the beach slope, H and L are the wave height and length, and the subscript o denotes deepwater measurements. ξ_o is effectively the ratio of the beach steepness to wave steepness. Swash-backwash driven by the arrival of wind- and swell-waves on reflective beaches is associated with values of $\xi_o > 1$, and swash-backwash driven by long waves on dissipative beaches is associated with values of $\xi_o \ll 1$. In general both swash frequency and swash height increase with increasing values of ξ_o . The statistical distribution of swash heights on both reflective and dissipative beaches typically follows a Rayleigh distribution.

The dynamic geometry and internal flow field of the swash-backwash lens is reasonably well established for wind- and swell-waves, but less well established for long waves. When a wind- or swell-wave arrives at the beach face it causes a nearly

instantaneous acceleration of the shoreline to its maximum velocity, termed the initial swash velocity. As a result of this impulse the shoreline climbs the beach with a velocity that decreases toward zero at a roughly constant rate. This deceleration is due largely to gravity opposing the motion. Throughout the swash the lens of water travelling behind the shoreline progressively shallows with both time and distance up the beach. When the shoreline velocity reaches zero the shoreline is at its maximum landward displacement, termed the swash limit, and the swash part of the cycle is complete. The shoreline now recedes back down the beach with a velocity that increases at a roughly constant rate due to gravity assisting the motion. The maximum shoreline velocity during the backwash occurs near the completion of the cycle. Both shoreline and internal flow velocities are therefore largest on the lower beach face. Toward the end of the backwash a hydraulic jump may occur on the lower beach face.

The internal flow field within the swash-backwash lens differs from the shoreline motion. At any position on the beach the landward-directed flow during the swash decreases to zero and then reverses direction before the swash limit is reached. As a consequence the duration of landward-directed flow is shorter than seaward-directed flow. This asymmetry in flow duration is most pronounced on the lower beach face and decreases toward the swash limit. In order to sustain a seaward-sloping beach face with this type of flow asymmetry, the relationship between the sediment transport flux and the flow field cannot be straightforward.

Swash marks and swash-related internal structures

The most widely recognized surface form in the swash zone is the upper-stage plane bed, which is consistent with the near-critical to super-critical flow regime that is characteristic of both swash and backwash. Other bed features observed include parting lineations, rolling-grain ripples, rhomboid ripples, antidunes, and swash marks.

Swash marks are typically low (<5 mm high), narrow (<20 mm wide) ridges of sand that mark the landward swash limit. In plan-form they are convex toward the landward direction, widely spaced on gentle slopes and more closely spaced on steep slopes. Two explanations have been proposed. The first is favored on fine-sand beaches and involves sediment flotation. When the bed sediment is not completely wetted (e.g., landward of the groundwater effluent zone) low density or platy grains (e.g., mica flakes and shell detritus) can be supported by surface tension on the narrow wedge of water at the leading edge of the swash lens. At the swash limit, this thin wedge of water seeps into the beach and deposits the floating grains in the form of a swash mark (Emery and Gale, 1951). The second explanation is favored for swash marks on steep, medium-coarse-sand beaches. The reverse grading observed within these swash marks (sediment fines with depth and also in the seaward direction) suggests that they are the result of a narrow, highly concentrated grain flow driven by the leading edge of the swash (Sallenger, 1981).

Because of the subtle relief of bed features in the swash zone the preservation potential of related internal stratification is low. The most likely internal structures to be preserved are those relating to beach-slope changes resulting from: (1) storm erosion and post-storm recovery; (2) profile cut-and-fill due to tidal translation of the swash zone; or (3) migration of beach cusps. Beach deposits are characterized by seaward dipping,

continuous planar to curved parallel laminae, often with alternating fine and coarse grained laminae. Coarsening upward sequences of beach laminae occur in relation to beach cusps. Reverse grading within individual beach laminae is ubiquitous, and results from dispersive pressure within the highly-concentrated bed-load transport layer that is characteristic of swash and backwash flows (see *Grain flow; Physics of Sediment Transport: the contributions of R.A. Bagnold*, for dispersive pressure). There is currently no proposed methodology for quantifying paleohydraulic conditions from ancient swash-backwash deposits.

SYNERESIS

Syneresis [*aka* synaeresis] is the process first identified in colloidal solutions whereby spontaneous contraction of a gel results in the expulsion of liquid. It is an intensively researched and industrially important transformation that takes place during the maturation of substances as diverse as polymers, cement paste and foams. An everyday example is provided by the gel formed by the acidification of milk that, during subsequent syneresis, expels fluid (whey) as the curd contracts to <30 percent of its original volume. In earth science it has been proposed that an analogous process takes place when recently-deposited clay-rich sediment comes into contact with a saline solution. As a result of syneresis, water is expelled from the sediment, and this causes the formation of shrinkage cracks on the sediment surface. In some instances these cracks may later be filled with sand or silt, and preserved on the base of the overlying bed, as in the case of desiccation cracks.

There are many published descriptions from the geological record of sand-filled cracks which have been interpreted as syneresis structures. These structures, which are also referred to as “subaqueous shrinkage cracks”, are inferred to have formed at, or near, the sediment–water interface. However, in all of these cases there is a lack of unambiguous evidence to confirm their mode of origin, and in recent years a number of workers have questioned the applicability of the syneresis mechanism in such situations. Likewise, no examples have been reported of syneresis cracks forming at the present day on the sediment–water interface in marine or brackish water environments, although these structures have been reported from sediments in more saline situations such as salt pans.

In recent years it has been proposed that, in suitable mudrocks having a high content of swelling clays (smectites), syneresis may take place at various depths *below* the sediment–water interface, during burial of these sediments. On a small scale this may result in the formation of interstratal dewatering structures, seen as complexes of sand-filled veins which commonly form polygonal patterns in plan view (see *Fluid Escape Structures*), or on a larger scale they may be seen as km-scale stratabound sets of randomly oriented normal faults.

History

Jüngst (1934) was responsible for introducing the syneresis concept into the realm of geological processes. White (1961) later carried out experimental work on clays and proposed that syneresis cracks may be found in sediments, in particular those containing swelling clays (smectites). Application of the syneresis mechanism to sedimentation gained further credence following the experiments of Burst (1965) on the action of strong electrolytes on clays sedimented in fresh water, and syneresis cracks were reported from many different geological settings around the world during the 1965–1985 period (e.g., Picard, 1966). The problem of correctly identifying syneresis cracks (Plummer and Gostin, 1981), which have proved difficult to distinguish from trace fossils, especially in Neoproterozoic rocks, was exemplified by the dispute over the origin of quartz-rich sand- and silt-filled cracks from Middle Devonian lake sediments of NE Scotland. Originally interpreted as syneresis cracks by Donovan and Foster (1967), they were reinterpreted by Astin and Rogers (1991) as being formed during subaerial desiccation, with many of the cracks having nucleated upon gypsum crystals. This disagreement heralded an increasing uncertainty over the reality of the traditional syneresis model as applied to mudrocks at the sediment surface (Pratt, 1998; Tanner, 1998), with the implication that it should be abandoned. At the same time, the importance of seismic shock as a catalyst for promoting a syneresis-like loss of fluid from mudrocks after they had been buried, to form either interconnected sets of sand-filled, interstratal dewatering structures (Pratt, 1998; Tanner, 1998), or basin-scale sets of normal faults (Cartwright and Dewhurst, 1998; Dewhurst *et al.*, 1999), was recognized.

Mode of formation

Syneresis occurs when a subaqueous layer of sediment rich in flocculated clays, especially smectites (swelling clays with a high water content), is brought into contact with a saline solution and spontaneously contracts in volume due to interparticle attraction. This causes the expulsion of water

which had previously occupied the spaces between the randomly organized clay particles, and the resulting isotropic contraction of mud-rich layers in the plane of the bedding at, or close to, the water–sediment interface leads to the formation of shrinkage cracks. These cracks have the potential to be filled with grains of sand and silt, and preserved in the geological record, in much the same way as desiccation or mud cracks (see *Desiccation Structures*).

Following the experiments reported by Burst (1965), the common mode of occurrence of syneresis cracks was thought to be as isolated, lenticular, filled-cracks. The cracks are small in size and restricted to a single mud layer (*cf.* interstratal dewatering cracks). The problem which has inhibited further work on the syneresis mechanism in sediments, is that it has proved impossible to erect criteria to distinguish between fossil sand-filled cracks formed by the passive contraction of a muddy layer due to sudden loss of part of its pore fluid (syneresis), and those resulting from the forced evaporation of the pore fluid (desiccation). The two processes have many features in common: as the tensile stress fields in the muddy layers in each case will be similar, both have the potential to form linked patterns of polygonal cracks. The precise morphologies of the resultant cracks, and of the patterns they make, will be controlled by features such as bed thickness, rheology, and anisotropy and, with one exception, will not be diagnostic of the geological process or setting. The exception is that, as desiccation results in a greater water loss than syneresis, special features such as mud curls may develop and confirm that sub-aerial exposure of the wet mudrock was responsible for their formation. No such positive feature for the recognition of syneresis cracks has been identified, and the first geological examples of such structures, figured by White (1961, his plates 3 and 4), could just as readily be interpreted as desiccation or interstratal shrinkage structures.

The interstratal mode of “syneresis” is thought to be caused by earthquake-induced ground motion which triggers off a combination of syneresis (*s.s.*), liquifaction, and water-escape processes relatively close to the sediment surface (Pratt, 1998). It differs from that thought by Cartwright and Dewhurst (1998) and Dewhurst *et al.* (1999) to be responsible for the development of a km-scale system of polygonal normal faults, in that the latter is inferred to occur by syneresis during compaction, without the mediation of earthquake shaking. The driving force in this case is the three-dimensional contraction of colloidal smectitic gels through interparticle forces in a saline medium, on a major scale.

Summary

It has been proposed that syneresis cracks form in smectite-bearing muds at two different levels in a sedimentary basin: at the sediment–water interface, and in rocks that have already been buried. The processes that occur at each level are also different. That taking place at the sediment surface in a marine environment is true syneresis, due to the spontaneous loss of fluid from a gel in contact with a saline solution; that taking place at depth apparently requires the intervention of seismic activity to act as a triggering mechanism, could also involve compaction-driven expulsion of fluid, and results in sets of interstratal, filled fractures. The nomenclature used to describe the small-scale interstratal cracks formed in this way is a problem. They are not true syneresis cracks and should be referred to by a descriptive, non-genetic, name such as

“interstratal dewatering structures”. To name km-scale fractures as syneresis structures is also misleading: syneresis may be involved in the production of these structures but it is probably not the only process involved.

“True” syneresis cracks formed at the sediment–water interface, if they exist in sedimentary systems apart from highly saline lakes, are impossible to distinguish from other shrinkage cracks, especially desiccation cracks, and there is a strong case for ceasing to use the term in such situations. As its use to describe the other types of fracture or crack is debatable, the term is best abandoned.

TALC

Talc is a 2:1 phyllosilicate with an ideal composition of $\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$. The 2:1 layer structure comprises two tetrahedral sheets of silica tetrahedra bound to one octahedral sheet of edge-linked octahedra. The octahedral sheet in talc is magnesium-rich, trioctahedral, and referred to as brucite-like. The 2:1 talc layer is electrostatically neutral and is bound to other layers by van der Waals forces. A small amount of ionic attraction between the layers may be present and result, in part, from cation substitutions (Giese, 1975). Although most talcs have compositions close to the ideal, substantial amounts of Fe may replace Mg in octahedral sites, minor amounts of Al may replace both Si and Mg in tetrahedral and octahedral sites, respectively, and small amounts of Ni, Mn, Cr, and Ti may substitute into the structure. Traces of Ca, Na, and K may occupy the interlayer site to satisfy any layer charge imbalance. The dioctahedral analog of talc is pyrophyllite, an aluminum-rich, dioctahedral 2:1 phyllosilicate.

Talc is triclinic (1-layer), although many earlier references report that it takes a 2-layer monoclinic form (Bailey, 1980). The mineral is green to white to silvery white, has a specific gravity of 2.58–2.83, and a hardness of 1, making it the softest mineral on the Moh's scale. It has a greasy feel, a pearly luster and is sectile. It often occurs in massive or foliated aggregates, but rare crystals are tabular and show perfect cleavage {001}. Massive talc is referred to as soapstone or steatite. The mineral forms in high-magnesian rocks, such as ultramafics, basic igneous rocks and siliceous dolomites that have been subjected to low grade metamorphism, contact metamorphism, hydrothermal alteration, or weathering (Evans and Guggenheim, 1988). Talc is associated with serpentinization and the transformation of magnesian-rich silicates such as olivine, enstatite, tremolite, and chlorite. Talc is used in the production of ceramics, paint, rubber insecticides, cosmetics, paper, and plastics. Soapstone blocks are used for ornamental materials and carvings.

Talc is not a major component of sediments and sedimentary rocks, but its occurrence is more common and widespread

than previously thought. In modern ocean hydrothermal environments talc forms as a direct precipitate when hot solutions emanating from fissures and vents mix with cold, Mg-rich bottom waters. The main hydrothermal vent field in the Tjornes Fracture Zone (depth of 400 m) north of Iceland consists of about 20 large mounds, chimneys, and spires of anhydrite and talc (Hannington *et al.*, 2001). Sediment coring through talc- and anhydrite-rich sedimentary layers that occur up to 7 m below the mounds revealed pore fluids with temperatures as high as 250°C. Talc also forms as an alteration product of basalts through which these hot fluids flow. Shau and Peacor (1992) studied trioctahedral minerals in DSDP drillhole 504B and found a sequence of hydrothermal alteration products in the basalt as follows: saponite (to a depth of 624 m); mixed-layer corrensite-chlorite + chlorite + corrensite (from 624 m to 965 m); chlorite + talc + mixed-layer talc-saponite (from 725 m to 1076 m). Mineral occurrences were not continuous as they were related to rock permeability and temperature variations. Seafloor hydrothermal activity has also resulted in the formation of talc from the alteration of epiclastic sediments and pumaceous tuffs in the Okinawa Trough (Marumo and Hattori, 1999) and from transformation of detrital clays in the Dead Sea Rift (Sandler *et al.*, 2001). In both these examples mineral assemblages changed with depth because mixing proportions of hydrothermal fluids and seawater resulted in different reaction temperatures. Talc has been observed in sediments and in metalliferous deposits accumulating in the Red Sea, on the Mid-Atlantic Ridge, in the Gulf of California and along the East Pacific Rise. Temperatures of the hot, brine solutions that give rise to the formation of talc on the seafloor are estimated to vary between 200°C and 400°C. Minerals associated with talc formation in these hydrothermal environments include sulfides of copper, iron, and zinc, magnesium-rich clays (e.g., smectite, chlorite, corrensite), anhydrite, sepiolite, and zeolites.

In some older sedimentary rocks talc has been reported to occur as a replacement product. Nesbitt and Prochaska (1998) suggested that dolomite, magnesite, and talc mineralization in the Middle Cambrian carbonate rocks of the southern Canadian Rocky Mountains occurred as warm,

Mg-enriched brines (originating from seawater) circulated through the rock units in the Late Devonian or Early Mississippian. Noack *et al.* (1989) reported that oolitic talc in the Upper Proterozoic rocks of the Congo formed from the transformation of original stevensite (or sepiolite) during diagenesis. Contact metamorphism resulted in the reaction of an assemblage of saponite + quartz + dolomite to produce grain-coating flakes of talc at temperatures estimated to be between 130 and 180 °C in the arkosic rocks of the Triassic Sherwood Sandstone Group in Northern Ireland (McKinley *et al.*, 2001). Talc along with chlorite formed in and near fractures in Cambrian dolostones in the vicinity of Winterboro, Alabama from hydrothermal solutions and metasomatic processes (Blount and Vassiliou, 1980).

Talc forms authigenically in evaporitic sedimentary environments and during burial diagenesis in evaporitic sediments when fluids and pore waters become highly alkaline (pH \geq 9) and concentrated with magnesium. Delicate rosettes and cornflake aggregates of talc in salt beds of the Paradox Formation, Paradox Basin, Utah, indicate an authigenic origin for the mineral (Weaver, 1989, p.413). Droste (1963) studied phyllosilicates in a variety of North American salt deposits and found talc, corrensite, serpentine, and other clays commonly present. Talc also is present in the Permian Zechstein salt deposits of Germany (Braitsch, 1971) and the Silurian evaporite deposits of New York (Bodine and Standaert, 1977), among others. Scrivenor and Sanderson (1982) reported that isolated flakes of talc in Triassic halite deposits in Somerset, England, likely formed from the reaction of dolomite + silica + water during burial diagenesis. In some evaporite deposits, talc may exist within a mixed-layer clay structure, such as talc-saponite or talc-chlorite. Talc in these sedimentary rocks is often associated with other syngenetic and epigenetic Mg-rich phyllosilicates such as saponite, stevensite, corrensite, trioctahedral chlorites, sepiolite, and serpentine, to name but a few.

Talc is found in soils derived from the weathering of ultramafic rocks and rocks containing Mg-rich minerals such as enstatite and hornblende (Nahon and Colin, 1982; Proust, 1982; Zelazny and White, 1989). The mineral may form both by transformation of preexisting silicates and by neof ormation involving congruent dissolution of the parent mineral and subsequent precipitation of talc from solution (Noack *et al.*, 1986). Talc occasionally is present in soils as a minor inherited component.

Finally, talc is present in oceanic surface waters, but it is rarely found as a significant component of modern-day marine sediments (Hathaway, 1979). The mineral has been identified in the suspended load of the Atlantic Ocean, the Caribbean and Mediterranean Seas, and in the Amazon River (Gibbs, 1967; Jacobs and Ewing, 1969; Poppe *et al.*, 1983). It has also been found in small quantities in Upper Pliocene-Holocene marine sediments from the Alboran Basin (Skillbeck and Tribble, 1999), and in beach sands along the coast of the Gulf of Mexico and Florida (Griffin, 1963). Because talc is widely used commercially, especially as a carrier of pesticides in crop dusting, it is suspected that some talc in the suspended load of surface waters derives from anthropogenic dust and industrial effluents. A second important source is likely long-range transport by atmospheric winds and dust storms.

TAPHONOMY: SEDIMENTOLOGICAL IMPLICATIONS OF FOSSIL PRESERVATION

Taphonomy is the study of processes that influence preservation of potential fossils; for general reviews, see Schäfer (1972), Müller (1979), Seilacher *et al.* (1985), Allison and Briggs (1991), Donovan (1991), Kidwell and Behrensmeyer (1993), Martin (1999). This field encompasses two major aspects: *biostratinomy*, the study of processes affecting organism remains or their traces, prior to their final burial, and *fossil diagenesis*, investigation of phenomena affecting potential fossils after burial (Figures T1–T3). Recently, taphonomy has developed, both as a means of assessing bias in the fossil record, and more positively, as a critical tool for paleo-environmental analysis. Taphonomic analyzes compliment sedimentological study and yield critical information on the physico-chemical parameters of ancient environments. Uniformitarianistic assumptions are applicable in taphonomy because the physical and chemical properties of organism skeletons have probably been relatively constant throughout geologic time, despite the nonuniformity imparted by evolution.

Biostratinomy: fossils as sedimentary particles

Disarticulation and rates of burial

Certain fossils, including bivalved shells and, especially, multi-element skeletons, are sensitive indicators of rapid, episodic sediment accumulation. The rate at which organism skeletons disintegrate after death is a function of their delicacy,

environmental energy, temperature, oxygen levels, and residence time on the seafloor.

Articulated, closed bivalve shells indicate burial that was rapid enough to prevent the shells from gaping open at the hinge (Schäfer, 1972). Conversely, abundant “butterflied” (splayed) bivalve shells indicate moderate rates of sedimentation. Hinge ligaments may remain intact for periods of up to months, but will ultimately decay and allow the valves to become disassociated. Brachiopod shells tend to remain closed after death. Closed shells filled with calcite spar, pyrite, or other minerals, as opposed to sediment, indicate pulses of burial that covered the shells while interiors were still occupied by soft parts, preventing infiltration of sediment. Tissues subsequently decayed, leaving a void space within the shells.

Ratios of articulated to disarticulated shells of bivalves or brachiopods may be an important indicator of the extent of time-averaging in a deposit (Kidwell and Bosence, 1991; Brett and Baird, 1993). Deposits containing very high proportions of articulated specimens, will be minimally time-averaged.

Organisms with multielement skeletons, composed of multiple articulated ossicles, e.g., trilobites, crabs, echinoderms, and vertebrates, are only rarely preserved intact (Figure T1). Field and experimental studies indicate that degradation of muscle tissues occurs within hours to days after death, while destruction of collagenous ligaments ensues very rapidly, such that most skeletons are completely disarticulated within days to months (Schäfer, 1972; Donovan, 1991; Plotnick, 1986; Brett *et al.*, 1997). Not all multielement skeletons are equally subject to disarticulation. Starfish and crinoid crown skeletons disintegrate within days of death (Figure T1). Likewise, most arthropods disintegrate very rapidly following death (Schäfer, 1972; Plotnick, 1986), but some barnacles, remain intact for much longer periods. Echinoid tests have interlocking sutures that may remain intact for periods of several years (Figure T1), depending on energy levels, oxygenation, and water temperature (Allison, 1990; Kidwell and Baumiller, 1990). Crinoid columns may disarticulate into more durable increments (pluricolumnals) of approximately equal length because of slight differences in the ligamental articulation at certain joints within the column (Baumiller and Ausich, 1992).

Some beds of intact pelagic fossils, such as fish, squids, or marine reptiles may represent carcasses that settled onto anoxic seafloors (Martill, 1991). Furthermore, Allison’s (1988) calculations demonstrate that larger organism bodies become anoxic microenvironments internally during early phases of decay. Inhibition of scavenging in these environments may prolong the association of skeletal elements and even preserve traces of soft parts (Seilacher *et al.*, 1985). However, even under conditions of anaerobiosis, bacterial decay of ligaments is rapid and the slightest currents will serve to disarray pieces (Allison, 1988), implying that burial is a critical prerequisite to articulated preservation.

Groupings of well-preserved, articulated, multi-element skeletons occur on certain planes that would not otherwise be recognizable as event-beds. Because such skeletons can not be reworked without dissociation, even a single intact specimen of a trilobite, crinoid crown or vertebrate skeleton, provides unambiguous evidence that the enclosing sediment accumulated rapidly and was not subsequently disturbed.

Under extraordinary conditions entire bodies with soft parts may be preserved (see Seilacher *et al.*, 1985). Such conservation Lagerstätten deposits reflect combinations of rapid

Category examples	Conditions with Varying Burial Rate

burial, anoxic sediments and early, bacterially-mediated mineralization.

Life orientations and *in situ* burial

Examples of *in situ* preservation, including trace fossils, are common among burrowing and hard substrate encrusting/endolithic organisms. Some assemblages of well preserved fossils, such as cemented oysters, tube worms, bryozoans, and rooted crinoids are demonstrably *in situ* and mark colonized discontinuity surfaces, such as hardgrounds.

Organisms, preserved in unstable orientations, such as ceratoid corals, or pedically-attached brachiopods preserved in upright position are very unlikely to have rolled into this position accidentally. Such life orientations record episodes of sediment input within low-energy settings.

Brachiopods and clams, preserved in life positions, may provide indicators of sedimentation events. Burrowing bivalves may die within their burrows; however, experimental, and observational studies have shown that, in most cases, when bivalves are stressed, they rise from their burrows (Schäfer, 1972). Thus, large numbers of articulated infaunal shellfish on bedding planes may be associated with depositional events.

Another sensitive indicator is provided by associated, though disarticulated arthropod (e.g., trilobite) molt parts. It is virtually impossible for different portions of the skeleton to be transported any distance and remain associated. Hence, their occurrence proves *in situ* biological activity in low energy environments.

Transport and reorientation

Fossils also provide evidence for reworking and/or transport of skeletons that would otherwise remain unsuspected (Allen, 1992). Articulated fragile fossils, e.g., crinoids or trilobites, are commonly thought to have been buried *in situ* in low energy environments. However, Allison (1986) demonstrated in tumbling barrel experiments that even soft-bodied organisms may be potentially moved considerable distances without disarticulating, providing that this happens very shortly (hours) after their death. Such may apply to articulated aligned skeletons found at the bases of turbidites or storm beds.

Many skeletal elements, including valves of most brachiopods, ostracodes, and clams, and trilobite cephalia and pygidia, have approximately concavo-convex or dish-shapes. Random orientations, including some lateral or edgewise shells, occur primarily in heavily bioturbated sediments or low energy traps.

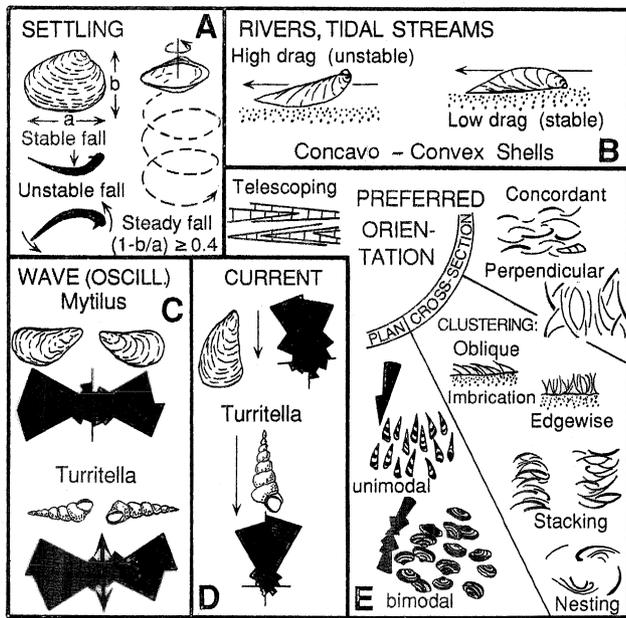

Figure T2 Orientations and fabrics of shells under varying conditions. (A) settling of concavo-convex shells under free fall conditions; (B) re-orientation of concavo-convex shells by currents; (C) bimodal orientations of shells in oscillating currents. (D) alignment of shells in unidirectional currents; rose diagrams show directions of apices of shells; arrows indicate current directions; (E) various types of shell fabrics in plan and cross sectional view. Modified from Allen (1992) and Kidwell and Holland (1991).

Concentrations of shells in localized pockets commonly display convex-downward or lateral-oblique positions along linear features that may be interpreted as subtle scours or gutter casts (Futterer, 1978). Their presence is a significant indicator of storm-generated erosion and redeposition.

Concavo-convex shells most commonly display preferred convex-upward orientations (Figure T2(B)). Even gentle currents will cause shells to flip into a hydrodynamically stable convex upward orientation (Middleton, 1967; Brenchley and Newall, 1970). Thus, the occurrence of abundant shells in convex-upward positions on bedding planes provides evidence for reworking of shells by one or more storm-generated gradient currents.

Beds of preferentially concave-upward shells are not as common. When the shells are allowed to resettle from suspension they will generally settle concave-upward (Figure T2(A)). Such reorientation might occur in areas close to storm wave-base, where gentle storm-generated waves would lift shells off the bottom and allow free-fall back to the substrate. Concave-upward accumulations in rippled, cross bedded sands also may arise from free-fall of shells down the lee sides of migrating bedforms (Brenchley and Newall, 1970).

Preferred orientation of elongate skeletons has been the subject of numerous experimental studies (see Nagle, 1967; Brenchley and Newall, 1970; Reyment, 1980; Kidwell and Bosence, 1991). Elongate particles typically orient themselves selectively in a current. Cylindrical objects may roll perpendicular to the current direction. Elongate objects that do not roll, e.g., rhabdosomes of graptolites, will become oriented parallel

to the current. Similarly, conical shells, including many nautiloid cephalopods, tentaculitids, and gastropods, will become aligned parallel to the current with the apex directed up-current (Figure T2(D)). Hence, depending upon the type of fossil, it may be possible to determine not only the line of current action, but also the direction of propagation.

Bimodal orientations are common and may result from more than one cause. In some instances, the bimodality is size dependent; for example, objects, such as fragments of large nautiloids, may approach a cylindrical shape and roll with the current, whereas smaller cone-shaped shells will orient in a preferred up-current direction. Conversely, conical shells of similar size and shape may show nearly perfect 180° bimodality, aligned parallel to subtle wave ripples (Figure T2(C)). Such fossil evidence indicates oscillatory currents or waves.

Stacks of edgewise or shingled shells (Figure T2(E)) apparently occur where densely packed shells were affected by oscillatory, storm-generated waves and indicate deposition within storm wave-base (Seilacher and Meischner, 1965; Grinnell, 1974). A similar mode of preservation in shell accumulations involves cup and saucer stacking in which concavo-convex shells are bundled together in nested groupings. These, too, seem to reflect the effects of settling and concentration of shells during turbulence events and they are commonly associated with minor sediment grading.

Another, perhaps related, phenomenon involves the cone-in-cone interpenetration of nautiloids observed in some densely packed cephalopod limestones (Figure T2(E)). These appear to represent turbulence effects that first align and then telescope cephalopods; perhaps septa had been weakened somewhat by dissolution or corrosional effects.

Upright ammonoids and nautiloids have been observed in a number of sections in the geologic record. Cephalopod phragmocones will initially settle in a vertical attitude during the flooding of the chambers. There is considerable variation based on shell shape and type, but most shells will settle vertically only up to about 10 m (Raup, 1973); beds with abundant upright ammonoids may thus provide a useful depth indicator. However, in orthoconic nautiloids, ballasting of the apical end of the phragmocone by cameral deposits may also cause shells to sink vertically and embed with apex downward following decay and removal of the soft body parts. In either case, preservation of this attitude demonstrates that the sediments were relatively soft to allow shells to penetrate some distance into the seafloor.

Sorting and fragmentation

Skeletal parts may be acted upon by various hydrodynamic processes, which serve to sort and fragment them. Sorting of skeletal elements by size, density, and even shape, is common in environments above wave base. Differential transport of left versus right valves of equivalved pelecypods (e.g., Figure T2(C)) may occur in environments where waves approach a coast obliquely (Müller, 1979). Hence, left-right sorting may be an excellent indicator of wave wash environments.

Biased ratios of skeletal parts may provide an indicator of time-averaging in shell-rich deposits. For example, brachiopod assemblages commonly show several times as many whole pedicle as brachial valves (Holland, 1988; Brett and Bordeaux, 1990). This indicates that the pedicle valves, which possess heavy hinge dentition and a thickened interarea, were better

able to withstand destructive processes. Offshore, low energy facies that show strongly biased valve ratios represent time-averaged accumulations. During prolonged intervals of exposure, occasional storm disturbances fragmented shells, preferentially removing the more fragile skeletal parts.

Fragmentation of shells may occur *via* biotic or abiotic means. Much fragmentation is thought to reflect physical impact of shells with one another. Generally, high proportions of fragmented skeletal material indicate repeated processing by high energy events.

Shattering of septa in nautiloid and ammonoid cephalopod shells is common in some offshore facies and has been used as a paleobathymetric indicator (Westermann, 1985). The shattered phragmocones may reflect hydrostatic pressures on an empty body chamber that shattered septa. Given this assumption, and septal strength indices for internally shattered cephalopods, approximate depths of implosion can be inferred. However, more recent work by Hewitt and Westermann, (1996) suggests that some of the shattering may actually take place due to explosion; i.e., septa blown forward owing to back pressures. Punctures in the shells may allow water to penetrate into back chambers of the shell to cause shattering of weaker early septa at much shallower depths than those predicted by the implosion model. If these two aspects of shell internal fragmentation can be sorted out, then shattered phragmocones may indeed provide a useful paleobathymetric indicator.

Corrosion and encrustation

It is often difficult to distinguish between shells that have been physically abraded and those corroded by biogeochemical processes. Brett and Baird (1986) suggested the term corrosion for cases of unspecified corrosion and abrasion. Even such unspecified shell damage may indicate exposure in the depositional environment.

Physically abraded fossils are common in many sandstones and siltstones, but rare in mudrocks, as clay sized particles are not affective abrasive agents. Abraded fossils in shales might indicate a complex burial history in which shells had been, at some point and time, affected by sediments coarser than the matrix in which they reside.

Corrosion and/or bioerosion of shells predominates over physical abrasion in offshore, low-energy environments (Kidwell and Bosence, 1991). Many apparently abraded shells in mudrocks have probably been chemically etched and/or acted upon by microboring organisms.

Microborings of endolithic organisms, identified by SEM, may be useful indicators of exposure and relative water depth. Endolithic algae of various sorts, for example, are confined to various portions of the euphotic to upper dysphotic zone (Vogel *et al.*, 1987). Absence of these sorts of endoliths on shells from sediments, in which independent evidence indicates shallow water deposition, might be used as an indicator of turbidity or elevated sedimentation rates.

Even in life, skeletons may become encrusted with epibiontic organisms, such as bryozoans. After death of their occupants, shells may be encrusted both externally and internally. Internal encrustation provides an excellent indication that shells remained unburied after death. Skeletons that have been corroded, or abraded may be subsequently encrusted and provide evidence for more prolonged exposure. Fossil corals that show one side with the epitheca perfectly intact and the

other side corroded and subsequently encrusted (Brett and Baird, 1986) must have lain partially buried in the mud; the upper surface was exposed to destructive and encrusting agents.

Fossil diagenesis: geochemical processing

Fossil diagenetic features also prove valuable in the interpretation of sedimentary environments. Early diagenetic phenomena may provide information regarding the geochemistry of bottom waters and the upper, "taphonomically active zone" (TAZ) of the sediment column (Martin, 1999; Figure T3). Diagenetic features of note include evidence for early dissolution, compaction, and mineralization of fossils.

Skeletal minerals and dissolution

Organisms secrete a variety of minerals, including calcite, aragonite, silica, and phosphate (apatite). Different skeletal mineralogies have varying stabilities.

Carbonate skeletons are commonly preserved in normal marine environments, although those composed of aragonite are more prone to dissolution. The large biocrystals of echinoderm plates are exceptionally resistant to dissolution and may be the only skeletal carbonates remaining after prolonged exposure.

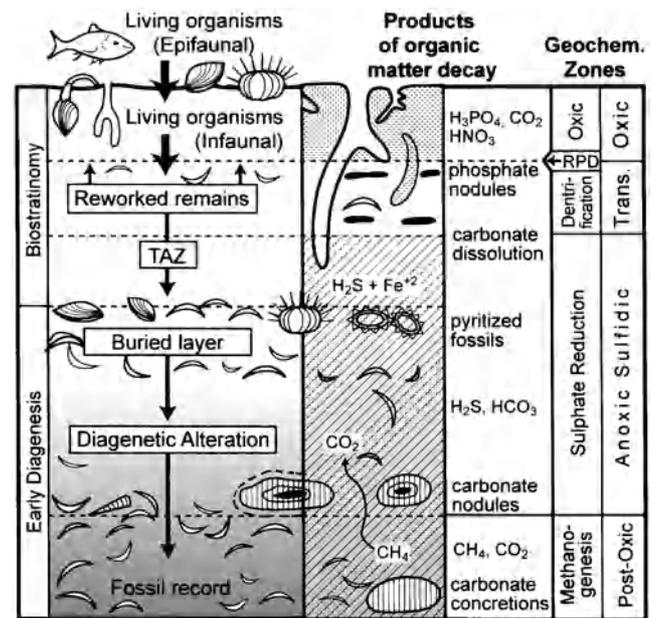

Figure T3 The realms of biostratigraphy and early diagenesis in marine sediments overlain by oxic water. Left columns show transition of organism remains from epifaunal and infaunal community into the physically/biologically mixed or taphonomically active zone (TAZ) and its transition to the permanent fossil record. Note some upward reworking of skeletal remains in the TAZ; also note intact skeletons in abruptly buried oblation deposit, which is also the site of pyrite nucleation. Middle columns highlight bacterially-mediated diagenetic processes and products; right columns identify geochemical zones. Abbreviations: RPD: redox potential discontinuity (oxic-anoxic boundary); Trans: transitional redox conditions. Adapted from diagrams in Martin (1999) and Wignall (1994).

Carbonate skeletons that dissolved prior to compaction may be preserved as plastically deformed molds. Such preservation would indicate undersaturation with respect to aragonite and/or calcite in the upper sediments. Conversely, many fossil molds display mosaic fracture patterns on their surfaces (Brett and Baird, 1986). Such shells survived without dissolution until after early phases of compaction and brittle fracture of the shells.

Even more stable than echinoderm plates, are skeletal elements composed of dense calcium fluorphosphate (apatite). In certain environments, particularly dysoxic, organic-rich sediments, bone apatite (organic fluorphosphate) may be replaced by the far more stable form calcium carbonate fluorapatite. Fluorapatite is stable over a wider pH/Eh range than calcite, and is one of the most stable biogenically associated components (Lucas and Prévôt, 1991). Once bones, teeth, conodonts, or fossil molds have been replaced by calcium fluorapatite, they are resistant to further dissolution. Such materials may form bone beds, which remain stably on the sea bottom for periods of hundreds of thousands to perhaps millions of years (Kidwell and Bosence, 1991; Martill, 1991).

Early diagenetic mineralization

Early diagenetic minerals in fossils, form as a result of the action of anaerobic bacteria (Allison and Briggs, 1991; Briggs, 1995). They may provide valuable information on sediment geochemistry and rates of burial.

Pyrite is common in marine mudrocks because of the availability of iron in terrigenous muds and the ubiquitous abundance of dissolved sulfate in marine (but not in fresh) water. In anoxic sediments generally low in organic matter early diagenetic pyritization tends to be localized in the vicinity of anaerobically decaying organisms (Hudson, 1982; Brett and Baird, 1986). As a result of local sulfate reduction, H_2S is liberated around decomposing organic material (Figure T3). Dissolved iron will react at these sites of sulfide production

Well preserved, pyritized fossils tend to occur in bioturbated mudstones, indicating environments with limited bottom water oxygenation, and anoxic, sulfidic microenvironments within the sediment (Hudson, 1982; Brett and Baird, 1986; Canfield and Raiswell, 1991a).

Fossils enclosed within carbonate concretions are typically three-dimensional; hence, the concretions formed before shells could be crushed by overburden pressure.

Most anaerobic decay processes generate bicarbonate (HCO_3^-) which may initiate the precipitation of calcite or siderite concretions around decaying organic matter in the zones of nitrate or sulfate reduction (Berner, 1981; Canfield and Raiswell, 1991b; figure 3).

However, mass balance calculations have shown that the bicarbonate generated by decaying carcasses is insufficient to form a concretion. Carbonate concretions, including those which enclose well preserved fossils, were largely generated by the decay of disseminated organic matter within the sediment.

The development of large concretions requires that the sediment surrounding a local nucleation center remains within the zone of sulfate reduction or methanogenic zone (Figure T3) in the upper few decimeters of the sediment column for prolonged periods, probably at least a few thousand years (Raiswell, 1976; Canfield and Raiswell, 1991b; Wignall, 1994).

Hence, horizons of fossil-bearing concretions may reflect episodes of sedimentation that were then followed by sediment starved intervals. Not surprisingly, many concretion beds underlie recognized diastems and concretions may also become reworked into erosion lag beds (Brett and Baird, 1986).

The decay of organic matter and reduction of phosphatic iron hydroxides liberates phosphate-bearing compounds (Lucas and Prévôt, 1991; Wignall, 1994; Figure T3). Dissolved phosphate may be released to the water column, if anoxia persists to the sediment-water interface. However, if a thin oxic zone exists in the upper sediment then the phosphates may be reprecipitated (Berner, 1981; Allison, 1988), especially around phosphatic skeletal nuclei, such as bones or lingulid brachiopods.

If the sedimentation rate is very low and geochemical conditions remain relatively constant, then phosphorus compounds will be sufficiently concentrated that phosphate minerals can precipitate. These minerals may replace organic remains or can form concretions. Thus, the occurrence of phosphatic fossil molds or concretions is nearly always an indicator of sediment starvation, commonly associated with deepening episodes.

Under less strongly reducing conditions the precursors of ironstones, such as berthierine or chamosite may precipitate in the upper part of the sediment, commonly as oolitic coatings or impregnations of skeletal grains. Later diagenesis may further chemically alter these precursors to hematite or goethite. "Fossil ores" commonly occur near the interfaces of reduced iron rich muds and carbonate shoals, suggesting critical redox boundary conditions that existed in relatively low sedimentation areas of mixed siliciclastic-carbonate deposition. Widespread beds of "fossil ore", i.e., hematite or chamosite coated fossils are also excellent indicators of sediment starved discontinuities; they commonly intergrade with phosphatic nodule beds (Brett, 1995).

Prefossilized material may be identified by breakage along formerly continuous structures, rotated geopetal structures, and shell infillings that do not match surrounding matrix sediment. Perhaps the most diagnostic feature is abrasion, bioerosion, or encrustation of diagenetically altered surfaces (e.g., abraded or bored phosphatic steinkerns) and preferential alignment (Kidwell and Bosence, 1991). In rare cases, even trace fossils may be diagenetically cemented and then reworked.

Summary discussion: preservational processes and taphofacies

Various aspects of fossil preservation may be combined to recognize *taphofacies* characteristic of various sedimentary environments (Speyer and Brett, 1986, 1988). Together with litho-, bio-, and ichnofacies, taphofacies tend to vary predictably with sedimentary environments as shown by studies in modern marine settings (e.g., Parsons and Brett, 1991). Fossils and their modes of preservation may provide important insights into a number of features of sediment deposition. These include: (i) sedimentary environment (depth, temperature, salinity, oxygen level, substrate consistency); (ii) dynamics of sediment accumulation, average rates, as well as evidence for episodicity of sedimentation and erosion; (iii) temporal scope of individual mudrock units; and (iv) sediment geochemistry and early diagenetic environments.

Taphonomic features, (e.g., articulation of delicate skeletal elements) may provide unambiguous evidence for episodic sedimentation; conversely, highly corroded fossil material provides a distinctive signature of time-averaging. The overall condition of skeletons may be assessed qualitatively or quantitatively, but certainly should be noted in the field. Semi-quantitative indices (e.g., of corrosion or fragmentation) may include the proportion of skeletal parts in different, arbitrarily defined preservational states. In such cases, it is commonly useful to develop a set of standards with which particular shells may be compared and assigned to a category in much the same way that grain shapes and roundness indices have long been assessed on the basis of standardized profiles by sedimentologists. Skeletal condition is particularly valuable for recognizing qualitatively the differing relative extents of sedimentary time-averaging that may be related to sequence stratigraphy (Brett, 1995).

Overall, condensed, highly time averaged, shelly accumulations will display high frequencies of disarticulation, fragmentation, valve ratio biasing, corrosion, and/or abrasion (Fürsich, 1978; Kidwell, 1991; Brett, 1995). Condensed intervals, associated with marine transgressions, thus may be readily recognized.

Conversely, rapidly accumulated sediments, typical of later highstands, will display higher proportions of articulated material with little or no shell breakage, including intact, delicate forms, such as branching bryozoans, little or no biasing of valve ratios, and few, if any, fossils that are heavily corroded, abraded, or otherwise altered in their surfaces (Kidwell, 1991; Brett, 1995).

Taphonomic observations should accompany any interpretation of fossiliferous sediments. By making even a qualitative assessment of the preservation states of fossils, a sedimentologist may be able to determine a great deal about the dynamics of sediment accumulation and many other paleoenvironmental parameters.

TECTONIC CONTROL OF SEDIMENTATION

Introduction

Sedimentation is influenced by three extrinsic variables: tectonics, climate, and sea level, with the latter two potentially dependent upon each other and upon tectonics. In addition, sedimentation is affected by processes inherent to the

depositional system, which act independently of the extrinsic variables. A primary goal in the study of sediment and sedimentary rocks is to decipher the relative effects of the extrinsic and intrinsic processes on the depositional history of a sedimentary basin.

Tectonics affects sedimentation in two different, but often related ways: subsidence of the crust and uplift of the land. Although sediment may be deposited temporarily in tectonically inactive, topographically low areas of the crust, it is subsidence over geologically significant intervals of time that continually provides the accommodation space for the accumulation and burial of sediment in sedimentary basins. Subsidence may be driven by vertical offset of faults, lateral flow of the mantle, cooling and concomitant increase in density of the crust and/or mantle, and isostatic response to loading of the crust, including the load provided by sediment within the basin (Ingersoll and Busby, 1995). Often working in concert with subsidence, uplift of the land provides detrital sediment to depositional basins through weathering and erosion. Vertical tectonic movement of the crust is required to maintain high regions or they will ultimately be reduced in elevation to near sea level.

Early attempts to classify sedimentary basins were hampered by the lack of a comprehensive model to explain crustal deformation (Schuchert, 1923; Kay, 1951). It is now widely accepted that the dominant tectonic process affecting the crust and upper mantle of the earth during most of its history is plate tectonics, with mantle plumes of secondary importance. Consequently, the following discussion of sedimentary basins is organized according to their plate-tectonic settings. Other references on this topic include Allen and Allen (1990) and Busby and Ingersoll (1995).

Sedimentary basins associated with diverging plates

Initial breakup of continental crust produces a long, linear extensional terrane referred to as a continental rift. In some cases rifting initially takes place simultaneously along three arms (triple junction), one of which eventually fails while the other two evolve into the rifted continental margin. The failed arm (aulacogen) represents a region of thick sediment that extends far into the continental interior (Hoffman *et al.*, 1974).

Continental rift basins are either bordered on both sides (full graben) or one side (half graben) by normal faults that extend at least into the middle crust. It is movement on the normal faults that provides the primary mechanism of basin subsidence and adjacent uplift. The margins of a continental rift basin commonly contain coarse detritus deposited on alluvial fans. In a half graben, small catchments on the footwall scarp result in small fans, while larger catchments in the hanging-wall mountains produce broad fans that extend far into the basin (Figure T4; Leeder and Gawthorpe, 1987). Basin-center facies in rift basins may include lakes, an axial river, and/or eolian sand field. Large lakes are particularly common in the East African rift (Soreghan and Cohen, 1996), while the Rio Grande rift of the southwestern United States has axial rivers (Mack *et al.*, 1997). Continental rift basins also may be inundated by shallow seas, particularly if the rift is near sea level at the onset of extension (Gawthorpe *et al.*, 1997).

Normal faults in continental rifts have finite lengths usually measured in a few tens to a hundred kilometers. Strain is transferred from the tip of one active fault to another via an

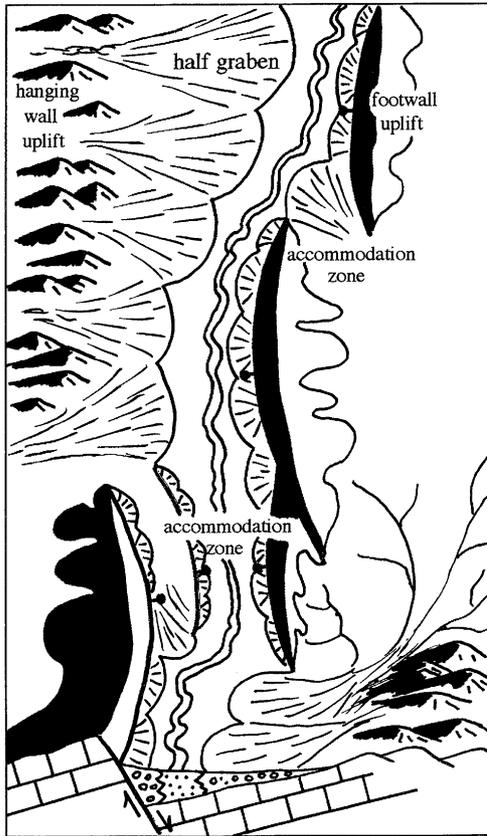

Figure T4 Schematic map and cross-section of a continental rift, showing basin-bounding normal faults (ball and stick on down side of fault), an accommodation zone in which the border faults overlap and dip in the same direction (upper part of diagram), an accommodation zone in which the border faults overlap and dip toward each other, and the asymmetrical distribution of alluvial-fan and axial-fluvial environments in half grabens.

accommodation zone, whose structural style depends on the degree of overlap and dip direction of the faults (Morley *et al.*, 1990). Because of large catchments, accommodation zones may be initially flanked by high escarpments, narrow coastal plains, and marine shelves, whose depositional environments include alluvial fan, fluvial, siliciclastic shoreline, including small deltas, and marine carbonates. With time the marginal rift blocks are reduced by erosion and overlapped by sediment. Because of a narrow connection to the open ocean and poor circulation, the incipient ocean basin may accumulate fine, organic-rich sediment and/or evaporites.

Continental rifting may eventually split the continental land masses apart, creating between them a narrow, incipient ocean basin floored by nascent oceanic crust, such as exists today in the Red Sea (Purser and Hotzl, 1988). The narrow seaway may be initially flanked by high escarpments, narrow coastal plains, and marine shelves, whose depositional environments include alluvial fan, fluvial, siliciclastic shoreline, including small deltas, and marine carbonates. With time the marginal rift blocks are reduced by erosion and overlapped by sediment. Because of a narrow connection to the open ocean and poor circulation, the incipient ocean basin may accumulate fine, organic-rich sediment and/or evaporites.

With increasing distance from the oceanic spreading ridge, the previously rifted continental margin subsides slowly and asymmetrically about a hinge on the landward side. Subsidence, which decreases exponentially with time, is primarily related to the amount of crustal thinning, cooling of the

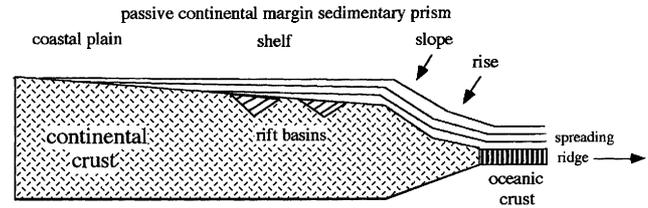

Figure T5 Cross-section of a passive continental margin showing the major depositional settings.

lithosphere, and sediment loading (Bond *et al.*, 1995). The resultant passive continental-margin prism of sediment is deposited in coastal plain, shallow-marine shelf, and deep-water rise environments, and consists predominantly of fine siliciclastic and/or carbonate sediment (Figure T5). Sedimentation may be locally influenced by and strata disrupted by contemporaneous rise of diapirs of salt deposited in the incipient ocean basin phase. Along-strike variation in passive margin sedimentation is related to continental transform faults that produce an orthogonal continental margin (Thomas, 1991).

The thickness of sediment deposited at active oceanic spreading ridges is initially influenced by half grabens in the oceanic crust. Although the earliest sediment may be amber, the iron- and manganese-rich fallout from black smokers (Robertson and Hudson, 1973), sedimentation on oceanic crust is dominated by pelagic sediment composed of carbonate and siliceous shells and clay that settle from suspension. The global distribution of pelagic sediment is primarily related to proximity to continental land masses and to the productivity of planktonic organisms (Davies and Gorsline, 1976). Tectonism comes into play in pelagic sedimentation through subsidence of the oceanic crust, a time-dependent process driven by cooling of the oceanic plate as it moves away from the spreading ridge. The subsiding plate may eventually fall below the carbonate and silica compensation depths, inhibiting the deposition of carbonate and siliceous oozes and promoting deposition of clay (Heezen *et al.*, 1973). Voluminous outpouring of basaltic lava on the ocean floor, such as occurs above mantle plumes, may build intraoceanic islands. Once the volcanism has slowed or ceased, however, the oceanic plateau will subside to abyssal depths, producing a stratigraphy that may include carbonate reef and shoal deposits overlain by pelagic sediment (Clague, 1981).

Sedimentary basins associated with subduction

The process of subduction of an oceanic plate beneath another oceanic plate or a plate with continental crust on its leading edge results in a series of depositional basins that are bordered by tectonic elements related to the subduction process (Figure T6). The topographic low at the junction of the two plates is the trench, and oceanic sediment and basaltic crust scraped off of the subducting slab onto the overriding plate creates the topographically high subduction complex. Partial melting of the asthenosphere above the subducting slab generates magma that rises to create a volcanic arc and its underlying plutons.

Mostly pelagic sediment, locally affected by thermohaline currents, is deposited on the outer trench slope, where flexure of the subducting slab may result in extensional basins

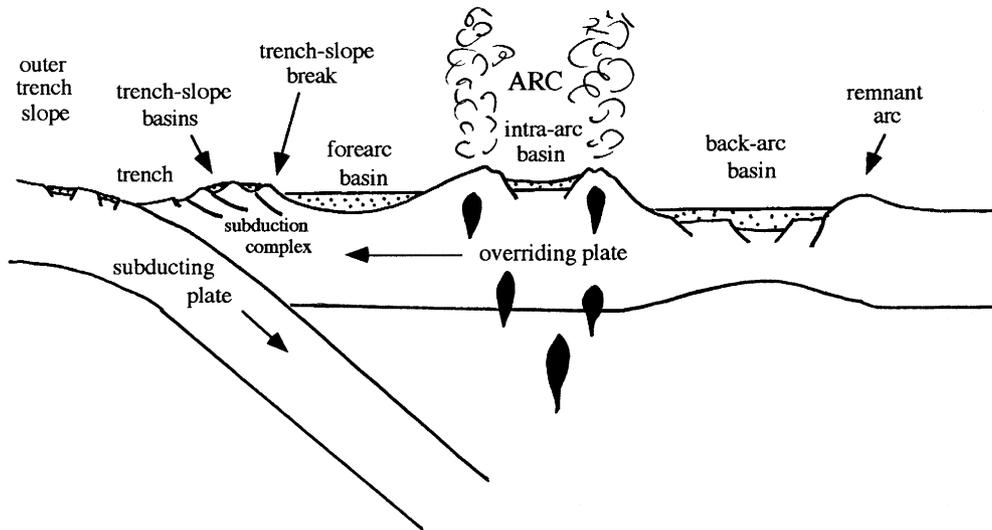

Figure T6 Cross-section of converging plates showing the subduction complex and arc, and their associated sedimentary basins.

(Figure T6; Underwood and Moore, 1995). In addition to pelagic sediment, the trench and trench-slope basins may receive transverse- or longitudinally dispersed gravity flows and submarine slides. The amount of sediment in the trench is highly variable and depends on the ratio of rate of sediment influx to the rate of subduction. Developing on the subduction complex, trench-slope basins may consist of grabens, linear valleys separated by fault- and fold-generated ridges, and/or a thin apron of sediment.

The forearc basin, which is situated between the magmatic arc and the subduction complex, is generally the largest of the subduction-related basins (Figure T6; Dickinson, 1995). Usually less than 150 km wide, forearc basins may extend laterally for thousands of kilometers or be segmented into a series of smaller basins. Sediment thickness in forearc basins may be up to 10 km, and the sediment commonly progressively onlaps both the arc and the subduction complex. Subsidence mechanisms of forearc basins are poorly understood, but may include downward pull of the subducting plate, tectonic loading by the subduction complex, cooling of a relict arc, and sediment loading. The principle source of siliciclastic sediment is the volcanic arc, although the plutonic core of the arc may be periodically exposed. Less commonly, the subduction complex may provide sediment to the forearc basin via submarine slides or by erosion of a complex that builds above sea level. Many forearc basins are primarily deep marine, in which hemipelagic muds and turbidite sands are deposited. It is also possible for forearc basins to infill with shallow-marine and nonmarine siliciclastic sediment, and marine forearc basins bordered by only a few volcanic islands may experience significant carbonate deposition.

Many active volcanic arcs contain intra-arc basins, which may be fault-bound or simply occupy topographically low regions between the volcanoes (Figure T6; Smith and Landis, 1995). Accumulation rates of sediment and volcanic rocks are high, because of active eruptions and erosion of high-relief volcanoes. Proximal to the volcanoes, lava flows and pyroclastic flows are interbedded with coarse gravity flow deposits, while in more distal settings volcanic ash is

interbedded with fine-grained alluvial-fan, fluvial, and lacustrine sediment. In oceanic areas, it is common for part of the intra-arc basin to be marine and contain fan-delta, delta, deep-sea fan, hemipelagic, and carbonate deposits. Intra-arc basins provide important information about the evolution of the arc, but may be difficult to distinguish from other arc-related basins in ancient rocks.

In some cases, lithospheric extension occurs behind the arc, creating a back-arc basin (Figure T6; Marsaglia, 1995). Back-arc basins may develop in intraoceanic arc (e.g., Mariana arc) or continental-margin arc (e.g., Sea of Japan) settings and are especially common in the western Pacific associated with rapid subduction of old, steeply dipping oceanic lithosphere. Extension is driven by mantle flow above the subducting plate and/or by relative movement of the trench toward the subducting plate (roll back) related to steepening of the angle of subduction. Initial breakup commonly takes place in the thermally weakened arc, splitting a remnant arc from the active arc. Tectonics and sedimentation of back-arc basins resemble that in rifts and acting spreading ridges, with the exception that the active arc is an important source of detrital sediment and volcanic rocks.

Sedimentary basins associated with compressional mountain building

Contraction of continental crust results in long (1,000s km), narrow (few 100 km) mountains characterized by thrust faults and associated folds. These fold-thrust belts may develop by continental collision, in which the edge of a continental plate collides with another continent, microcontinent, or oceanic terrane, such as an arc, subduction complex, or aseismic ridge. Fold-thrust belts comparable in style and scale to those formed by collision may also develop in a back-arc setting, such as the subandes of South America. The sedimentary basins that are complementary to fold-thrust belts are termed foreland basins and can be separated into peripheral (associated with collisional fold-thrust belts) and retroarc (associated with back-arc fold-thrust belts) (Dickinson, 1974). Tectonic

subsidence of foreland basins is primarily driven by loading of the crust by thrust sheets (Jordan, 1981), but also may be influenced by downward pull of the crust by the subducting slab (Royden, 1993) or mantle flow above the subducting slab (Gurnis, 1992).

DeCelles and Giles (1996) divided foreland basins into four potential depozones that may migrate laterally through time (Figure T7). The wedge-top depozone represents locally derived sediment deposited on top of the active, frontal part of the fold-thrust belt, including piggyback basins (Ori and Friend, 1984). A common feature of wedge-top strata are progressive unconformities, which develop by rotation of syntectonic sedimentary beds on fault-bend folds (Riba, 1976; Burbank *et al.*, 1996). The greatest volume of sediment in foreland basins is deposited in the foredeep depozone, which is typically 100–300 km wide and receives the bulk of its sediment from the fold-thrust belt. Foredeeps of peripheral foreland basins often begin with deep-water sedimentation (*flysch*), followed by shallow-marine, shoreline, and nonmarine sedimentation (*molasse*). Fluvial systems within the foredeep may be transverse or axial, and large drainages may emerge onto the foredeep at the tips of major thrust faults. Flexural bending of the floor of the foreland basin may result in a forebulge located on the craton side of the foredeep. Generally hundreds of kilometers wide and a maximum of a few hundred meters high, the forebulge is the site of erosion or deposition of thin sediment derived from the fold-thrust belt or the craton. The slowly subsiding back-bulge depozone lies cratonward of the forebulge and contains relatively thin, fine siliciclastic sediment derived from the fold-thrust belt and/or the craton, or is a site of marine carbonate deposition.

Another type of back-arc contractional deformation of continental crust occurs today in the Sierras Pampeanas of Argentina and occurred in latest Cretaceous–Eocene time in the Western Interior of the United States (Jordan and Allmendinger, 1986). This type of deformation is located over 500–1000 km from the active trench and is associated with subhorizontal subduction. Deformation produces discrete, basement-cored uplifts tens of kilometers wide and hundreds of kilometers long bordered by thrust and reverse faults. The uplifts are separated by intermontane basins the same scale or larger than the uplifts. In the modern and ancient examples cited above, the basins are entirely continental, include alluvial-fan, fluvial, and lacustrine environments, and may display subsidence histories and sediment distribution similar

to that of the wedge-top or foredeep depozones of foreland basins (Seager *et al.*, 1997).

Several other sedimentary basins may be associated with continental collisions. Deep-sea sediment derived from collisional mountains may be deposited in remnant ocean basins, which exist between and may eventually be deformed by the colliding continents (Graham *et al.*, 1975). The best modern example of a remnant ocean basin is the Bay of Bengal and associated Bengal deep-sea fan. Continental collisions may also generate deformational structures hundreds to thousands of kilometers inboard of the orogen. Such structures may include extensional basins (impactogens) and strike-slip faults (Sengor *et al.*, 1978; Tapponnier *et al.*, 1982).

Sedimentary basins associated with strike-slip faults

Strike-slip faults exist in a variety of different tectonic settings and can be divided into transform and transcurrent types (Sylvester, 1988). Transform faults define plate boundaries and penetrate the lithosphere. Examples of transform strike-slip faults include those at oceanic spreading ridges and the San Andreas fault, which forms the boundary between the North American and Pacific plates. In contrast, a transcurrent strike-slip fault, such as the North Anatolian fault in Turkey, is confined to the crust and is located within a plate. Most strike-slip basins are related to bends in the trace of strike-slip faults or are associated with en echelon strike-slip faults (Figure T8). Extensional fault-bound basins form at releasing bends in strike-slip faults and tend to be elongate or lens-shaped (Crowell, 1974). Restraining bends tend to produce thrust faults and associated transpressional basins, which subside in response to thrust loading (Nilsen and Sylvester, 1995). In addition, parallel but offset strike-slip faults may form extensional stepover basins, such as in the Dead Sea rift (Aydin and Nur, 1985), and transrotational basins form among crustal blocks rotated about a vertical axis between strike-slip faults (Ingersoll, 1988).

Strike-slip basins may contain a variety of marine and nonmarine depositional systems arranged similar to that in rift or foreland basins. Most diagnostic of strike-slip basins are high sediment accumulation rates, abrupt lateral and vertical facies changes, lateral migration of the depocenter producing stratal shingling, and stratigraphic variations in provenance related to lateral displacement of source terranes (Sylvester, 1988; Nilsen and Sylvester, 1995). Although generally not

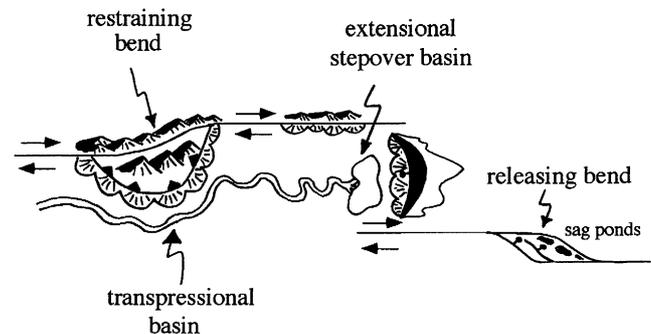

Figure T8 Schematic map of three types of sedimentary basins associated with en echelon, right-lateral strike-slip faults. Ball and stick on down side of normal fault; bold triangles on up side of thrust fault.

associated with distinct sedimentary basins, transform faults at oceanic spreading ridges may develop vertical scarps that supply gravity flows to the adjacent ocean floor (Simonian and Gass, 1978).

Cratonic sedimentary basins

Cratonic basins are large ($>10^5 \text{ km}^2$), generally elliptical basins that develop within the interior of continents far from active plate boundaries. Despite relatively slow and erratic subsidence, they may accumulate thousands of meters of sediment because of histories measured in hundreds of millions of years. The basin fill consists predominantly of nonmarine and shallow-marine fine-grained siliciclastics, carbonates, and evaporites, and unconformities are common. Sloss (1963) defined six Phanerozoic depositional sequences separated by continental-scale unconformities in the cratonic basins of North America, some of which could be correlated with cratonic basins in Asia (Sloss, 1972), South America (Soares *et al.*, 1978), and Africa (Peters, 1979). Stratigraphic similarities of cratonic basins in Europe and India were also noted by Klein and Hsui (1987). Throughout their histories, cratonic basins may be affected by a variety of tectonic processes, including various types of thermal and isostatic subsidence, lower crustal phase changes or melting, and stress related to plate interactions (Klein, 1995). A comprehensive model to explain the origin and apparent synchronicity of cratonic basins remains elusive, although Klein (1995) proposed that they evolve in response to breakup of supercontinents.

Summary

- (1) Plate tectonics is the primary driving force for crustal uplift and basin subsidence through the processes of faulting, isostatic response to loading and unloading, lateral flow of the mantle, and change in density of the crust and mantle due to heating and cooling.
- (2) Sedimentary basins associated with diverging plates include continental rifts (e.g., East African rift), incipient ocean basins (e.g., Red Sea), passive continental margins (e.g., Atlantic coast of North America), and oceanic basins created at active spreading ridges (e.g., Mid Atlantic Ridge).
- (3) Subduction-related basins may develop on the outer-trench slope of the subducting slab, in the trench, and on the overriding plate, including trench-slope basins, forearc basins, and intra-arc basins. Extensional back-arc basins may develop in areas of trench roll back or asthenospheric upwelling.
- (4) Continental collision and back-arc compression produce fold-thrust belts and their complementary foreland basins, which can be divided into wedge-top, foredeep, forebulge, and back-bulge depozones. An usual type of back-arc compression associated with subhorizontal subduction results in discrete uplifts separated by intermontane basins. Continental collision may produce extensional basins and strike-slip faults far inboard of the collisional orogen.
- (5) Strike-slip faults may define plate boundaries (transform faults) or reside within a plate (transcurrent fault). Basins are created at releasing and restraining bends in fault traces, between en echelon faults, and by rotation of fault-bound blocks about a near vertical axis.
- (6) Cratonic basins develop far from active plate margins and may have long histories of intermittent subsidence and erosion. Cratonic basins on different continents may have similar histories, but their origin remains poorly understood.

TIDAL FLATS

Definition

Tidal flats are sandy-muddy depositional systems along marine and estuarine shores periodically submerged and exposed in the course of the rise and fall of the tide (*cf.* Bates and Jackson, 1987). They differ from tidal beaches in spatial extent, topographic complexity, and facies differentiation. Perhaps the oldest reference to tidal flats dates back to the 1st Century AD when the Roman historian Pliny the Elder, after visiting the Wadden Sea coast in the year 47 AD, described it in his epochal work “*Naturalis historia*” as an area which is inundated by the sea with forceful currents twice a day and of which it was doubtful whether it formed part of the land or the sea.

Physical setting, dimensions, and hydrologic classification

On a global scale, tidal flat environments are exposed to two dominant tidal types, a semi-diurnal and a diurnal one which are separated by two mixed types consisting of a predominantly semi-diurnal and a predominantly diurnal one. The local tidal type controls the daily frequency and rate of inundation of a tidal flat (Allen, 1997). The most prominent tidal period recorded in rhythmic tidal deposits is the fortnightly spring-neap cycle (e.g., Visser, 1980). Another short-term astronomical feature influencing depositional processes on tidal flats is the daily inequality of the tide which results from the inclination of the earth’s axis relative to the plane of the ecliptic, and hence the tidal bulge (e.g., De Boer *et al.*, 1989). The daily inequality increases from the equator toward higher latitudes. The largest astronomical tides in the course of a year, i.e., the highest spring and lowest neap tides, occur at the vernal and autumnal equinoxes. These are the periods of maximum tidal energy flux and hence of greatest sediment transport potential. In addition to these short-period cycles, the tide is also modulated over longer astronomical periods such as the 18.6 year nodal cycle (Oost *et al.*, 1993). Good examples of rhythmic tidal deposits have been described from ancient tidal deposits (e.g., Archer *et al.*, 1991; Williams, 1991).

A second important factor affecting depositional processes on tidal flats is the tidal range. In combination with the size of

the tidal basin it determines the volume of the tidal prism and hence the tidal discharge. Being an easily determined parameter, the tidal range has been used to classify tidal coasts. The most widely applied scheme to date is that of Davies (1964) in which microtidal shores (0–2 m) are distinguished from mesotidal (2–4 m) and macrotidal (>4 m) ones. An alternative scheme comprising five subdivisions, and thus offering greater differentiation, is that of Hayes (1979) in which microtidal shores (0–1 m) are distinguished from low-mesotidal (1–2 m), high-mesotidal (2–3.5 m), low-macrotidal (3.5–5.0 m), and high-macrotidal (>5 m) ones. This latter scheme takes distinct, process-related geomorphic features into consideration.

Modern tidal-flat depositional systems are commonly found in estuaries and along low-lying coastal-plain shores between the equator and the polar seas at tidal ranges above about 0.5 m. They can attain shore-normal widths of several kilometers, alongshore extensions of many 10s to 100s of kilometers, and vertical accretion heights of several 10s to 100s of meters (Davis, 1994; Ehlers, 1998). They occur along barred and non-barred sea shores, and within estuaries. Along non-tidal or microtidal shores with less than 0.5 m tidal range, “pseudo-tidal” flats may be found which have much in common with true tidal flats, but lack the regular tidal rhythm. Here the inundation interval is controlled by wind set-up, the resulting depositional environment being known as “wind flats”. Back-barrier tidal flats are limited to tidal ranges between about 0.5 m and 3.5 m, the transition to nonbarred tidal flats being controlled by the interaction between the tidal range and wave action (e.g., Hayes, 1979). At tidal ranges above 3.5 m tidal flats are always nonbarred, irrespective of the wave climate. Extreme macrotidal ranges occur where the length of a shallow, funnel-shaped bay approximates a quarter wavelength of the tidal wave. In such cases, the natural oscillation of the water body resonates with the tidal period and the tidal wave is hence superimposed on a standing wave. This results in strong amplification of tidal water levels at the head of such bays as, for example, in the Bay of Fundy, Canada (Dalrymple and Zaitlin, 1989), in the Severn Estuary, Great Britain (Allen, 1990), or in the Bay of Mont St Michel, France (Larsonneur, 1994). French (1997) distinguishes no less than seven intertidal coastal types based mainly on morphology and facies successions.

Sedimentology, stratigraphy, and facies associations

Tidal flats occur in both siliciclastic and carbonate depositional systems (e.g., Ginsburg, 1975) and have been documented in the rock record since Archaean times over 3,300 Ma ago (e.g., Hobday and Eriksson, 1977). Important benchmark papers in tidal flat research published before 1970 can be found in Klein (1976). Following the settling lag/scour lag mechanism along the tidal energy gradient (Van Straaten and Kuenen, 1957), grain sizes progressively fine toward the shore. The result is a sedimentary facies succession that has recently been classified on the basis of mud content (*cf.* Flemming, 2000). It commences with sand flats (<5 percent mud) at the high-energy end near the low-tide level, and proceeds through slightly muddy sand flats (5–25 percent mud), muddy sand flats (25–50 percent mud), sandy mud flats (50–75 percent mud), slightly sandy mud flats (75–95 percent mud), to mud flats (>95 percent mud) at the low-energy end (high-tide level). Sand flats can usually be further subdivided

into a variety of size classes, the total range depending on overall sediment supply and energy flux. Numerous aspects of mudflat properties and processes, including a typological classification of mud flats and a discussion of mass physical properties, can be found in Dyer (2000).

Along the energy gradient, tidal flats display numerous physical and biological sedimentary structures, both on the surface and in cross-section (e.g., Klein, 1977; Reineck and Singh, 1980), only a few (such as tidal rhythmites) being unequivocally diagnostic (e.g., Visser, 1980). Exposed sandy tidal flats are dominated by physical structures generated by waves and currents (complex wave and current ripple structures, dune cross-bedding, upper plane bed lamination, fluid escape structures, etc.). Strong bioturbation is rare in sand flats. As energy levels decrease, burrowing organisms such as polychaete worms and molluscs in temperate climates or callianassid shrimps in tropical and subtropical climates begin to bioturbate the sediment, the degree of bioturbation generally increasing toward the finer-grained sediment facies. Mud enters the sedimentary system in the form of either sortable silt particles or flocs and aggregates (including faecal pellets) composed of finer-grained components (generally <10 μm). Deposition of the low-density mud flocs and other aggregates follows the principle of hydraulic equivalence as reflected in the progressive increase in mud content along the energy gradient (Flemming, 2000). As a result, muddy intertidal sediments are actually well sorted. At the same time, primary sedimentary structures such as mud-draped ripple cross-beds evolve into flaser, wavy, and lenticular bedding units before merging into horizontally laminated muds at the landward margin. Contorted and convoluted mud beds with mud-cracked surfaces appear at the transition to the lower supratidal environment as desiccation at neap tide promotes compaction, while storm-generated silt layers may be interspersed along more exposed parts of the system. Above the mean high-tide level, root-structures of salt-marsh plants begin to intensely bioturbate the sediment.

Tidal flat depositional systems evolve in response to the longer-term sediment budget which, in turn, is a function of the rate of sediment supply from external sources and the rate of sea-level rise (or fall). Thus, if the sediment supply exceeds the deficit created by sea-level rise, the system will prograde seawards while aggrading. If both are balanced, then the system will simply aggrade in place. On the other hand, if the deficit exceeds the supply, then reworking along the seaward margin results in transgressive landward displacement of the individual facies belts (Figure T9).

Biological aspects

Besides the influence of physical parameters such as currents, wave action and grain size, the nature of intertidal deposits is strongly affected by the presence or absence of particular animal and plant associations. In recent years, the importance of microbial communities has received increasing attention (e.g., Krumbein *et al.*, 1994). The nature of biological influence on tidal-flat depositional systems depends on species composition and community structure which both change with geographic locality and climatic setting (e.g., Chapman, 1974; Reise, 2001). As a result, tidal flats in different parts of the world can often be distinguished on the basis of characteristic biological surface structures and bioturbation patterns. A systematic study of biologically generated

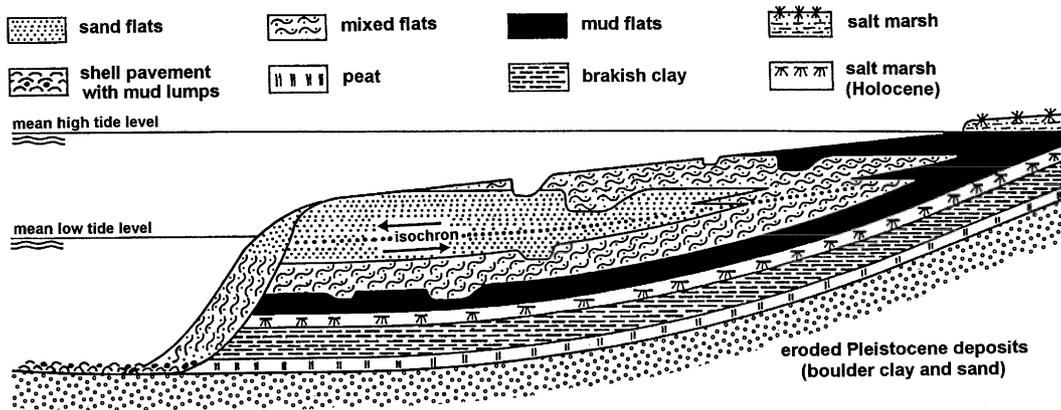

Figure T9 Typical facies associations and stratigraphy of a nonbarred tidal flat depositional system of the southern North Sea (modified after Reineck and Singh, 1980). Below the line marked "isochron" the sequence is transgressive (retrogradational), above the line it is regressive (progradational).

sedimentary structures in the Wadden Sea can be found in Schäfer (1972). Furthermore, the transition from upper intertidal to lower supratidal environments is characterized by well-developed microbial mats and distinct floral zones. In tropical regions these are associated with mangrove, in temperate regions with salt marsh plant communities (e.g., Allen and Pye, 1992; Augustinus, 1995).

Outlook

Tidal deposits, both modern and ancient, have remained a focus of ongoing research to this day the world over. Up to date summaries of this work can be found in the proceedings and field trip guides of the 4-yearly international tidalite conferences held in different parts of the world since 1985 (De Boer, Van Gelder and Nio, 1988; Flemming and Hertweck, 1994; Flemming and Bartholomä, 1995; Alexander, Davis, and Henry, 1998; Park and Davis, 2001). An aspect that requires more attention in the future is the integration of different research fields, especially sedimentology, hydrology, geochemistry, biogeochemistry, microbiology, paleontology, and ecology.

TIDAL INLETS AND DELTAS

A *tidal inlet* is an opening in the shoreline through which water penetrates the land thereby providing a connection between the ocean and bays, lagoons, marsh, and tidal creek systems. Tidal currents maintain the main channel of a tidal inlet. The second half of this definition distinguishes tidal inlets from large, open embayments or passageways along rocky coasts. Tidal currents at inlets are responsible for the continual removal of sediment dumped into the main channel by wave action. Thus, according to this definition tidal inlets occur along sandy or sand and gravel barrier coastlines, although one side may abut a bedrock headland. Some tidal inlets coincide with the mouths of rivers (estuaries) but in these cases inlet dimensions and sediment transport trends are still governed, to a large extent, by the volume of water exchanged at the inlet mouth (tidal prism) and the reversing tidal currents, respectively.

Tidal inlets are found along barrier coastlines throughout the world. They provide a pathway for ships and small boats to travel between the open ocean to sheltered waters. Diversity in the morphology, hydraulic signature, and sediment transport patterns of tidal inlets attests to the complexity of their processes. The variability in oceanographic, meteorological, and geologic parameters, such as tidal range, wave energy, sediment supply, storm magnitude and frequency, fresh water influx, and geologic controls, and the interactions of these factors, are responsible for this wide range in tidal inlet settings. At most inlets over the long-term, the volume of water entering the inlet during the flooding tide equals the volume of water leaving the inlet during the ebbing cycle. This volume is referred to as the *tidal prism*. The tidal prism is a function of the open water area and tidal range in the backbarrier as well frictional factors, which govern the ease of flow through the inlet.

The formation of a tidal inlet requires the presence of an embayment and the development of barriers. In coastal plain settings, the embayment or backbarrier was often created through the construction of the barriers themselves, like much of the East Coast of the United States or the Friesian Island coast along the North Sea (FitzGerald and Penland, 1987; FitzGerald, 1996). Breaching of a barrier and spit accretion across a bay are the common mechanisms of inlet formation. In other instances, flooding of former river valleys has also produced embayments associated with tidal inlet development.

Tidal deltas

A tidal inlet is specifically the area between two barriers or between the barrier and the adjacent bedrock or glacial headland. The deepest part of an inlet, the *inlet throat*, is located normally where spit accretion of one or both of the bordering barriers constricts the inlet channel to a minimum width and minimum cross sectional area. Here tidal currents normally reach their maximum velocity. Commonly, the strength of the currents at the throat causes sand to be removed from the channel floor leaving behind a lag deposit consisting of gravel or shells or in some locations exposed bedrock or indurated sediments. Closely associated with tidal inlets are sand shoals and tidal channels located on the landward and seaward sides of the inlets. Flood tidal currents deposit sand landward of the inlet forming a *flood-tidal delta* and ebb-tidal currents deposit sand on the seaward side forming an *ebb-tidal delta*.

Flood-tidal deltas

Their presence or absence, size, and development are related to a region's tidal range, wave energy, sediment supply and backbarrier setting. Tidal inlets that are backed by a system of tidal channels and salt marsh (mixed-energy coast) usually contain a single horseshoe-shaped flood-tidal delta (e.g., Essex River Inlet, Massachusetts; Figure T10). Contrastingly, inlets that are backed by large shallow bays may contain multiple flood-tidal deltas. Along some microtidal coast, such as Rhode Island, flood deltas form at the end of narrow inlet channels cut through the barrier. Changes in the locus of deposition at these deltas produce a multi-lobate morphology resembling a lobate river delta (Boothroyd *et al.*, 1985). Flood delta size commonly increases as the amount of open water area in the backbarrier increases.

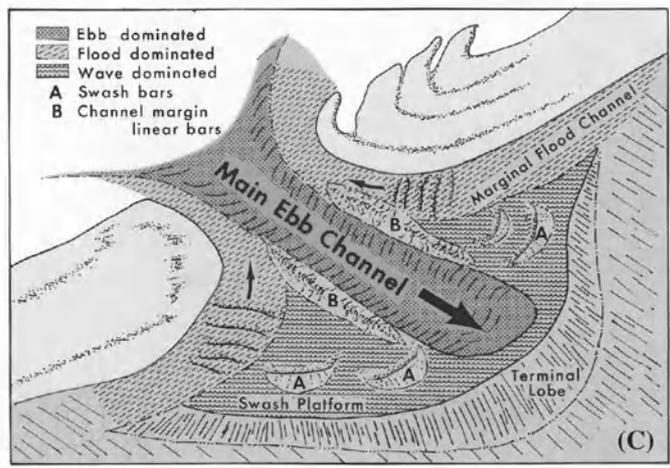

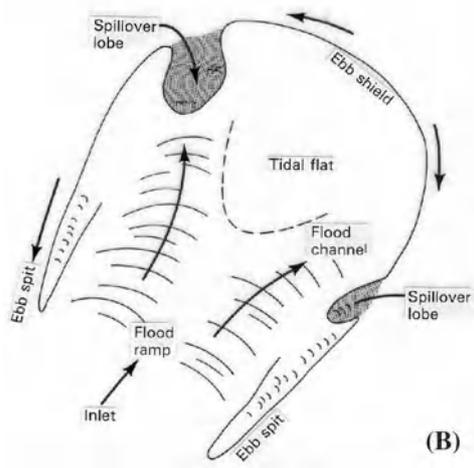

Figure T10 (A) Vertical aerial photograph of Essex River Inlet, Massachusetts with well developed flood and ebb-tidal deltas. (B) Flood-tidal delta model (from Hayes, 1975). (C) Ebb-tidal delta model (from FitzGerald *et al.*, 1976, after Hayes, 1975).

Flood-tidal deltas are best revealed in areas with moderate to large tidal ranges (1.5–3.0 m) because in these regions they are well exposed at low tide. As tidal range decreases, flood deltas become largely sub-tidal shoals. Most flood-tidal deltas have similar morphologies consisting of the following components (Hayes, 1979). *Flood ramp* is a landward shallowing channel that slopes upward toward the intertidal portion of the delta. Strong flood-tidal currents and landward sand transport in the form of landward-oriented sandwaves dominate the ramp. The flood ramp splits into two shallow *flood channels*. Like the flood ramp, these channels are dominated by flood-tidal currents and flood-oriented sand waves. Sand is delivered through these channels onto the flood delta. *Ebb shield* defines the highest and landwardmost part of the flood delta and may be partly covered by marsh vegetation. It shields the rest of the delta from the effects of the ebb-tidal currents. *Ebb spits* extend from the ebb shield toward the inlet. They form from sand that is eroded from the ebb shield and transported back toward the inlet by ebb-tidal currents. *Spillover lobes* are deposits of sand that form where the ebb currents have breached through the ebb spits or ebb shield depositing sand in the interior of the delta.

Through time, some flood-tidal deltas accrete vertically and/or grow in size. This is evidenced by an increase in areal extent of marsh grasses, which require a certain elevation above mean low water to exist. At migrating inlets new flood-tidal deltas are formed as the inlet moves along the coast and encounters new open water areas in the backbarrier. At most stable inlets, however, sand comprising the flood delta is simply recircu-

lated. The transport of sand on flood deltas is controlled by the elevation of the tide and the strength and direction of the tidal currents. During the rising tide, flood currents reach their strongest velocities near high tide when the entire flood-tidal delta is covered by water. Hence, there is a net transport of sand up the flood ramp, through the flood channels and onto the ebb shield. Some of the sand is moved across the ebb shield and into the surrounding tidal channel. During the falling tide, the strongest ebb currents occur near mid to low water. At this time, the ebb shield is out of the water and diverts the currents around the delta. The ebb currents erode sand from the landward face of the ebb shield and transport it along the ebb spits and eventually into the inlet channel where once again it will be moved onto the flood ramp thus completing the sand gyre (Boothroyd, 1985).

Ebb-tidal deltas

Ebb-tidal deltas are accumulations of sand that has been deposited by ebb-tidal currents and which have been modified subsequently by waves and tidal currents. Ebb deltas exhibit a variety of forms dependent on the relative magnitude of wave and tidal energy of the region as well as geological controls. Along mixed energy coasts, most ebb-tidal deltas contain a set of general features. *Main ebb channel* is a seaward shallowing channel that is scoured in the ebb-tidal delta sands. It is dominated by ebb-tidal currents. Sediment transported out the main ebb channel is deposited in a lobe of sand forming the *terminal lobe*. The deposit slopes relatively steeply on its

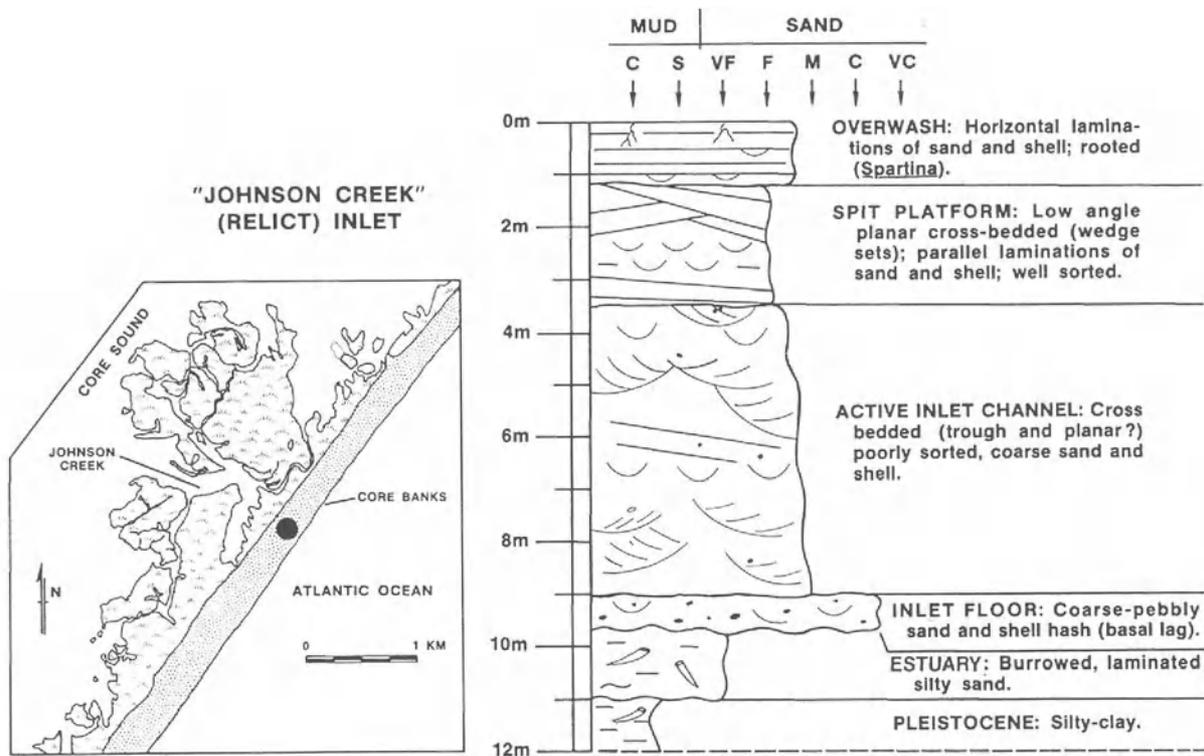

Figure T11 Sedimentary sequence through a former tidal inlet along Core Bank, North Carolina as determined from a sediment core (from Moslow and Tye, 1985). This model does not depict the large-scale accretionary beds that have been observed in ground-penetrating radar profiles across tidal inlet fills (FitzGerald *et al.*, 2001).

seaward side. The outline of the terminal lobe is well defined by breaking waves during storms or periods of large wave swell at low tide. *Swash platform* is a broad shallow sand platform located on both sides of the main ebb channel, defining the general extent of the ebb delta. *Channel margin linear bars* border the main ebb channel and sit atop the swash platform. These bars tend to confine the ebb flow and are exposed at low tide. Waves breaking over the terminal lobe and across the swash platform form arcuate-shaped *swash bars* that migrate onshore. The bars are usually 50–150 m long, 50 m wide, and 1–2 m in height. *Marginal-flood channels*, the shallow channels (0–2 m deep at mean low water) located between the channel margin linear bars and the onshore beaches, are dominated by flood-tidal currents.

The general shape of an ebb-tidal delta and the distribution of its sand bodies tell us about the relative magnitude of different sand transport processes operating at a tidal inlet (FitzGerald, 1988). Ebb-tidal deltas that have elongated main ebb channel and channel margin linear bars that extend far offshore are tide-dominated inlets. Wave-generated sand transport plays a secondary role in modifying delta shape at these inlets. Because most sand movement is in onshore-offshore direction, the ebb-tidal delta overlaps a relatively small length of inlet shoreline. This has important implications concerning the extent to which the inlet shoreline undergoes erosional and depositional changes.

Wave-dominated inlets tend to be small relative to tide-dominated inlets. Their ebb-tidal deltas are driven onshore, close to the inlet mouth by the dominant wave processes. Commonly, the terminal lobe and/or swash bars form a small arc outlining the periphery of the delta. In many cases the ebb-tidal delta of these inlets is entirely subtidal. In other instances, sand bodies clog the entrance to the inlet leading to the formation of several major and minor tidal channels. At mixed energy tidal inlets the shape of the delta is the result of tidal and wave processes. These deltas have a well-formed main ebb channel, which is a product of ebb-tidal currents. Their swash platform and sand bodies substantially overlap the inlet shoreline many times the width of the inlet throat due to wave processes and flood-tidal currents. Ebb-tidal deltas may also be highly asymmetric such that the main ebb channel and its associated sand bodies are positioned primarily along one of the inlet shorelines. This configuration normally occurs when the major backbarrier channel approaches the inlet at an oblique angle or when a preferential accumulation of sand on the updrift side of the ebb delta causes a deflection of the main ebb channel along the downdrift barrier shoreline.

Sand transport patterns

The movement of sand at a tidal inlet is complex due to reversing tidal currents, effects of storms, and interaction with the longshore transport system. The inlet contains short-term and long-term reservoirs of sand varying from the relatively small sandwaves flooring the inlet channel that migrate meters each tidal cycle to the large flood-tidal delta shoals where some sand is recirculated but the entire deposit may remain stable for hundreds or even thousands of years. Sand dispersal at tidal inlets is complicated because in addition to the onshore-offshore movement of sand produced by tidal and wave-generated currents, there is constant delivery of sand to the inlet and transport of sand away from the inlet produced by the longshore transport system. In the discussion below the

patterns of sand movement at inlets are described including how sand is moved past a tidal inlet.

The ebb-tidal delta has segregated areas of landward versus seaward sediment transport that are controlled primarily by the way water enters and discharges from the inlet as well as the effects of wave-generated currents. During the ebbing cycle the tidal flow leaving the backbarrier is constricted at the inlet throat causing the currents to accelerate in a seaward direction. Once out of the confines of the inlet, the ebb flow expands laterally and the velocity slows. Sediment in the main ebb channel is transported in a net seaward direction and eventually deposited on the terminal lobe due to this decrease in current velocity. One response to this seaward movement of sand is the formation of ebb-oriented sandwaves (dunes) having heights of 1–2 m.

In the beginning of the flood cycle, the ocean tide rises while water in main ebb channel continues to flow seaward as a result of momentum. Due to this phenomenon, water initially enters the inlet through the marginal flood channels, which are the pathways of least resistance. The flood channels are dominated by landward sediment transport and are floored by flood-oriented bedforms. On both sides of the main ebb channel, the swash platform is most affected by landward flow produced by the flood-tidal currents and breaking waves. As waves shoal and break, they generate landward flow, which augments the flood tidal currents but retards the ebb tidal currents. The interaction of these forces acts to transport sediment in a net landward direction across the swash platform. In summary, at many inlets there is a general trend of seaward sand transport in the main ebb channel, which is countered by landward sand transport in the marginal flood channels and across the swash platform.

Preservation of tidal inlets sequences

A typical sandy barrier-inlet model of sedimentary facies succession grades upward from coarse channel sand, and in some cases fine gravel, into medium to fine beach and dune sand (Reinson, 1984). The fining upward sequence characterizing tidal inlets contrasts with coarsening upward facies of most barriers. Tidal inlet and tidal delta facies have been described in the rock record by Barwis and Makurath (1978). Channel-fill facies and large-scale accretionary bedding resulting from inlet migration characterize tidal inlet sequences. Small scale bi-directional stratification is also typical of inlet facies. Tidal inlet deposits are distinguished from riverine and tidal channel facies by their discontinuous nature in dip section. Because tidal inlets commonly scour to depths of 8 m and deeper, their fill sequences have a high preservation potential. Ebb-tidal delta facies sit atop the shoreface and have a low preservation potential. The exception to this trend are fill sequences associated with migrations of the main ebb channel, which may be partially preserved due to the depth of channel scour. Flood-tidal deltas may be preserved as a series of stacked sand lobes (1–3 m thick) dominated by landward dipping stratification (Boothroyd, 1985).

Migrating inlets may account for a net loss of sand from the littoral system. If the inlet channel scours below the base of the barrier sands, then beach sand, which fills the channel, will not be entirely compensated by the deposits excavated on the eroding side of the channel. Because up to 40 percent of the length of barriers is underlain by tidal inlet fill deposits ranging in thickness from 2 m to 10 m (Moslow and Heron, 1978;

Moslow and Tye, 1985) this volume represents a large, long-term loss of sand from the coastal sediment budget.

Sediment Transport by Tides
Tidal Flats

TIDES AND TIDAL RHYTHMITES

Introduction

Oceanic tides are the regular (periodic) daily rise and fall of the oceans; a direct consequence of the gravitational attraction of the Moon and Sun on the Earth. Tidal rhythmmites, as used herein, include small-scale primary sedimentary structures consisting of: (1) stacked sets of clay-draped ripples that as cosets can be classified as lenticular, wavy, and flaser bedding; and (2) flat-laminated siltstone and silty claystone with thin

intercalated claystone layers. In the rock record the tidal influence on the origin of these features is indicated by the very regular progressive vertical thickening and thinning of individually accreted sets in response to changing current velocities associated with lunar or lunar-solar tidal cycles (Kvale *et al.*, 1999). Recognition of the changing set thickness as a function of these cycles is important because a repetitive sequence of similar-appearing bedding can be generated via processes other than tidal (e.g., lacustrine varves).

What generates tides?

To understand oceanic tides and tidal rhythmmites it is sometimes useful to think in terms of purely astronomical tides and equilibrium tidal theory. By definition, equilibrium tides are ideal and defined by the tractive gravitational forces of the Moon, and to a lesser extent the Sun, on an idealized Earth completely covered by deep water of uniform depth that is capable of instantly responding to changes in tractive forces (MacMillan, 1966). In the equilibrium model, the tidal forces from the Moon and Sun in combination with centrifugal forces associated with the spin of the Earth produce oceanic bulges on opposite sides of the Earth (Figure T12(A)). The bulges tend to more closely follow the motion of the Moon as the Moon accounts for approximately 70 percent of the tide-raising forces because of its closer proximity to the Earth than the Sun. The rotation of the Earth through each of these bulges once a day produces two tides a day (the semidiurnal tide). As a point on the Earth's ocean enters the bulge, tides rise (flood tide), and as that point moves out of the bulge, tides fall (ebb tide). The relative difference in elevation between the heights of the flood and ebb tides is referred to as the "tidal range."

It is important to note that in the real world there are not two tidal bulges through which the Earth spins but rather water within the ocean basins is displaced and forced to rotate as discrete waves or bulges about a series of fixed (amphidromic) points by a combined force generated by the spin of the Earth and the gravitational forces of the Moon and Sun (Figure T13). Because of the Coriolis effect, these discrete tidal bulges or waves typically rotate about the amphidromic point in a counterclockwise direction in the northern hemisphere and clockwise in the southern hemisphere. In an open-ocean semidiurnal tidal system, a tidal bulge completes one rotation about an amphidromic point every 12.42 hours.

As the open-ocean tides approach continental shelf areas, tidal energy is concentrated and tidal ranges generally increase independent of latitude. In some cases, the geometry of an embayed area along a coastline is such that the period of time it takes for a tide to move in and out of the basin is close to one of the astronomical tidal periods (discussed below) and significant tidal amplification takes place. An extreme example of this is the Bay of Fundy in eastern Canada where there is a significant resonant amplification of the open-ocean tides (generally 1 m or less) with tides rising and falling up to 16 m/day.

Because of the inadequacy of the equilibrium tidal theory to explain the complexities of real world tidal systems, the concept of harmonic analysis of tidal constituents was developed and should be considered when attempting to understand tides (see discussions in Pugh, 1987; and Kvale *et al.*, 1999).

Tidal cycles

The intensity or height of the daily or twice daily tides can vary in a number of ways. The semimonthly variations in daily or semidaily tidal heights are known as neap-spring tidal cycles. In a semidiurnal tidal system, neap-spring tidal cycles are the result of the phase changes of the Moon. Spring tides occur when the Earth, Moon, and Sun are nearly aligned at new and full Moon every 14.76 days (Figure T12(B)). Neap tides occur when the Sun and Moon are aligned at right angles from the Earth at first and third quarter phases of the Moon. The result is that spring tides are higher than neap tides (Figure T12(E)). The time it takes for the Moon to go from new Moon to new Moon is called the synodic month, which has a modern period of 29.53 days.

The tidal force also depends on the declination of the Moon, the tide-raising force at a given location being greater when the Moon is closer to the zenith. The period of the variation in lunar declination is called the tropical month and is the interval of time it takes the Moon to complete one orbit moving from its maximum northerly declination to its

maximum southerly declination and then returning (Figure T12(C)). The current length of the tropical month is 27.32 days. The effect of the tropical month in most semidiurnal systems is to cause the diurnal inequality of the tides in which the morning high tide is greater or lesser than the evening high tide. Ideally, the diurnal inequality is reduced to zero when the Moon is over the equator (Figure T12(E)). However, in all dominantly diurnal systems having primarily one tide per day, tropical monthly tides are responsible for generating neap-spring cycles every 13.66 days (Figure T12(F)). In such cases, the dominant tidal force depends on the declination of the Moon, with the force being greatest (thereby generating spring tides) when the Moon is at zenith.

Because the lunar orbit is slightly elliptical, the Moon's orbital travel carries it between perigee (closest approach to the Earth) and apogee (farthest distance from the Earth) (Figure T12(D)). The period of time for the Moon to move from perigee to perigee is called the anomalistic month. The anomalistic month currently is 27.55 days. During a lunar month there are two spring tides that are often of unequal

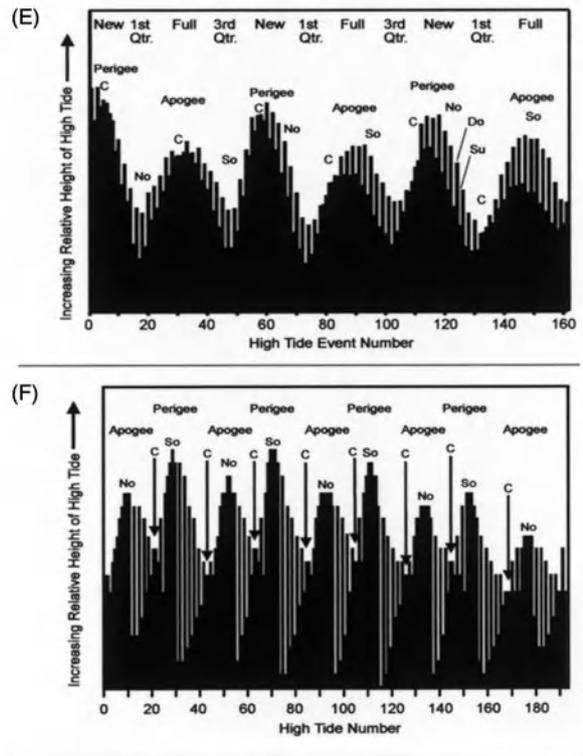

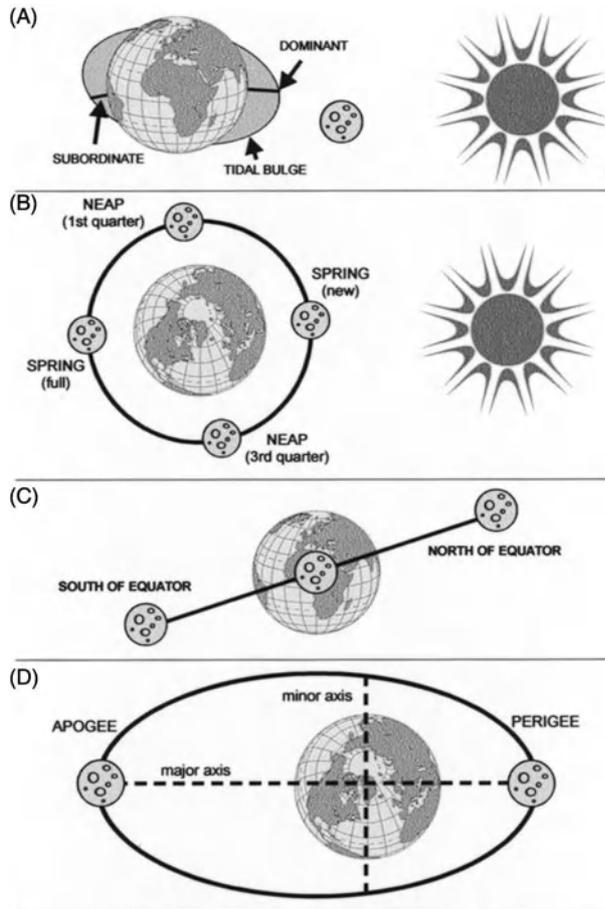

Figure T12 Idealized equilibrium tidal models that illustrate semidiurnal tides (A), the synodic month (B), the tropical month (C), and the anomalistic month (D). Figure T12E depicts a segment of the 1991 predicted high tides from Kwajalein Atoll, Pacific Ocean. Figure F depicts a segment of the 1994 predicted high tides from the Barito River, Borneo. "Su"—Subordinate semidaily tide; "Do"—Dominant semidaily tide; "C"—Equatorial passage of the Moon (Crossover); "No"—Moon at maximum northern declination; "So"—Moon at maximum southern declination. Figures modified from Kvale *et al.* (1998).

magnitude (Figures T12(E) and (F)). These are most noticeable when spring tides occur during or near a time of lunar perigee and apogee.

Beyond the semidaily, daily, semimonthly, and monthly tidal cycles mentioned above, there are also longer period tidal cycles that can impact sedimentary processes. These include the semiannual tidal cycle and the 18.6 year lunar nodal cycle. These are discussed in detail in Kvale *et al.* (1999) and Miller and Eriksson (1997). Even longer multiyearly tidal periods exist but any impact on sedimentation by these longer tidal periods is undocumented.

Tidal rhythmites

Tidal rhythmites occur in mud- and tide-dominated systems and have been identified through a significant part of Earth's history. In modern settings they have been identified in subtidal delta front settings (Cowen *et al.*, 1998) and subtidal to intertidal tidal flats associated with deltaic distributary channels (Staub *et al.*, 2000) and estuaries (e.g., Dalrymple and Makino, 1989; Tessier, 1993). Ancient analogs to these modern rhythmite depositional systems are also known (e.g., Feldman *et al.*, 1995; Miller and Eriksson, 1997; Brenner *et al.*, 2000; Choi and Park, 2000). Typical of modern tidal rhythmites are tidal ranges generally greater than or equal to 3 m, although a sub-Recent example that formed in a 2 m tidal range is known

(Roep, 1991); significant accommodation space; high sedimentation rates and significant suspended load; a general absence of bioturbators; and brackish to fresh water chemistries at the depositional site (typically within fluvial-tidal transition zones). Normal marine salinities, however, have been suggested for at least one heavily bioturbated ancient example (Martino and Sanderson, 1993).

A basic understanding of tidal theory allows for the interpretation of precise paleoastronomical information from tidal rhythmites (Figure T14). Because tidal rhythmites are small-scale sedimentary features, relatively small amounts of accommodation space (tens of centimeters to a few meters) allow for the build up of relatively long records of ancient semidaily to even multiyearly tidal cycles. These long tidal rhythmites tidal records have been used to interpret ancient paleoclimates (Kvale *et al.*, 1994), paleo-ocean seiches (Archer, 1996), and even ancient Earth–Moon distances (e.g., Kvale *et al.*, 1999).

TILLS AND TILLITES

Till (often termed *diamict* or *diamicton* today, to avoid the genetic connotation that the term till carries) has been defined by Dreimanis and Lundqvist (1984, p.9) as “a sediment that has been transported and is subsequently deposited by or from glacier ice, with little or no sorting (disaggregation) by water”. However, controversy surrounds the usage and definition of the term

(Hambrey and Harland, 1981; Dreimanis, 1988; Menzies and Shilts, 2002). Tills exhibit a wide range of grain size, from very poorly to well-sorted. Tills contain a variable percentage of clasts (usually sub-angular and often striated) and mineral grains that have been transported considerable distances from up-ice sources. In general, the majority of the clasts and finer particles are of local origin (<15 km up-ice). Many tills contain intraclasts of exotic sediments often stratified or laminated. Some tills are crudely bedded and have been termed stratified tills. In the past the terms deformation and comminution tills indicative of secondary mobilization were used but, today, all tills are acknowledged as having suffered some form of deformation (Ruszczynska-Szenajch, 2001). Boulton and Deynoux (1981) introduced the concept of primary and secondary deposition applied to tills but with ancient tills such terminology is difficult to apply. Tillites are lithified tills. The AGI (1997, p.666) defines tillite as “a consolidated or indurated sedimentary rock formed by the lithification of glacial till”. Both till and tillite are genetic terms that presuppose in their application a knowledge of the nature of the processes and mechanics of deposition.

The term till, a dialect term from Scotland, appears to have been first applied by Geikie (1863, p.185) to a “a stiff hard clay full of stones varying in size up to boulders produced by abrasion carried on by the ice sheet as it moved over the land”. Synonymous with till are “boulder clay” and “ground moraine”. Tillite seems to have been first used by Penck (1906) when describing the Dwyka Formation of South Africa.

Table T1 Classification of Tills (modified from Dreimanis, 1988; with pers comm, van der Meer, 2002)

Tills may form within several distinct glacial sub-environments: subglacial, englacial, proglacial (terrestrial/subaquatic) and supraglacial; and may be deposited from active temperate wet-based and polar cold-based ice masses, under stagnant ice conditions, and subaquatic environments of both grounded and floating ice masses (Figure T15(A),(B)). Table T1 illustrates the complexity and interrelationships that exist within till-forming glacial environments.

Under wet-based, active temperate conditions considerable input from meltwater can be expected, as well as thermal fluctuations, and transient fluctuations in ice velocity and stress conditions. Subglacial tills formed under active temperate conditions are recognized as Lodgement, Flow, and Mélange, with a variety of local till sub-types. Sub-types of tills are often identified owing to some peculiar characteristic of grain size, provenance and/or structural attribute. Where ephemeral passive ice conditions occur within active ice masses Melt-out tills can be deposited. Although comparatively rare, under dry polar climates sublimation or meltout tills can form. Both lodgement and meltout tills have been extensively described in the literature (Dreimanis, 1988; Brodzikowski and Van Loon, 1991), whilst subglacial mélanges have only recently been recognized as separate, distinct subglacial sediments (Curry *et al.*, 1994; Hoffman and Piotrowski, 2001; Menzies and Shilts, 2002). These subglacial tills are formed as a consequence of: (1) high shear stress resulting in debris being released from basal ice in a “smearing on” process where high pervasive shear stress results in ice pressure melting and debris

release (*Lodgement till*); or (2) by slow undermelt releasing debris gradually (*Melt-out till*) (Shaw, 1987); or (3) as a result of portions of a soft deforming subglacial bed either reaching shear strengths higher than the mobilizing basal ice stresses due to onset of freezing temperatures, or reduced porewater content, or porewater pressure reduction due to reduced overburden stress (Menzies, 1989; Fuller and Murray, 2000) producing *Mélange*; and finally; (4) by the glacial crushing of basal debris and bedrock (H-bed conditions, Menzies, 1989) resulting in a form of pulverized sediment being produced (*pers.comm.* van der Meer, 2002).

Within the Supraglacial environment (Figure T15(A)) tills have been recognized as Flow tills where sediment approaching an effective stress level of zero slip, slide, and flow off the ice (Boulton, 1968); and, where temperatures and debris cover permit, sediments are directly released (melt-out till) from the ice by melting (Bouton, 1970) or, in rare arid conditions, by sublimation (Shaw, 1977). The degree to which meltwater is associated with and influences the mechanics and subsequent deposition of a melt-out till remains somewhat controversial (Rappol, 1987; Paul and Eyles, 1990).

A complex set of conditions can be found within Proglacial environments whether terrestrial or subaquatic. In terrestrial environments (Figure T15(A)) the dominant process of till formation tends to be by mass movement thus flow tills are formed, and where debris-laden ice, in some instances buried and re-exhumed in the proglacial environment, melt-out thus producing melt-out tills. Where lakes exist deposition may

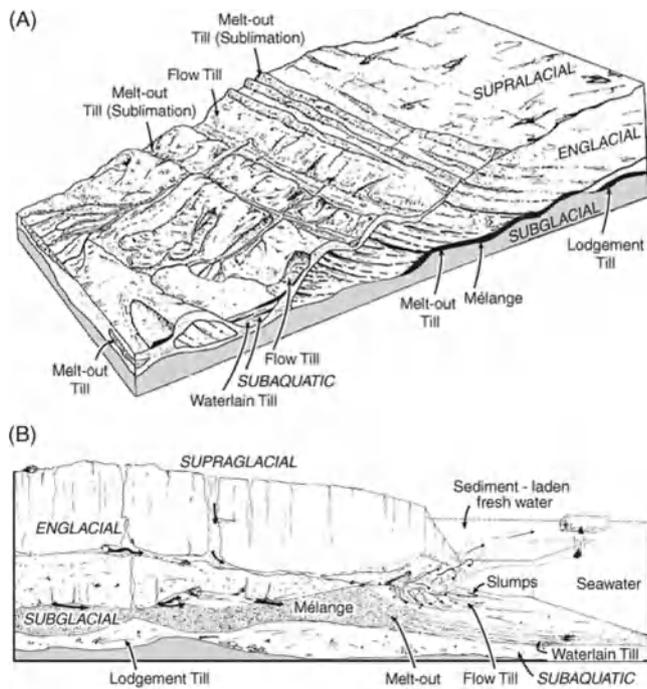

Figure T15 Locations of till types within terrestrial and aquatic margins (adapted and revised from Menzies and Shilts, 2002).

occur by rain out through the water column from debris-laden meltwater streams or floating ice rafted debris producing *Waterlain Till*s.

As Figure T15(B) illustrates a complex set of sub-environments exists where ice masses either float or are grounded within large bodies of fresh or brackish water. Where a floating ice mass exists large amounts of debris are likely to come off the surface of the ice, from ice cliff melting, from calving ice bergs, and from englacial and subglacial meltwater tunnels. The result of these sediment release processes is to cause an enormous rain-out of sediment through the water column resulting in a *Waterlain Till* being deposited on the lake or ocean floor. Beneath grounded ice masses sediment will be squeezed, pushed or otherwise extruded from the subglacial contact at the ice/bed grounding line. Where debris is mobile and extruded from the grounding line a *Mélange*, perhaps in the form of a "till delta or tongue", may form (Alley *et al.*, 1986; King and Fader, 1986; Anderson *et al.*, 2001).

There are several mistaken ideas concerning tills and tillites that persist, *viz.*, that tills typically exhibit a bi-modal grain size distribution, are overconsolidated, have a very low permeability, are unstratified, homogenous, massive, and unstructured, and, finally, that tills of differing colors are of different depositional phases and therefore indicative of more than one glaciation. As in all myths there are occasional truths but, as a general rule, all are essentially incorrect. Where tills can be seen forming at present the usage of the term till seems appropriate. Where, as is so often the case, either the actual means of deposition is obscured or the sediments are ancient,

then the till-forming mechanisms and environments within which they were originally deposited are unknown: then the nongenetic terms diamict or diamicton for un lithified sediments and diamictite for lithified sediments may be preferred. A persistent, and perhaps unsolvable problem, remains in identifying as tills those sediments that are marine as opposed to glaciomarine. With the advent of glacial micromorphology a clearer understanding of the internal *in situ* stratigraphy and microstructures within till has great potential in furthering our understanding of this complex, and often enigmatic, glacial sediment (Van der Meer, 1996; Menzies, 2000).

TOOL MARKS

A tool mark is a mark produced by the impact against a muddy bottom of a solid object driven by a current moving over the bed. It is generally preserved as a cast, seen on the

base of a sand or silt bed deposited on the muddy bottom soon after the marks have been formed. The term was originally proposed by Dzulynski and Sanders (1962, p.72). A large number of different types were named during the 1960s by geologists, mostly from observations on the soles of turbidite sandstones (see *Turbidites*; Dzulynski and Walton, 1965; Allen 1982, volume 2, chapter 13). Tool marks are also found in other environments, however, notably in fluvial deposits and marine storm deposits (see *Storm Deposits, Gutter and Gutter Cast*). They are valuable indicators of paleocurrent direction (see *Paleocurrents*) and also give some information about the nature of the clay bottom and the sediment transport mechanism operating in the flow that deposited the overlying sand.

Allen (1982, pp. 509–520) classified tool marks into: (i) *drag marks*, formed by protracted contact of a tool moved by traction; (ii) *roll marks*, formed by protracted contact of a tool rolling over the bed; (iii) *prod marks*, formed by a brief contact of a tool with the bed; (iv) *tumble marks* (also called skip marks) made by a saltating tool that produced a series of marks; (v) *skim marks*, produced by grazing contact of a tool with the bed; and (vi) marks related to near approaches, a category which includes chevron marks (see Figure T16; and see Allen, 1982, for references to original sources for these terms). Some authors (e.g., Ricci Lucchi, 1995, pp.134–139) distinguish *bounce casts*, with an almost symmetrical shape, from prod marks which are asymmetrical (deeper on the down-current side) and therefore permit determination of the current direction. *Brush marks* are similar to prod marks but have wrinkles produced by drag of mud on the up-current side. For good photographs see Allen (1982) or Ricci Lucchi (1995).

TOXICITY OF SEDIMENTS

Overview

As water quality has improved over the past three decades in North America, diffuse sources of pollution such as storm-water runoff and sediments are now recognized as long-term, widespread pollutant sources to aquatic systems. Substantial impacts on the ecosystem from sediment-associated contaminants range from direct effects on benthic communities to substantial contributions to contaminant loads and effects on upper trophic levels through food chain contamination (e.g., McCarty and Secord, 1999).

Sediment contamination primarily occurs because many chemicals bind to organic or inorganic particles that eventually settle to the bottom of our streams, rivers, reservoirs, lakes, estuaries, or marine waters. Once contaminants bind to a particle surface or sorb into its interior matrix, they become less likely to be biotransformed and desorption is usually very slow; therefore, sorbed contaminants will reside for long periods in the sediment. Sediment-associated contaminants tend to accumulate onto small, fine-grained particles and settle in depositional areas. This is promoted largely by the very high surface area and the tendency for higher concentrations of organic matter in the fine particles.

From a contamination perspective, we understand that sediments are extremely important to the food web and serve as a habitat for the benthic community as well as contaminant reservoir for bioaccumulation and trophic transfer. Once chemical contamination reaches a concentration whereby it causes adverse effects to biota, then it is considered polluted. The greater the evidence of sediment contamination within a watershed, the more likely a fish consumption advisory exists (US EPA, 1997).

Extent of the problem

There are over 9 billion cubic meters of surface sediments (upper 5 cm) in the United States of which approximately 1.2 billion can currently be considered contaminated to levels that pose potential risks to fish and to humans and wildlife who eat fish (US EPA, 1997). This estimate is derived from a literature search on sediment contamination and represents 65 percent of the watersheds in the continental US. However, only 11 percent of the nation's rivers had data with any

toxicity information available and of those 77 percent had at least one station that was sufficiently contaminated such that adverse effects are probable or possible. This leaves 89 percent of the data sets with no available toxicity data (US EPA, 1997). Therefore, the true extent of sediment contamination remains unknown.

Sediment associated contaminants are found in every type of aquatic environment within the US from mountain streams to large rivers, from small lakes to the Great Lakes and in estuaries and bays (US EPA, 1997). Further, recent investigations have found sediment pollution in areas previously not thought to be contaminated (e.g., estuarine areas of North Carolina, Pelley, 1999). While the true extent of sediment contamination is not known, it is apparent that huge quantities of sediments in industrialized countries are contaminated with metal and organic chemicals at levels that pose risks to both aquatic life and to humans consuming aquatic species.

Effects on ecosystems and components

Despite a concentrated research effort over the past two decades, our ability to assess the impact of contaminated sediments on ecosystems remains a challenge that is inherent in the very nature of sediments. The most obvious effect in most assessments of sediment contamination is that of a direct adverse impact on the benthic (or bottom-dwelling) community, (e.g., Peterson *et al.*, 1996). Because alteration of the benthic community structure can result from the mixture of contaminants present as well as from potential for confounding factors, such as poor habitat, high flows, or low dissolved oxygen in the water column, it is often difficult to establish cause and effect for sediment associated contaminants. Studies of field sites where direct biological effects are obviously contaminant-induced, are often located in watersheds containing high levels of industrial and shipping activities. Here, sediments are likely to be visibly contaminated with petroleum products and may contain a myriad of metals, pesticides, and other synthetic nonpolar organic chemicals, e.g., Grand Calumet River, Indiana. Thus, assigning cause-effect between single, specific chemicals and benthic communities becomes nearly impossible. Most of the detailed biological assessments dealing with contaminated sediments have dealt with freshwater systems, although several sediment risk assessments are currently underway in coastal harbor areas. Unfortunately, most of these risk assessments are only published in the "grey" literature and difficult to obtain.

It is not just infaunal (burrowing) benthic invertebrate organisms that demonstrate effects from sediment-associated contaminants. Many bottom-feeding fish have hepatic and epidermal neoplasms (tumors). There is a strong link between contaminated sediment and fish neoplasms in all the major water bodies of the US (Harshbarger and Clark, 1990). The sediment link for these neoplastic growths was clearly demonstrated in the Black River in Lorain, OH. The high incidence of neoplasms in brown bullhead showed a high correlation with high PAH sediment concentrations. These neoplasms resulted in age specific mortality in the bullheads. Once most of the PAH contaminated sediments were removed by dredging, the incidence of neoplastic growths declined sharply (Baumann and Harshbarger, 1995).

Sediment-associated contaminants have also become linked via food web transfer to impacts on upper trophic levels. Such transfer occurs with mercury and some organochlorines, such

as PCBs and DDT that are poorly biotransformed and are hydrophobic; however with other chemicals these connections are more difficult to establish. From modeling exercises, food web transfer of persistent contaminants is important for maintaining the chemical concentrations observed in upper trophic levels and the benthic component is essential to account for the observed concentrations (Thomann *et al.*, 1992; Morrison *et al.*, 1996). Trophic transfer of sediment-associated contaminants has been documented in both freshwater systems (e.g., Lester and McIntosh, 1994) and marine systems (e.g., Maruya and Lee, 1998). In Saginaw Bay, Lake Huron, tree swallows were found to accumulate PCB from sediments. In some areas of the Great Lakes and in the Hudson River, NY, system reproductive damage has been observed for this species directly linked to PCB (Bishop *et al.*, 1999; McCarty and Secord, 1999). Further, impacts to birds were observed in the Saginaw Bay system with reproductive effects on the Caspian terns following a 100 year flood event suggesting impacts through food web transfer from a latent sediment source (Ludwig *et al.*, 1993). Thus, fresh pulses of contaminated sediments from the watershed can recharge the system resulting in impacts on the receiving system.

Developing cause-effect links

The complexity of the distributions of contaminants, nutrients, other sediment/habitat characteristics and resident biota make accurate determinations of exposure and effects difficult, but not impossible. This reality suggests that accurate assessments of contaminant effects use a weight-of-evidence approach (i.e., gathering supporting data from several lines of investigation) to determine the extent or magnitude and cause of the contamination problem. The initial ideas on the weight-of-evidence approach took data from sediment chemistry, benthic community structure and sediment laboratory bioassays to establish a triad of information that could be used to determine hazard (Chapman, 1986). This approach is continually improving with additional development on sediment bioassays (toxicity tests), interpretability of sediment chemistry, and the addition of new types of information such as *in situ* toxicity tests and residue (tissue chemical concentration)-effects information.

Sediment toxicity testing on whole field collected sediments and laboratory dosed sediments are an essential line-of-evidence that the contaminants in sediment can produce the effects that are observed in benthic communities. The earliest sediment bioassay was performed in the early 1970s and demonstrated avoidance behavior by amphipods for contaminated sediments. However, much of the work demonstrating the effect of sediment-associated contaminants came in the 1980s. By the mid 90's, standardized methods for whole sediment toxicity testing occurred within the US EPA, American Society for Testing and Materials (ASTM), and Environment Canada. These tests measured acute (short-term ≤ 10 days) toxicity in benthic macroinvertebrates such as the amphipods *Hyalella azteca*, *Rhepoxynius abronius*, *Ampelisca abdita*, *Eohaustorius estuarius* and *Leptocheirus plumulosus* and the midges *Chironomus tentans* and *Chironomus riparius* (US EPA, 1994a,b; ASTM, 2000a). The primary measured response was mortality, but in the case of the midge, growth was included and reburial was an additional endpoint for the *Rhepoxynius abronius*. Unfortunately, most sediment toxicity test methods are focused on acute (short-term exposure) and

not chronic (long-term exposure) toxicity. The measures of acute toxicity are not often adequate to detect the impacts on benthic communities. For instance, the 10-d test with *Rhepoxynius abronius* was not sensitive enough to describe the loss of amphipods from Lauritzen Channel in San Francisco Bay (Swartz *et al.*, 1994). In reality, chronic toxicity is the more pervasive problem and it is the chronic responses, such as changes in reproduction that lead to population level responses. While recently developed chronic methods (US EPA, 2000, 2001) will greatly aid our ability to determine if sediments are toxic, their long duration and increased costs may impede their widespread adoption.

A large number of other species have been used for determining the toxicity of sediments, ranging from bacteria to fish and amphibians (Burton, 1991). The commonly used test species encompass trophic levels ranging from decomposers and producers to predators and representing multiple levels of biological organization. Comparisons of their sensitivities have shown a wide range of responses to different types of sediment contamination, with an equally wide range of discriminatory power (ability to detect differences between samples) (Burton *et al.*, 1996). This reality suggests that more than one or two species may be necessary to determine with certainty whether or not sediment contamination is ecologically significant.

The freshwater species that have been used successfully and most often in assessments of sediment toxicity include both water-column and benthic species: *Selenastrum capricornutum*, *Daphnia magna*, *Ceriodaphnia dubia*, *Pimephales promelas*, *H. azteca*, *C. tentans* and *C. riparius*, and *Hexagenia limbata*. Standard guides for whole sediment toxicity testing have also been published by the American Society for Testing and Materials for invertebrates, including *H. azteca*, *C. tentans*, *C. riparius*, the cladocerans *Daphnia magna* and *Ceriodaphnia dubia*, the mayfly *Hexagenia*, the Great Lakes amphipod *Diporeia*, and the oligochaete *Tubifex tubifex* (ASTM, 2000a-e). Dredged material evaluations in the US follows the protocols published by the US EPA and US Army Corps of Engineers; in 1991 for dredged material proposed for ocean disposal, and protocols published in 1998 for dredged material proposed for disposal in "inland" waters of the US (USEPA-USACE, 1998). Canada's Ontario Ministry of the Environment has also published solid-phase test methods (Bedard *et al.*, 1992).

Toxicity tests for marine and estuarine species also range from fish to bacteria. The marine and estuarine species frequently and successfully used in studies of sediment contamination include: the fish *Cyprinodon variegatus* and *Menidia beryllina*, and amphipods *Rhepoxynius abronius*, *Ampelisca abdita*, *Eohaustorius estuarius*, *Grandidierella japonica* and *Leptocheirus plumulosus*, the bivalves *Haliotis rufescens*, *Crassostrea gigas* and *Mytilus* sp. the echinoderms *Strongylocentrotus purpuratus*, *Dendraster excentricus*, and *Arbacia punctulata*, the polychaetes *Dinophilus gyrociliatus* and *Neanthea arenaceodentata*, the mysid *Americamysis bahia* (formerly *Mysidopsis bahia*), the alga *Champia parvula*, and the bacterial assay Microtox using *Vibrio fischeri*. As with freshwater tests, several "standard" methods for marine and estuarine organisms exist. The US EPA has standardized protocols for toxicity testing with the amphipods *Rhepoxynius*, *Ampelisca*, *Eohaustorius*, and *Leptocheirus* using a 10-d survival assay, a chronic 28-d survival, growth reproduction assay with *Leptocheirus*, and 28-d bioaccumulation assays with *Macoma* and *Nereis*

(US EPA 1994b, 2001). The European OECD (Organization of Economic Cooperation and Development) is discussing the possibility of developing standardized sediment tests. Environment Canada has developed methods for sediments, elutriates, and leachate samples using *Vibrio fischeri* luminescence, sea urchins and sand dollars (echinoids), and seven amphipod species. Methods were recently published by the Chesapeake Bay Program for benthic testing using *Lepocheirus plumulosus*, *Ampelisca abdita*, *Lepidactylus dytiscus*, and *Monoculodes edwardsi*. Dredged materials in the US are tested using US EPA and US Army Corps of Engineers protocols. The American Society for Testing and Materials has standard procedures for amphipods, fish, mysids, echinoderm, and oyster early life stages, polychaetes, and algae (ASTM, 2000b–e).

Another component that is useful in establishing causality is linking sediment contaminant exposure and tissue-residue effects in organisms. Because many factors appear to alter the bioavailability of contaminants in sediments (Hamelink *et al.*, 1994), approaches to establish links between the body-residue concentrations and effects in aquatic organisms provide the insight to better link the toxic response directly to contaminants. Data has been amassing over the course of the past several years that allow the direct comparison of some residue levels with acute and chronic effects (www.wes.army.mil/el/ered; Jarvinen and Ankley, 1999). However, the data base is very limited at this time, thus there is still need to establish a weight-of-evidence approach for developing the link between the observed response and the presence of contaminants in sediments.

The second recent development to assist in the formation of the link between sediment contaminants, responses in the laboratory and observed responses in the field is that of *in situ* tests. These are tests that are conducted in the field. One approach uses confined organisms, such as traditional surrogates (e.g., *Daphnia magna*, *Ceriodaphnia dubia*, *H. azteca*, *C. tentans*, *Lumbriculus variegatus*, *Pimephales promelas*) or indigenous species in chambers, cages, bags, or corrals. Organisms are placed in test chambers, which optimize exposures to sediments, pore waters, and/or overlying waters, and are exposed in the field from time periods ranging from a day to months. This approach has a number of advantages, in that it can better simulate real-world exposures, which may fluctuate dramatically over a period of hours, reduces sampling/experimental related artifacts, and allows for more natural interactions of potentially critical physical and chemical constituents than do laboratory conditions (e.g., Chappie and Burton, 2000).

Traditionally sediment contamination was determined by assessing the bulk chemical concentrations of individual compounds often comparing to some background or reference value. The desire to have chemical parameters to evaluate the hazard of sediments has focused primarily on two approaches: (1) a statistical approach to establish the relationship between sediment contamination and toxic response; and (2) a theoretically based approach that attempted to account for differences in bioavailability through equilibrium partitioning.

The original sediment quality guidelines (SQGs) that were compared to a reference or to background provided little insight into the impact of sediment contaminants. Therefore, SQGs for individual chemicals were developed that relied on paired field sediment chemistry with field or laboratory

biological effects data. They are often based on frequency distributions and account for the impact of all chemicals present, but do not establish cause and effect. These approaches have also been shown to be useful and predictive of biological effects in many (but not all) marine and freshwater systems (e.g., Long *et al.*, 1998).

However, the issue of bioavailability remains (that portion of the chemical that is available for biological uptake and subsequent adverse effects). The equilibrium partitioning approach attempts to address this issue specifically. This approach suggested that interstitial water concentrations represented the equivalent chemical activity for exposure of aquatic organisms, and chemical concentrations could be determined from an equilibrium partitioning calculation (Di Toro *et al.*, 1991). The equilibrium partitioning calculation was particularly important for attempting to account for the changes in bioavailability that occur with changes in amounts of organic matter in sediments.

This method has also been applied to metals by accounting for the interactions with acid volatile sulfide. Five metals, Cd, Ni, Pb, Zn, and Cu, form insoluble sulfides and so their toxicity is limited by the amount of sulfide in the sediment. Toxicity is observed when the amount of metal stoichiometrically exceeds the amount of sulfide that can bind it. A clear demonstration of the utility of this approach was shown for Cd toxicity to amphipods, *Ampelisca abdita* and *Rhepoxynius hudsoni* in marine sediments. Like the case for organic contaminants, the toxicity predicted from this approach has been sometimes over predicted usually because of the presence of other ligands that bind the metals (Ankley *et al.*, 1993).

When comparisons have been made between the equilibrium-partitioning (EQP) method and other measures of sediment quality to estimate toxic response, the sediment quality guideline values and their predictive ability were comparable, i.e., in greater than 70 percent of samples toxicity or absence of toxicity were correctly predicted. However, when comparing the predictive ability for field sites, EQP consistently gave more type II errors, false negatives, than other sediment quality guidelines (Ingersoll *et al.*, 1997). This likely results from failure to account for the wide variety compounds that exist in sediment and their interactions.

Risk-assessment for sediment-associated contaminants is a relatively new field and is developing rapidly (Ingersoll *et al.*, 1997). The strengths and limitations of the various assessment methods dictates that a weight-of-evidence approach define the significance and role of sediment-associated contaminants on the aquatic environment and also through food web transfer to terrestrial species. This approach should include an integrated approach, which identifies and ranks stressors using habitat, physical, and chemical measures, biological community structure, toxicity, and bioaccumulation descriptors. Use of these tools can provide essential characterizations of key watershed sources, sensitive receptors, natural variation, and both natural and anthropogenic stressors. Only with the use of multiple tools and an understanding of their interactions can reliable determinations of sediment pollution and long-term consequences be made. Then cost-effective, environmentally protective management decisions can be made about the type, extent, and need for sediment remediation.

TRACERS FOR SEDIMENT MOVEMENT

For the purposes of studying sediment dynamics, tracers are defined here as marked particles introduced into a river, estuary, or coastal system, to obtain general information on the characteristics of sediment movement within such environments. Tracers provide a relatively simple means of overcoming technical and sampling problems without the need for a detailed kinematic study of the sedimentary regime (Crickmore *et al.*, 1990). The type of tracer to be used will largely depend on the objectives, environment characteristics, and intended observation period of the experiments (Hassan and Ergenzinger, in press). In addition, one must consider each method and materials, the sample size and expected recovery rate, detection, data collection and analyzes.

Both artificial and natural tracers are available for tracking coarse and fine material. In selecting an artificial tracer, the geochemical and physical properties, and hydrodynamic conditions must be considered. Some tracing techniques can be used for fine and coarse sediment, though tagging silt and clay sizes is complex. With fine material, physical characteristics make tracing and detection difficult for several reasons: (i) the fine sediment is usually carried in suspension, and its movement dispersion over large areas is rapid; (ii) coating or attaching tags onto the fine sediment may change the physical characteristics of the particle; and (iii) the cohesive nature of clay and silt causes flocculation, and labeling may lead to changes in the chemical properties of the sediment.

A variety of detection methods have been tried, ranging from simple visual identification of the tracers, to magnetic or metal detection, radioactive detection, neutron activation, and radio wave detection. Some detection methods, using paint, magnets, and radio transmitters, permit individual identification of tracer particles whilst others such as radioactive material do not. The approach will clearly influence how much information can be gathered, and hence subsequent data analyzes and interpretations. Detection strategies include: individual location of particles; fixed automatic detection of particle passage; periodic dynamic detection and automatic dynamic detection (Hassan and Ergenzinger, in press).

A brief background and explanation is provided below on the most commonly-used tracers.

Painted particles are probably the simplest method of tracing gravels. Paint is easy to apply and can be detected visually, but field detection is limited to the surface. In the fluorescent method a special dye is applied to a set amount of sediment. Upon light stimulation, the treated sediment emits light of a wavelength characteristic of the dye (Crickmore *et al.*, 1990). Samples can then be taken within the study area to assess the dispersion of sediment. The fluorescent method is suitable for sand tracing, and even larger material. Suitable fluorescent dyes include rhodamine, auramine, eosine, primulin, fluorescein, and anthracene.

The *radioactive technique* is very versatile and can be used in both fine and coarse sediment (Crickmore *et al.*, 1990). It allows *in situ* continuous detection of exposed and buried particles and, hence, permits immediate data processing and rapid evaluation of the tracking strategy. The presence of the radioactively labeled sediment is detected from the radiation emitted by the tag (e.g., Crickmore *et al.*, 1990). Wide ranges of

radioisotopes provide a choice of tracers with a half-life to match most objectives. According to the method of labeling, the radioactive tracers can be grouped into three categories: manufacture of radioactive grains of the same density and shape as the bed material, application of the isotope to the outside or within the natural grains, and introduction of natural radioactive minerals. The most commonly used isotopes are ^{140}La (half-life of 40.2 hours), ^{51}Cr (half-life of 27.8 days), ^{46}Sc (half-life of 83.9 days), and ^{110}Ag (half-life of 253 days). The method is toxic and dangerous to the environment and therefore it is very difficult to obtain permission to use.

In the *neutron activation method*, a chemical element is fixed to the sediment and its concentration is measured after activation in a nuclear reactor. The sediment is labeled by an element with a high thermal neutron which, after irradiation, is detectable above the natural radioactive background. Studies have used, among other elements, cobalt, tantalum, iridium, rhenium, and gold (e.g., Crickmore *et al.*, 1990).

The *fingerprinting technique* can be used to define sediment sources and transfer within a drainage basin, and sedimentation rates in lakes and reservoirs. This method is based on (i) the selection of physical and/or chemical properties that distinguish a particular source material, and (ii) the comparison of measurements of the same properties of the sediment with the equivalent values obtained for the source material (e.g., Oldfield *et al.*, 1979; Walling and Woodward, 1992).

Fallout radionuclides have been used to pursue a wide range of studies within drainage basins (e.g., Walling *et al.*, 1999). On reaching the earth's surface by either wet or dry fallout, radionuclides are adsorbed onto the soil and become useful for tracing the movement of fine sediment. Applications include the study of suspended sediment sources, sedimentation rates and sediment yield, gully erosion, floodplain sedimentation, sediment budget, residence time of fine sediment, redistribution of soil, and lake and reservoir sedimentation. Three fallout radionuclides have primarily been used: ^{137}Cs , unsupported ^{210}Pb , and ^7Be , of which ^{137}Cs is the most favored. Caesium-137 is an artificial radionuclide produced as a result of global fallout from the testing of nuclear weapons. With a half-life of 30.1 years, ^{137}Cs provides an average value of surface erosion for a period of about 45 years. It has been found that eroded soils lose ^{137}Cs in proportion to the severity of erosion. At erosion sites ^{137}Cs will be present in quantities smaller than the reference value, whereas at deposition sites the opposite is observed. Both ^{210}Pb and ^7Be are natural radionuclides that reach the earth's surface *via* atmospheric fallout at a constant rate through time. Because of a relatively short half-life, the ^7Be technique is useful for short-term measurements that can be related to specific events.

Ferruginous tracers include metal strips, acid coating, artificial magnets, and mineral magnetite (Hassan and Ergenzinger, in press). The underlying principle is that when a tracer passes over an iron-cored coil of wire, a measurable electrical pulse is generated. Magnet or metal locators are used to find tagged particles, and automatic detection systems are also available. The latter type of system can provide *in situ* continuous measurements of sediment movement to record an unlimited number of clasts. Due to the high recovery rate, magnetic methods are the most widely used technique. The method permits the location of buried particles, as well as those at the surface. Both natural and artificial magnetic tracers have been used. If no naturally magnetic material is

present and suitable for use where the research is to be carried out, then it is necessary to use artificially magnetized tracers. For tracing gravel larger than 16 mm, a magnet can be inserted into pre-drilled holes. Manufactured synthetic magnetic clasts, made from resin or concrete with a magnetic core in the center, have been used for tagging small and large particles (>8 mm). This approach allows the manufacture of clasts of different shapes and densities. Magnetic enhancement is another method, which is based on the enhancement of natural magnetism by strong heating of naturally iron-rich pebbles. Through the heat treatment the particle mineralogy is altered and the magnetism is enhanced up to 300 times its original strength to a level that can be detected and distinguished from the bed material. Magnetic properties of the soil can be used to trace sediment sources and fine sediment transport in alluvial streams (e.g., Oldfield *et al.*, 1979). The upper part of the soil profile has a higher concentration of magnetic content than the lower part or the parent material due to pedogenic processes and burning. The enhanced magnetism (see artificial magnetic enhancement, above) helps to differentiate between the surface and subsurface soil and hence the suspended sediment sources.

The *Radio transmission* method permits the active detection of tracers in cobble size material (Schmidt and Ergenzinger, 1992). A transmitter capsule, about 65 mm long and 20 mm in diameter and with a battery life expectancy of about three months, is inserted into the clast. Within a set of tracers, the stones will each emit slightly different frequencies so that they can be individually identified. The detection system consists of a transmitter, an antenna, receiver, and a data logger.

TUFAS AND TRAVERTINES

Tufas and travertines are rare in Paleozoic and Mesozoic successions, but become frequent in the Cenozoic. Nevertheless, the majority of recorded examples are Quaternary and Holocene (Waring, 1965; Pentecost, 1995; Ford and Pedley, 1996). The term “tufa” is recommended for the description of all ambient temperature freshwater carbonate deposits with “travertine”, an alternative name, being reserved for all hydrothermal freshwater deposits (Pedley, 1990). In contrast, many employ the term “travertine” for all types with distinction into high temperature “thermogene” and ambient temperature “metogene” deposits (Pentecost, and Viles, 1994). Tufas commonly contain abundant evidence of mosses and higher plants, whereas thermal sites encourage physico-chemical precipitates and colonization is restricted to microbes. Travertine (hydrothermal) deposits frequently contain unusual geochemical signatures (e.g., high sulfur and carbon dioxide components). Many deposits have been dated using radiocarbon methods (Srdoc *et al.*, 1986), and uranium series isotopes (Hennig *et al.*, 1983). Stable isotopes of oxygen and carbon have proved valuable as proxy-environmental indicators (Andrews *et al.*, 2000).

Speleothems (*q.v.*) are similar to travertines but are physico-chemical cave and cavity precipitates.

Tufas

Tufas typically are rich in plants, but may also contain insects, pollen, molluscs, and ostracods (Preece, 1991; Vadour, 1994; Taylor *et al.*, 1998). Mosses, liverworts, and semi-aquatics commonly provide a framework upon which fringes of low-magnesian calcite cements precipitate. Precipitation is partly controlled physico-chemically by CO₂ degassing which renders the dissolved calcium carbonate less soluble (Lorah and Herman, 1988). However, there is also an important biomediated contribution triggered as a by-product of photosynthesis and associated metabolic processes connected with diatoms, cyanobacteria, and heterotrophic bacteria. These microorganisms are ever present within surficial (procaryote-microphyte) biofilms and many tufas and travertines are commonly entrapped within the associated fringe cements. Lithification is virtually instantaneous in many fluvial, waterfall, and lake margin settings and forms laminated, freshwater plant-dominated framestone reefs or “phytoherms” (Buccino *et al.*, 1978; Pedley, 1990). Oncoids are common and are often associated with allochthonous tufa debris (phytoclast tufa) in channels and point bars. Fine lime mud-grade tufa formed in lakes is derived either from marginal stromatolite microherms and phytoherms or is a by-product of

microbial (“picoplankton”) metabolism within the water column (Thompson, 2000).

Tufa classifications are diverse (e.g., Chafetz and Folk, 1984; Ordonez and Garcia del Cura, 1983; Pedley, 1990). Confusion is reduced if studies are based on facies associations (Buccino *et al.*, 1978; Pentecost and Viles, 1994; Ford and Pedley, 1996). These demonstrate that lithofacies complexity is a function of slope angle, irregularities in substrate, and velocity and flow-frequency of carbonate-enriched water supply. Although there is a facies continuum, probably four common models can be derived from the spectrum.

Fluvial tufa model

This may be flow dominated (braided fluvial tufas) and dominated by oncoid and phytoclast channel fills. Small phytoherms and microherms (especially stromatolites) may occur on the stream bed or along the channel margins. Alternatively, gorges may be dominated by several cycles of fluvial barrage tufas (Golubic, 1969). Barrages are narrow, downstream arcuate dams of phytoherm framestone that create lakes. The pool depocenters commonly contain thick lime mud and organic-rich deposits (Pedley *et al.*, 2000). The contained pollen assemblages are useful proxy-climatic indicators.

Perched springline tufa model

This consists of a multilobate mound that develops in close proximity of valley side resurgences. Typically, such mounds have a virtually flat top and steep distal face, the latter often associated with cascades and trailing mosses (Violante *et al.*, 1994). Detrital (phytostlastic) deposits, developed distal to the lobe, typically contain land snails and paleosols.

Lacustrine tufa model

This model develops in association with large standing water bodies. Their margins are sites of “bacterioherms” which develop characteristic flat-tops controlled by the position of the air/water interface. In the shallow marginal waters oncoids occur and *Chara* stands are common. Lime silts and muds dominate the deepest waters.

Paludal tufa model

Poorly drained slopes colonized by hydrophytic vegetation (especially moss hummocks and grass cushions) are sites of lime mud precipitation (e.g., Belgian “Crons”). More extensive tufa sheets are developed in valley bottom situations and may be associated with shallow ephemeral pools and ill-defined watercourses. Small tufa mounds may form where lime-rich springs issue into otherwise organic dominated ponds. Frequent desiccation encourages paleosol development throughout many deposits.

Saline tufas

Tufa variants which do not fit into the four models are the “mound tufas” and “towers” which develop within saline lakes (e.g., Pyramid, USA, Benton, 1995; also in China Arp *et al.*, 1998). They consist of bacterial microherms. They develop at freshwater resurgence points on the lake bed where microbial colonization is encouraged by local salinity dilution. Marginal microbial phytoherms can also occur.

Travertines

Waring (1965) lists several hundred thermal (travertine-forming) springs. Many deposits are physico-chemical calcium carbonate precipitates from simple degassing and cooling of lime-rich waters close to thermal springs. Cyanobacteria live in the near boiling water and trigger further calcium carbonate precipitation. However, toxic sulfides can inhibit biofilm colonization. Temperature and toxicity generally decline down-flow. Consequently, higher plants are able to colonize these cooler water (tufa) domains. The two commonest associations are:

Fissure ridges

In tectonically active areas calcium-rich thermal waters can rise along fault-lines and crystalline travertine are deposited to form elongate mounds with cleft-like median valleys. Pinacles and mounds can develop from the same process where the water is point sourced (e.g., Mammoth Hot Springs, Wyoming). The deposits are often composed of thin laminae, which dip steeply away from the fissure.

Terraces

Alternatively, lobate, planar sheets can develop into an intricate series of microterraces and gutters associated descending flights of small rimstone pools (e.g., Guo and Riding, 1998).

Diagenesis

The vast majority of tufas and travertines are composed of low magnesian calcite. They are prone to early “spar-micritization” by microborers, however, many retain sharp internal fabric boundaries. The addition of physico-chemical cements further reinforces older deposits. Metastable carbonates (e.g., aragonite in some travertines) soon neomorphose to calcite spar. Selective dissolution within tufas and travertines appears common. However, many voids are primary cavities lined by later cements.

TSUNAMI DEPOSITS

A tsunami deposit is a sedimentary layer deposited in low-lying coast regions by a tsunami generated by some form of seafloor deformation, such as earthquakes and submarine landslides, or by a subaerial event that significantly disturbs the water surface, such as a landslide or glacier calving event. Tsunami deposits most commonly form sheets of well-sorted sand that extend inland as much as several kilometers across coastal lowlands. Sheets of coral gravel or pebbles have also been reported. The sand sheets typically contain marine fossils, lack bedform sedimentary structures, and fine both upward and landward. A tsunami may produce a single upward-fining bed, or its waves may produce a vertical series of such beds.

Tsunamis may also deposit boulders. Modern tsunamis are known to have moved boulders as much as 30 m in diameter (Simpkin and Fiske, 1983). Diamicts and imbricated boulder fields have also been ascribed to tsunamis, but they so far lack modern analogs.

Although early scientific papers about tsunamis mention their deposits (Platania, 1909; Billings, 1915), tsunami sedimentology probably begins with a paper describing onshore erosion and deposition by the 1960 Chile tsunami on the northeastern coast of Japan (Konno, 1961). The 1960 locally deposited a sheet of sand up to 20 cm thick blanketing coastal lowlands. The sand is described as structureless except for vertical grading, which formed one or more cycles within the bed (Figure T17). The sand filled low places, such as furrows in plowed fields, but it also thinned landward in some places. Konno interpreted the sand as depositing from suspended load.

Tsunamis since 1960 have also produced sand “sheets” on coastal lowlands (Dawson *et al.*, 1996; Minoura *et al.*, 1997; Goldsmith *et al.*, 1999; Caminade *et al.*, 2000). In general, “modern” tsunami deposits have consisted of well-sorted sand sheets up to about 40 cm thick extending inland up to about 300 m inland. The sand source is generally inferred to have been either at the shoreline or just offshore, and the presence of erosional features along the shoreline tends to support the idea that sand is mined from the coastline and moved inland. These later surveys have shown that individual fining upward “pulses” of sedimentation can be traced in the deposit, possibly correlated to individual waves in the tsunami train, and have established the concept of overall landward fining in the direction of wave motion. One result of these recent surveys is a set of criteria for identifying ancient tsunami deposits (Dawson and Shi, 2000).

Criteria for identifying tsunami deposits include both sediment composition and physical properties. In addition to deposit fining landward and upward, researchers have noted that modern tsunami deposits appear to be well-sorted to moderately well sorted and positively skewed (Dawson *et al.*, 1996). Local overwash fans caused by tsunami typically show foreset bedding, but sand sheets have not yielded sedimentary structures other than normal grading. Tsunami deposits contain marine microfossils (Hemphill-Haley, 1996) and often retain evidence of landward movement in the form of bent-over plant debris at the base of the deposit (Atwater and Hemphill-Haley, 1997). Like their modern counterparts, ancient tsunami deposits show some subset of these criteria,

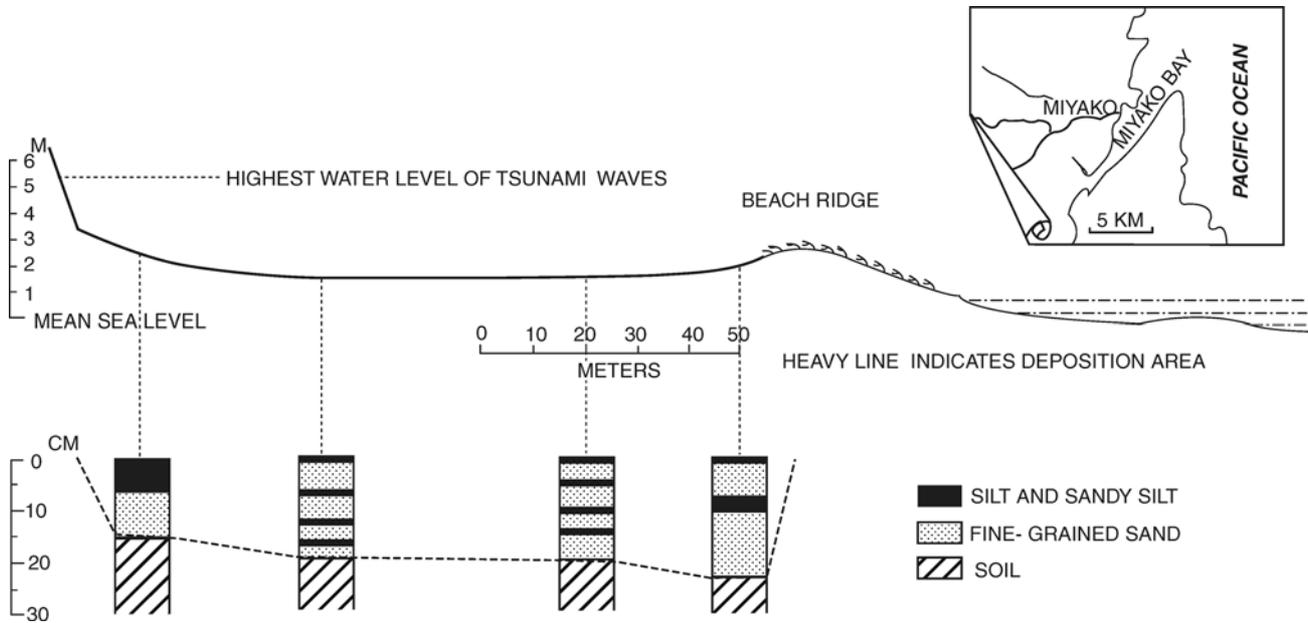

Figure T17 Deposit from the 1960 Chile tsunami near Miyako, Japan, showing four graded units (Konno *et al.*, 1961).

and are generally closely associated with a geologically inferred causal mechanism (e.g., earthquake evidence such as coastal subsidence for subduction zone related tsunamis) (Atwater, 1987).

As early as 1984, onshore deposits ascribed to tsunami have been described in sequences of coastal sediments, and have often served as the first warning of the tsunami hazard faced by coastal communities. Sandy paleotsunami deposits have been described from Scotland (Dawson *et al.*, 1988), Norway (Bondevik *et al.*, 1997), Kamchatka, Japan (Minoura and Nakaya, 1991), New Zealand (Goff *et al.*, 2000), the Mediterranean (Dominey-Howes *et al.*, 1999), and the Pacific coast of North America (Clague *et al.*, 2000). Most are sand sheets in sequences of peaty or muddy deposits of coastal lowlands.

As with sandy deposits, onshore movement of large boulders has been noted in many early descriptions of tsunamis (Makino, 1980; Simpkin and Fiske, 1983; Yamashita, 1997). Modern tsunamis have also moved boulders (McSaveney *et al.*, 2000), and (Yeh *et al.*, 1993) describe boulders from the 1992 Flores tsunami within sandy deposits. These deposits differ, however, from poorly sorted diamictons ascribed to tsunami (Bryant, 2001) in that the Flores boulders lie as individual large blocks protruding from an extensive, thin sand sheet rather than incorporated into the deposit. Ancient tsunamis have also been inferred based solely on the presence of onshore boulder deposits (Bryant *et al.*, 1992; Moore *et al.*, 1994; Hearty, 1997), but these ideas remain controversial because boulders can be transported inland by coastal processes other than tsunami, such as storms.

Storm Deposits

TURBIDITES

Turbidites are the deposits of turbidity currents, which are gravity-driven turbid suspensions of fluid (usually water) and sediment. They form a class of subaqueous sediment gravity flow (see *Gravity-Driven Mass Flows*) in which the suspended sediment is supported during transport largely or wholly by fluid turbulence. Turbidites range in grain-size from mud to gravel, and may be of any composition—siliciclastic, carbonate, or even sulfide near deep-sea hydrothermal vents. Turbidite beds range in thickness from millimeters to tens of meters, and individual events can, in extreme cases, involve the resedimentation of hundreds of cubic kilometers of sediment.

They are amongst the commonest of sedimentary deposits, and turbidite depositional systems such as submarine fans and basin plains form the largest individual sedimentary accumulations on the Earth. Thick sequences of synorogenic turbidites (*flysch*) are common in the ancient record.

Turbidity currents were first so named in 1938, although the existence of density underflows in lakes had been recognized earlier (see review by Walker, 1973). Their potential importance as agents of sediment transport into deep water was not fully recognized till Kuenen and Migliorini (1950) (see *Sedimentologists: Kuenen*) combined experimental work with field observations to suggest that turbidity currents were the cause of graded sandstone beds deposited in deep water. The name *turbidite* for the deposits of turbidity currents came into use about 1960, and Bouma's (1962) analysis of sandstone turbidites shortly thereafter generated the first and, for some time, the sole depositional model. The last three decades of the 20th Century saw an exponential increase in turbidite research. This was driven in part by new techniques of investigation in the deep sea, including the development of side-scan sonar, and drilling by the Deep Sea Drilling Project and its successor, the Ocean Drilling Program. However this increase was also due to the rising importance of turbidites as hydrocarbon reservoirs. Turbidites contain some of the worlds largest and most prolific reservoirs outside of the Middle East, and Cenozoic turbidite systems of the continental margins are a major target for hydrocarbon exploration.

Turbidity currents move by virtue of gravity acting upon the density excess due to the presence of suspended sediment, and flow down-slope, or spread by collapse over low-gradient basin floors. Concentrations of suspended sediment range from a few parts per thousand up to 10 percent or more, though the upper limit for what can truly be regarded as a turbidity current is a matter of debate. Deposition of sediment from the current occurs when fluid turbulence decays, generally as a result of deceleration of the current. Although turbidity currents tend to flow toward gravity base (i.e., the lowest point on the transport path), deposition—especially of coarser grained sediment—may also occur on the slope. Turbidite deposits thus occur on submarine slopes (see *Slope Sediments*), in canyons, slope channels, submarine fans (see *Submarine Fans and Channels*), slope aprons and ramps, and basin plains. They also occur as fans and basin plain deposits in lakes and artificial reservoirs.

Initiation

Turbidity currents are commonly initiated by the failure of unstable material on subaqueous slopes, the failure being triggered by earthquakes, pore fluid pressure imbalance, decomposition of clathrate (*q.v.*), or simply by over-steepening of the slope by deposition (Normark *et al.*, 1991; Rothwell *et al.*, 1998). In these circumstances turbidity currents may arise by the entrainment of water into flows that were initially more viscous and concentrated (such as slumps and debris flows, *q.v.*) that were generated high on the slope or within a submarine canyon. Such currents may deposit sediment over the course of hours. However, some turbidity currents may be generated by highly sediment-charged river outflow where the concentration of suspended material is sufficiently high to render the river effluent denser than the water into which it flows, and where the river discharges directly onto a slope (Mulder and Syvitski, 1995). Such hyperpycnal flows are

	GRAIN SIZE	BOUMA (1962) DIVISIONS	INTERPRETATION
	Mud	E Laminated to homogeneous mud	Deposition from low-density tail of turbidity current ± settling of pelagic or hemipelagic particles
	Silt	D Upper mud/silt laminae	Shear sorting of grains & flocs
	Sand	C Ripples, climbing ripples, wavy or convolute laminae	Lower part of lower flow regime of Simons <i>et al.</i> (1965)
		B Plane laminae	Upper flow regime plane bed
	Coarse Sand	A Structureless or graded sand to granule	Rapid deposition with no traction transport, possible quick (liquefied) bed

Figure T18 The Bouma sequence of sedimentary structures (and its interpretation) formed by turbidity currents of low to moderate density (after Pickering *et al.*, 1989, reproduced with permission).

more commonly achieved in fresh water, but may occur in the marine realm as frequently as annually in association with “dirty” rivers, or less frequently in association with catastrophic events in the subaerial realm such as major floods, landslides or glacial lake outbreaks (e.g., Zuffa *et al.*, 2000). On their passage down submarine canyons and channels, turbidity currents may erode substantial amounts of sediment from the seafloor, increasing their momentum and erosive power in a positive feedback loop known as autosuspension (*q.v.*) or ignition (Bagnold, 1962; Fukushima *et al.*, 1985). In this way, coarse sediment introduced into canyons between turbidity current events is flushed out, significantly increasing the volume and altering the grain-size mix of the resulting current (e.g., Hughes Clarke *et al.*, 1990).

Depositional models

Turbidites commonly show graded bedding (*q.v.*) and a sequence of sedimentary structures indicative of waning flow during passage of the turbidity current, and progressively declining bed shear stress during deposition of the bed. The rather common occurrence of these structures in a particular order led Bouma (1962) to propose an idealized vertical sequence for graded sand-to-mud turbidites (Figure T18) that remains the standard for comparison in normally-graded sandy turbidites. These divisions have been interpreted in terms of the hydraulic regime that produced them (Figure T18; Walker, 1973) and reflect the longitudinal structure of the current (Allen, 1991). The lowest part of the bed (often overlying a basal erosion surface) commonly consists of structureless graded sandstone—Bouma’s T_a division. This is interpreted as the result of deposition from suspension so rapidly as to inhibit movement of material in traction; this may occur via a transient liquefied bed (Middleton, 1967) or zone of hindered settling (*q.v.*). This precludes the formation of traction-generated structures (Allen, 1991, Kneller and Branney, 1995). The T_b division consists of a parallel-laminated interval (see Plane and Parallel Lamination) indicative of an upper stage plane bed, indicating slower deposition rates and an extended period of traction. The ripple-laminated T_c division (see Ripples) commonly shows upward-increasing rates of climb, and by inference increasing rates of deposition. Convolute lamination is common but by

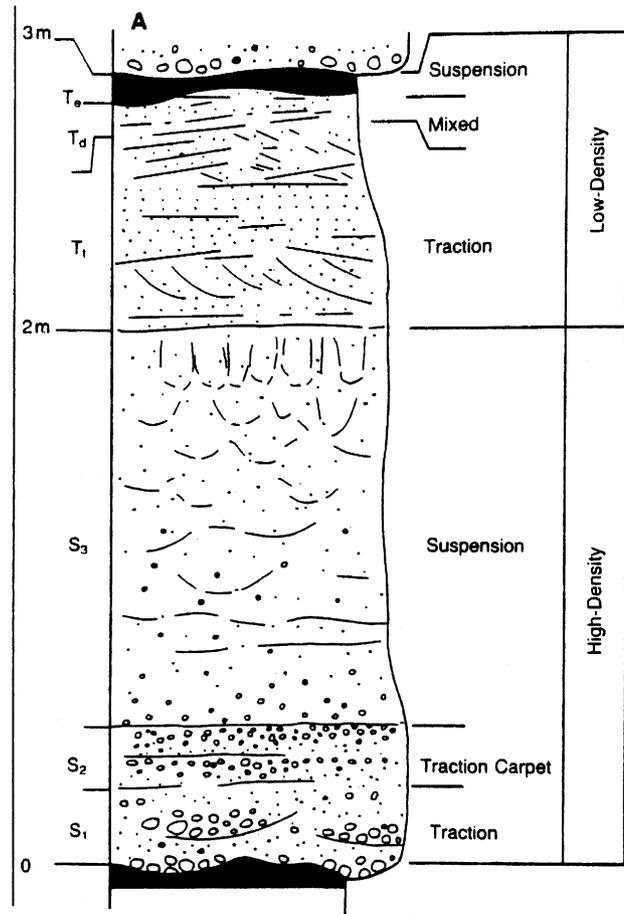

Figure T19 The idealized sequence of sedimentary structures formed by turbidity currents of high density (after Lowe, 1982, reproduced with permission).

no means universal within the T_c division. The T_d division consists of parallel laminated silt or hydraulically equivalent flocculated clay formed under the weakest of currents, while the T_e division represents sedimentation of mud from suspension in the absence (or virtual absence) of a current.

Complete Bouma sequences are rather uncommon. Partial sequences in which lower divisions may be missing (“base-absent”) are widespread, especially in the distal parts of turbidite systems, or in overbank settings where the finer-grained upper parts of turbidity currents have spilled out of channels (see Submarine Fans and Channels). Divisions within the sequence may also be absent or poorly developed (e.g., T_{abce}), sometimes with a sharp grain-size break at the level of the missing division.

The Bouma sequence describes some of the features associated with deposits of currents of low to moderate density. An analogous model for the deposits of high density turbidity currents was proposed by (Lowe, 1982) (Figure T19). A lowermost S_1 division is dominated by traction of coarse-grained material. This is overlain by an S_2 division dominated by inverse-graded layers, interpreted by Lowe as the deposits of a succession of “frozen” traction carpets; subtle inverse-to-normally graded layers corresponding to this division may

represent deposition during the passage of large eddies (Hiscott, 1994; Kneller *et al.*, 1999). Corresponding R1 and R2 intervals are differentiated in gravelly turbidites. The overlying S₃ division (more or less corresponding to an expanded T_a division) consists of sand that is structureless or dominated by fluid escape structures (*q.v.*). The ensuing T₁ division is dominated by traction and in part this corresponds to Bouma's T_b and/or T_c divisions, but may also include cross-stratified sands, sometimes well-sorted, that reflect partial bypassing of the flow (Mutti, 1992). As with the Bouma sequence, the model for high-density turbidity current deposits is idealized. Basal divisions may be absent, and the deposit may include grain-size breaks, especially common above or below intervals with cross-stratification (*q.v.*).

Comparable models for fine grained turbidites have been developed by, amongst others, Piper (1978) and Stow and Shanmugam (1980). Facies classifications of turbidites attest to the wide diversity of depositional facies (Ghibaudo, 1992; Mutti, 1992; Pickering *et al.*, 1989), most of which do not conform to the idealized models, and reflect the range of variables that affect deposition (Kneller, 1995).

Other depositional and post-depositional features

The base of coarse-grained turbidites commonly reveals evidence of erosion. This may take the form of casts of erosional structures such as flutes (see *Scour, Scour Marks*) or tool marks (*q.v.*) formed in fine grained substrate (commonly the muddy top of the underlying turbidite) during passage of the frontal, nondepositional parts of the flow (Dzulynski and Sanders, 1959). These form good paleocurrent indicators (see *Paleocurrent Analysis*). Such structures often contain grains that are significantly coarser than those in the remainder of the bed, suggesting that the head of the current carries the coarsest grains. Trace fossils preserved on the sole of the bed also bear witness to this erosion. Where erosion has completely removed the muddy top of an underlying graded sand-to-mud bed, the sandy portions of successive beds become amalgamated. Where repeated this can produce composite "beds" of sand many meters thick in which the amalgamation surfaces may be hard to discern. Such amalgamated beds are common in thick-bedded sandy and gravelly turbidite sequences such as those found in submarine canyons and channels.

Bases of turbidite sandstones commonly show load structures (*q.v.*), often associated with liquefaction structures (see *Liquefaction and Fluidization*) in the underlying and/or overlying bed. The load casts often amplify pre-existing perturbations of the bed, such as flute casts. Dewatering structures (commonly developed in S₃ divisions) may be arranged in a vertical sequence from consolidation laminae (wavy and/or anastomosing) near the base, through dish structures (*q.v.*) to pipes or sheets, which in some instances may be inclined down-current due to shear within the dewatering sediment mass. Liquefaction of the deposit can result in the creation of sand volcanoes on the tops of beds (where liquefaction of the bed occurred at the surface) or injection of clastic dykes and sills (*q.v.*) into surrounding sediments (Nicholls, 1995), upward, downward or sideways from the parent bed. Another common feature of the deposits of presumed moderate to high concentration turbidity currents is the presence of shale clasts, some of which may have experienced considerable transport after incorporation into the flow during initiation or by erosion of the bed, while others may be incorporated during

deposition via a highly concentrated (perhaps liquefied) depositional layer that may behave as a transient debris flow (Stow and Johansson, 2000).

Some turbidity currents experience reflection from basin-bounding surfaces and intrabasinal topography, resulting in distinctive current changes within the bed, commonly associated with small reversals in grading (Pickering and Hiscott, 1985; McCaffrey and Kneller, 2001).

Current controversies

Considerable debate exists about what constitutes a turbidity current, and thus what may or may not correctly be interpreted as a turbidite (Shanmugam, 2000). Some authors (e.g., Middleton and Hampton, 1973; Mulder and Alexander, 2001) restrict their definition of turbidity currents to flows in which the grains are supported almost exclusively by fluid turbulence, whereas others (e.g., Lowe, 1982) take a broader view. It is useful to recall that the root of the term turbidity current is the word *turbid* (i.e., opaque with sediment) as distinct from *turbulent* (i.e., disturbed by eddies). Much uncertainty arises from the lack of direct observations from large natural currents, and from the difficulty in producing in the laboratory nondepositional sand-bearing currents of even moderate density. This renders the debate largely speculative.

UPWELLING

Introduction

One principle characteristic of upwelling systems is that they occur predominantly in the same location due to the combination of physiographic factors (coastline, shelf bathymetry) and seasonal features such as wind strength and direction. Upwelling may occur in the open ocean as a consequence of divergence between major current and frontal systems, or along continental margins (often referred to as coastal upwelling). Although both open ocean and coastal upwelling influence the underlying sedimentary record, the predominant diagnostic sedimentary facies relation to upwelling are developed along continental margins. The hydrographic features of an upwelling system commonly drive undepleted nutrients (especially nitrate and phosphate) into the euphotic zone resulting in intense, and often seasonal, primary production of phytoplankton and related trophic grazing by zooplankton, fish, and higher predators. This high primary and secondary production produces large quantities of biomass which subsequently sinks and decays during transit through the water column resulting in major decreases in dissolved oxygen levels caused by aerobic microbial respiration of the decomposing organic matter. Where the "oxygen minimum zone" impinges on the seafloor the accumulating sediments are commonly anaerobic giving rise to a particular set of facies relationships and diagenetic processes (Figure U1). Frequently, at continental margins where wind-driven upwelling occurs, there are high levels of lithogenic detritus derived from the adjacent land mass added to the organic-rich anaerobic sediment. At the present day, such coastal upwelling systems are characteristic of continental margins off California, Peru, Mauritania, Namibia, Oman, Pakistan, and Australia with open ocean upwelling systems characterized by the Eastern Equatorial Pacific and the Antarctic Polar Front.

Historical development

The study of upwelling systems and their resulting imprint on seafloor sediments has long attracted significant scientific study (e.g., see the following edited volumes; Theide and Suess, 1983; Summerhayes *et al.*, 1992; Summerhayes *et al.*, 1995). In part, this has been due to the long-known association between organic matter, black metalliferous shales and siliceous deposits characteristic of petroleum source rocks (e.g., the Miocene Monterey Formation of the western USA), but more latterly, the emerging significance of upwelling systems as part of the oceanic carbon cycle and resulting implication for the climate system. Through the study of such systems, there have grown up important geological paradigms, such as the enhanced preservation of organic matter under anaerobic depositional conditions (Demaison and Moore, 1980), and subsequent challenges to the paradigm based on detailed modern oceanographic studies (Pedersen and Calvert, 1990). Other major areas of study have centered on the issues of allocthonous versus autocthonous carbon burial at shelf depocenters (Walsh, 1991; Jahnke and Shimmiel, 1995), and increased levels of carbon burial at upwelling centers during past glacial episodes (Muller *et al.*, 1983). Current research aims to use the complex composition of biogenic microfossils, sediment organic and inorganic geochemistry, and microfabric lithology (laminations) to reconstruct the history of upwelling systems over a variety of timescales from decades (e.g., reconstructing El Nino variations), to tens of thousands of years relevant to the study of the waxing and waning of the ice sheets and associated climatic change.

Current understanding and applications to paleoceanography

Coastal upwelling systems, although small in areal extent compared to whole ocean, account for over 50 percent of oceanic primary production and more than 95 percent of the sedimentary accumulation of organic carbon (Romankevitch, 1984). The accumulating sediment, derived from organic matter, biogenic skeletal material (calcite and opal), fish scales and bones, and lithogenic minerals carried by wind and fluvial

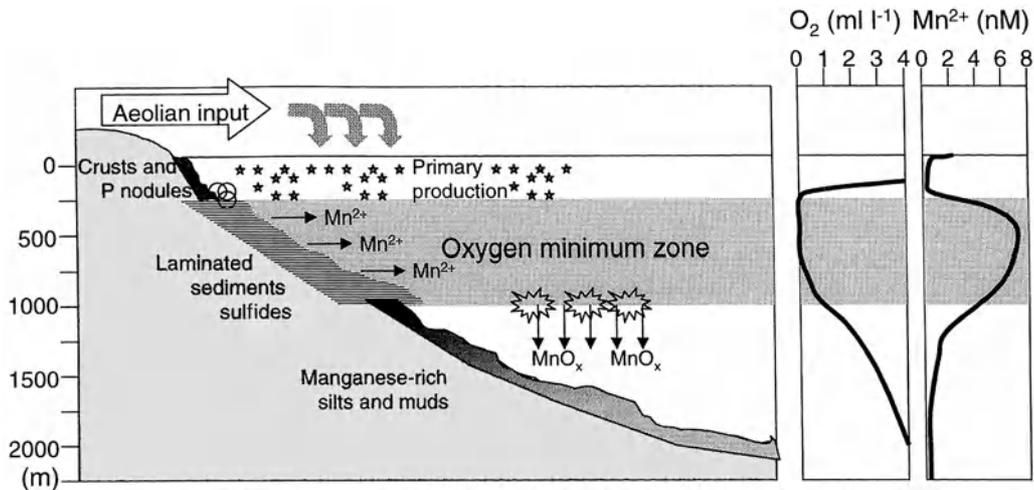

Figure U1 Schematic diagram illustrating the effect of an intense oxygen minimum zone, produced as a consequence of upwelling water fuelling primary production and subsequent microbial decay of the organic matter, on the sediment lithology and geochemistry. Such OMZ formation can result in substantial leakage of dissolved Mn into the water column and resulting recycling and reprecipitation in underlying sediments. The profiles of dissolved oxygen and manganese are typical of a modern upwelling system, such as in the northwest Arabian Sea.

discharge, become augmented by diagenetic processes leading to the concentration of phosphorites and sulfide minerals under the suboxic and anoxic sedimentary conditions prevailing. Linking the processes sediment supply to the locus of sedimentary deposition is notoriously difficult at continental margins (Jahnke and Shimmield, 1995; Bertrand *et al.* 1996). Frequently, the organic matter actually accumulating may be older than the surrounding sediment based on ^{14}C age dating (Anderson *et al.*, 1994), or the quantity of carbon in the sediment does not appear to be related to the bottom water oxygen (Pedersen *et al.*, 1992), but instead to the intensity of sediment resuspension and reworking. Such physical reworking may be relatively common at coastal upwelling centers—the Oman margin is characterized by refractory carbon diagenesis (Pedersen *et al.*, 1992) and deep sulfate reduction in the pore waters, and the Peru margin has large areas of hard pavement and phosphorite pellet beds (Jahnke and Shimmield, 1995). In contrast, the absence of oxygen in bottom waters at continental margin upwelling sites can lead to an absence of benthic infaunal and minimal sediment disturbance through bioturbation. Under these conditions quite labile organic matter is found and the sediment retains a remarkable microfabric with annual laminations related to the changing surface ocean productivity (Brodie and Kemp, 1994). Even the changing percentages of diatoms, radiolaria, and foraminifera in the sedimentary laminations may be used to interpret interannual variability in upwelling associated with events such as El Niño (Lange *et al.*, 1987). Even under open ocean upwelling conditions, such as those associated with the eastern equatorial Pacific divergence, Kemp and Baldauf (1993) have found historical evidence for very rapid deposition of giant diatom mats and resulting excellent preservation in the sedimentary record.

The geochemistry of sediments underlying upwelling centers is varied and fascinating. A wide range of redox environments are commonly found, often with redox gradients in the sediments that can be measured on a scale of millimeters,

rather than meters commonly found in open ocean sedimentary settings. Rapid consumption of oxygen, nitrate, and sulfate is commonly observed with attendant dissolution of carbonate and degradation of the organic matter. Sulfide mineral precipitation occurs during sulfate reduction and the release of iron III from the oxidized coatings on mineral grains transported by winds from the adjacent, often arid, landmass. One key factor influencing organic matter preservation under upwelling systems is burial rate. Often the sediments are accumulating relatively rapidly (say $>5\text{ cm ky}^{-1}$) giving rise to burial efficiencies of greater than 10 percent. The elemental and isotopic composition of the organic matter (*Kerogen*, *q.v.*) has long been used as a proxy for the changes in upwelling, circulation, and bottom water oxygen (Reimers and Suess, 1983). Over the past 15 years the discovery that changes in the C_{37} alkenone unsaturation index (U_{37}^k) could be related to the water temperature in which the phytoplankton lived, as enabled reconstructions of past upwelling history such as for the Peru margin (McCaffrey *et al.*, 1990). Upwelling centers also provide inorganic proxy indicators of changes in oceanic productivity, such as the sedimentary concentration of the element barium in the mineral phase, barite. Bishop (1988) showed the precipitation of barite in the decaying organic matter within frustules of sinking diatoms. Von Breymann *et al.* (1992) summarized the known information on high barium in hemipelagic sediments but also identified the potential Achilles' heel for the use of Ba as a paleoproductivity proxy in organic-rich sediments; namely that strong sulfate reduction diagenesis caused sedimentary barite to dissolve.

The changes in the faunal composition of the upwelling sediments can give important clues as to the temperature of the upwelled waters, the intensity of the primary and secondary production, and the species succession through a seasonal upwelling event. Typically, the calcareous tests of the foraminifera are most often studied, both for species diversity and abundance, and the oxygen and carbon isotopic record they contain. Particular species have now come to be

associated typically with upwelling conditions, such as *Globigerina bulloides* (Prell and Curry, 1981). However, close examination of both the species succession, and the isotopic make-up (particularly the $\delta^{13}\text{C}$ signature) reveals complexity in the response of production of the foraminifera, the depth of the thermocline, and the origin of the upwelled water (Kroon and Ganssen, 1989).

Summary

The sediments underlying upwelling systems, and particularly those at continental margins, are a very important repository of organic matter in the world's biogeochemical cycle of carbon. The upwelling process fuels high levels of marine primary productivity which induces low levels of dissolved oxygen in the overlying water column during decomposition of the sinking organic matter. The resulting sediment, rich in organic carbon and with accelerated diagenetic reactions, ultimately forms some of the most valuable hydrocarbon source rock. In certain cases, phosphorite formation augments the mineralogical value. Modern upwelling systems have become the type areas for testing paradigms on organic matter preservation and for proving inorganic and organic proxy paleo-indicators of productivity and ocean temperature. Intense episodes of oceanic productivity have been recorded in massive diatom mat accumulations, and under certain conditions, well preserved laminated sediments deposited under anaerobic conditions are helping to provide a detailed historic record of interannual climatic variability, such as that associated with the El Niño episodes in the Pacific.
